Contraindications: Inadequate access is the most important contraindication for TLM resection of cancer of the hypopharynx. Extensive invasion of the larynx and base of the tongue and bilateral arytenoid extension or fixation preclude function-preserving conservation surgery, and thus, patients with these features will not benefit from transoral resection. Circumferential or near-circumferential spread to the cervical esophagus, gross invasion of the cricoid cartilage, significant extralaryngeal spread, and encroachment on major vessels in the neck are other contraindications for TLM in cancer of the hypopharynx. Patients with cancer of the posterior pharyngeal wall with invasion into the prevertebral and parapharyngeal spaces are also not suitable for TLM.

Technique: Resection in TLM is performed using the principles first popularized by Steiner.[20] Access is achieved with a combination of distending or fixed bore laryngoscopes (e.g., Steiner, Kleinsasser, Lindholm) or bivalved scopes. A key maneuver to enhance exposure of the tumor and surrounding landmarks, especially in patients with redundant, collapsing mucosa, is to maximally suspend and distend the long Steiner endoscope, thus creating luminal working space. For exophytic cancers, debulking at the onset also creates improved exposure of the surgical field. The CO_2 laser beam is usually delivered to the operative site via a micromanipulator attached to the operating microscope. TLM is initiated with a *transtumoral* incision, which transects the cancer for depth estimation, and is completed by *multibloc* resection until negative margins are obtained (**Fig. 16.2**). Mucosal margins of at least 5mm for superficial and 10mm for infiltrating cancers are recommended; however, confirmation of margin-negative resection by frozen sections from the perimeter of the resection defect is fundamental to the TLM technique. The principles of TLM resection of SCC of the hypopharynx are outlined in **Table 16.2**, and hypopharyngeal subsite-specific resection techniques are discussed below.

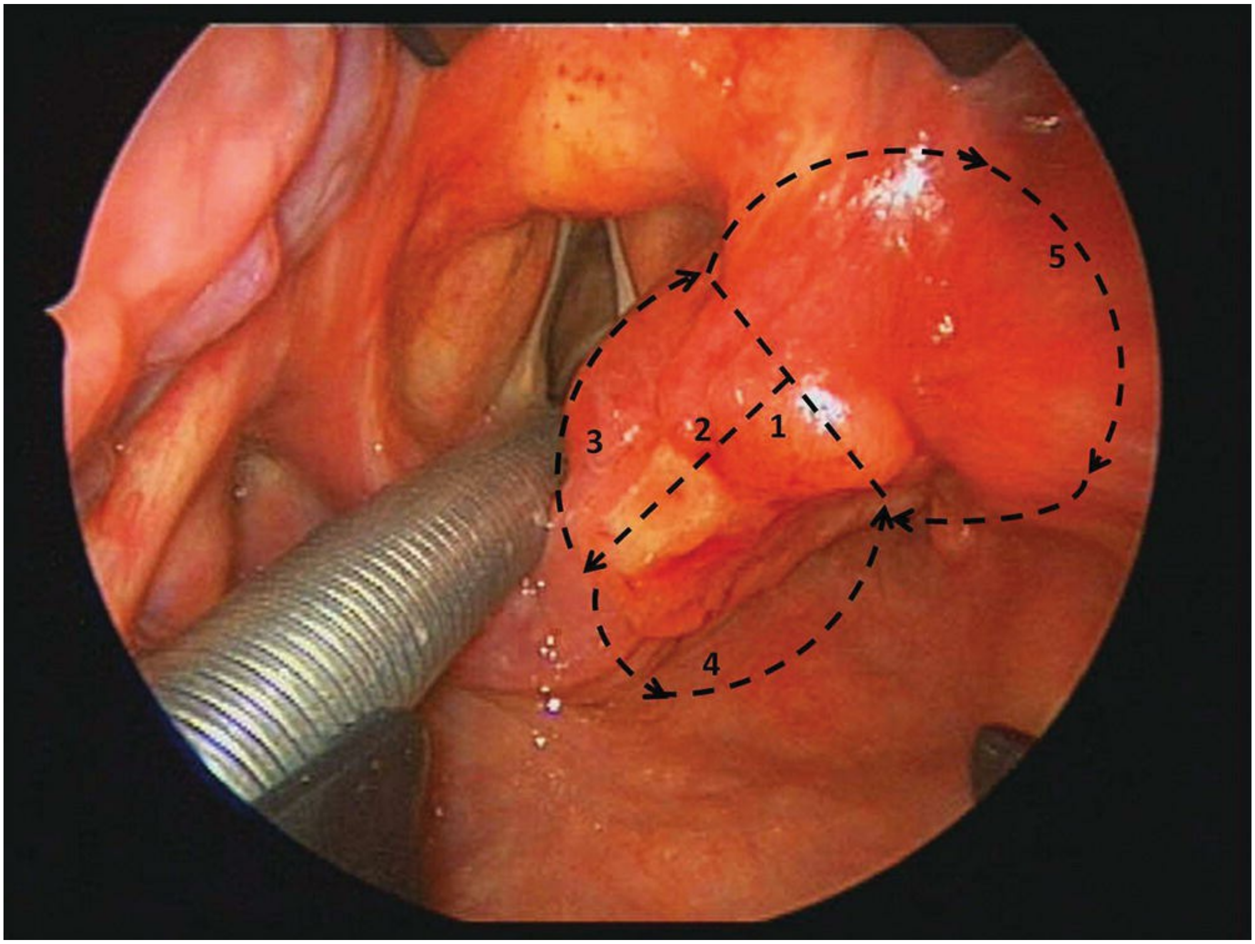

Figure 16.2. Sequential incisions and *multibloc* design for TLM resection of the medial wall of the right pyriform sinus/aryepiglottic fold (AEF) cancer ([*1*] transverse *transtumoral* cut, [*2*] longitudinal, splitting posterior AEF cut, [*3* and *4*] completion medial [*3*] and lateral [*4*] AEF/arytenoidectomy cuts at perimeter, [*5*] anterior AEF, lateral epiglottic and PFS wall cut).

Table 16.2 Requisites and Fundamental Principles of Hypopharynx SCC Management with TLM Approach

Preoperative	
▪	Knowledge of "inside-out" anatomy for transoral resection and patterns of tumor spread
▪	Training in the instrumentation and techniques of TLM
▪	Rigid endoscopic examination under anesthesia to evaluate access and feasibility of complete transoral oncologic resection
Operative	
▪	Maximal endoscope distension and suspension, for luminal expansion
▪	Debulking for exophytic tumors to create access
▪	Transtumoral cuts for depth assessment
▪	*Multibloc* tumor resection in craniocaudal direction
▪	Meticulous hemostasis: vessel control with clips during TLM resection and prophylactic ligation during neck dissection
▪	Combined approach via lateral pharyngotomy if indicated by limited access or tumor extent
▪	Neck dissection in the same operative session
▪	Prophylactic tracheotomy in patients with poor performance status or body habitus or resection that includes the arytenoid or paraglottic space or deep mucosal space
Postoperative	
▪	Swallowing and speech rehabilitation with a speech pathologist
▪	Pathologic risk factor-based adjuvant therapy

Pyriform sinus: Resection commences proximally and advances distally in a craniocaudal direction,[20] widening the exposure as incisions are made around the anterior extent from the lateral toward the medial side (**Fig. 16.3**). Another approach is first to divide and resect the AEF and then proceed on to

removal of the anterior and lateral components. Extension into the pre-epiglottic space is also addressed early in a TLM approach, thereby facilitating exposure. For cancers involving the medial PFS that approach, but do not frankly invade, the AEF and the arytenoid cartilage, complete oncologic clearance can be achieved by carefully peeling the mucosa from the surface of the arytenoid without sacrificing the cartilage itself. This technique minimizes the risk of aspiration versus a more extensive arytenoidectomy to facilitate postoperative swallowing. In patients for whom the arytenoid needs to be resected, preservation of at least one functional arytenoid is required to prevent aspiration. For cancers of the lateral PFS that approach the thyrohyoid membrane, the membrane may be excised as a margin and the tumor is followed out to the strap muscles, if required. Thyroid perichondrium may also be stripped off to ensure clear margins, but delayed healing may result. For cancers that infiltrate the thyroid cartilage, the involved areas of the cartilage are resected along with accessible extracartilaginous extensions. For extensions of the cancer that are not completely accessible, the transoral approach can be combined with a lateral pharyngotomy parallel to and posterior to the thyroid lamina, using the access provided by the neck dissection. This approach is also used in situations where there is inadequate access to resect extensions of the cancer of the PFS. The pharyngotomy or laryngotomy is repaired by advancement of the constrictor muscles and adjacent strap muscle and/or an additional patch of cadaveric acellular dermis.

There is no evidence of thyroid cartilage invasion. **B:** Preoperative endoscopic images of the cancer of the left PFS with extension of the cancer into the anterior and medial walls of the PFS and the posterior wall of the hypopharynx; the contralateral right PFS is uninvolved. Note extension to the left post cricoid area, with a clear esophageal inlet ([*1*] posterior wall of the hypopharynx, [*2*] postcricoid area, [*3*] esophageal inlet). **C:** Intraoperative image showing resection bed ([*1*] lateral wall of the PFS, [*2*] thin layer of soft tissue overlying the left thyroid cartilage, [*3*] anterior remnant of the cancer awaiting resection, [*4*] left posterior cricoarytenoid muscle, [*5*] posterolateral wall of the left hypopharynx). Resection included the medial walls of the PFS, anterior wall of the PFS, the pharyngoepiglottic fold, the pre-epiglottic space, and a component of the lateral pharyngeal wall. **D:** Postoperative image of the superior, oropharyngeal extent of the resection bed ([*1*] constrictor muscles, [*2*] prevertebral fascia, [*3*] epiglottis). *Arrow* denotes the point from which the resection continued into the left PFS.

Postcricoid area: TLM can be used for cancers that are superficial and

confined to the postcricoid area. For cancers with minimal inferior extension into the esophageal inlet, a long expanding or bivalved laryngoscope is used to gain access. Excision is performed down the upper esophagus in separate blocs by making longitudinal, then curvilinear incisions around the inlet and assessing the specimen for complete clearance of the cancer with a margin of normal esophageal mucosa. No more than 180 degrees of the circumference should be demucosalized. Because the operative field is very close to the posterior cricoarytenoid muscle, resection should be extremely cautious because there is a high risk of postoperative airway compromise due to injury to the sole abductor muscle of the vocal cord.

Posterior wall of the hypopharynx: Cancers in this subsite usually have excellent transoral access (**Fig. 16.4**). TLM incisions can be used to detect and follow cancer infiltration into or beyond the buccopharyngeal fascia, even into the prevertebral fascia. Even though there is limited or focal infiltration of the prevertebral fascia, the musculature and the anterior spinal ligament can be adequately addressed by TLM, although there is a risk of postoperative complications such as vertebral osteomyelitis or abscess, especially after adjuvant radiotherapy.

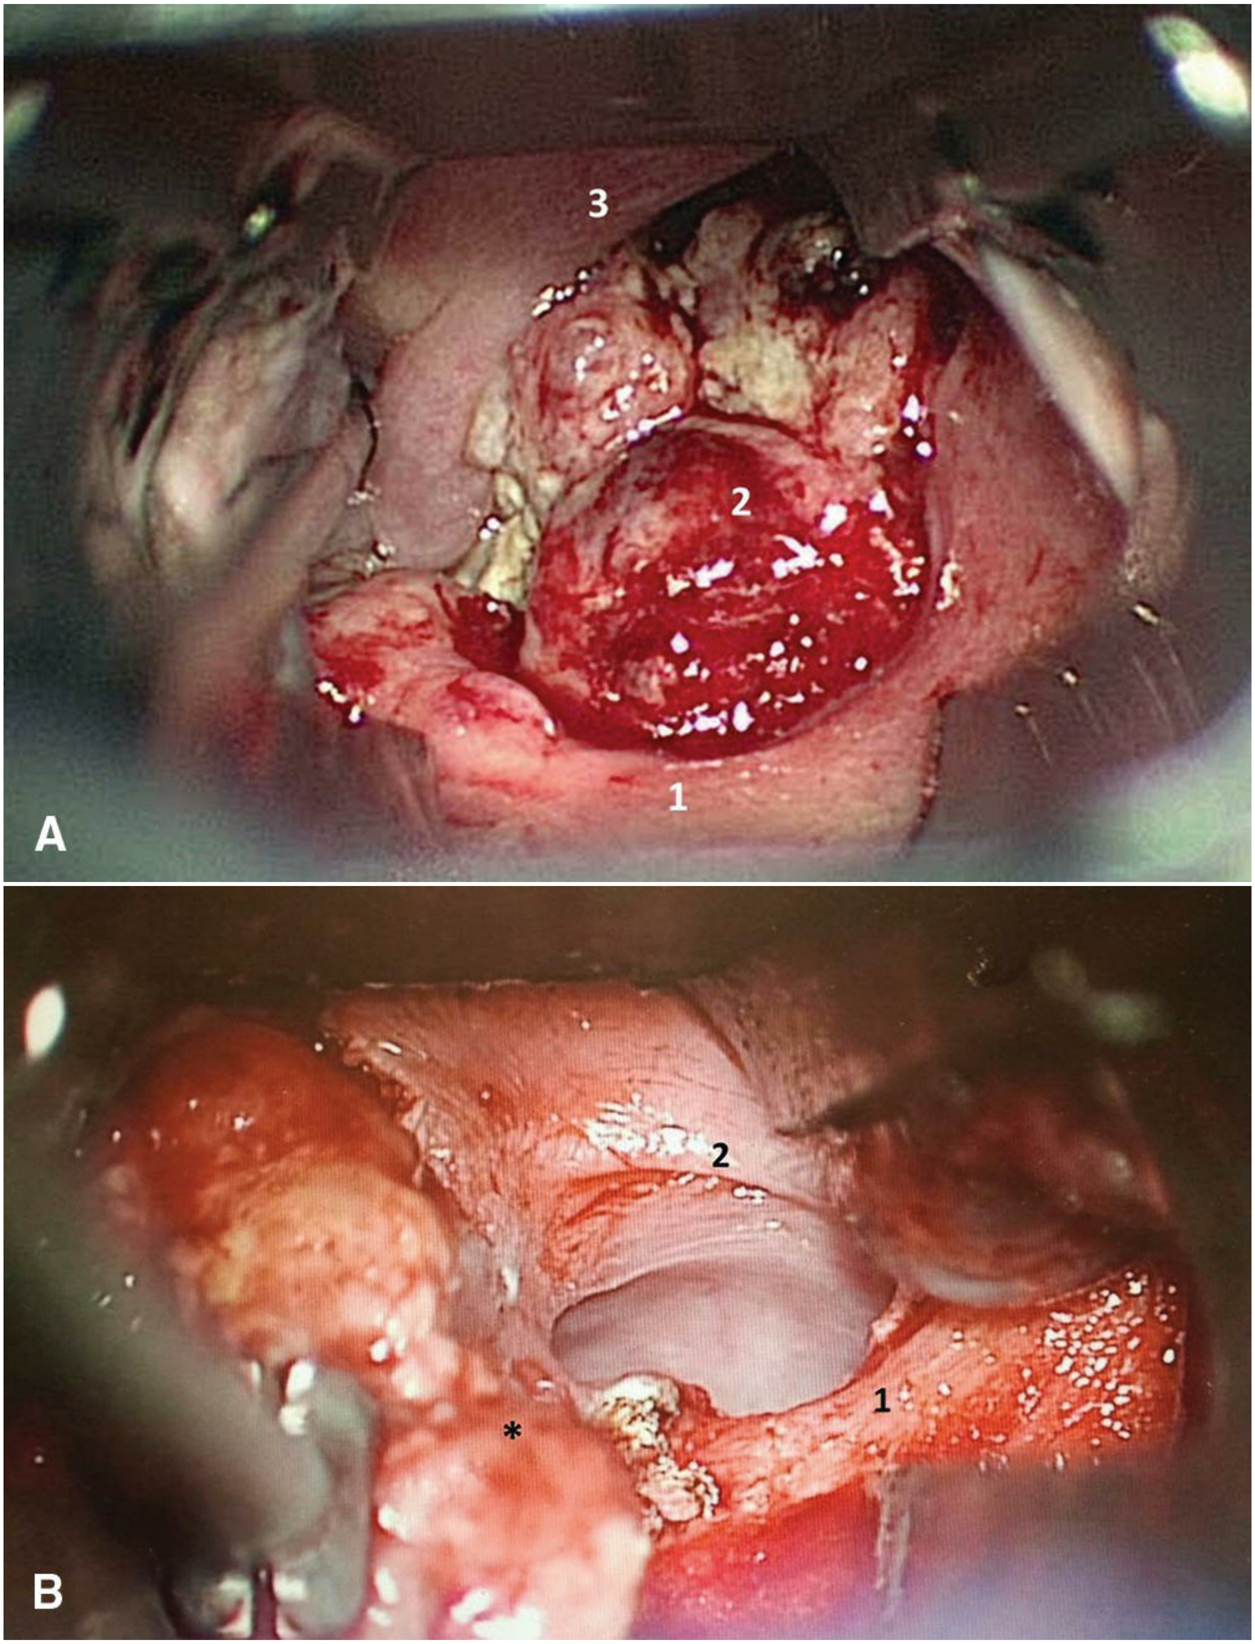

Figure 16.4. TLM resection of an exophytic cancer of the posterior wall of

the hypopharynx, abutting but not invading the postcricoid area and extending inferiorly to the esophageal inlet. **A:** Preoperative endoscopic image of the cancer ([*1*] posterior pharyngeal wall, [*2*] cancer, [*3*] postcricoid area). **B:** Intraoperative image depicting the esophageal inlet prior to resection of the final segment (*8 o'clock). Note intact mucosa at anterior and right lateral 180 degrees ([*1*] resection bed, [*2*] intact mucosa with cervical esophageal lumen distally).

Postoperative care: Patients with TLM resection for early-stage cancer tolerate extubation well or may require an overnight intubation. Tracheostomy for protection from aspiration is performed in patients with advanced cancers who undergo significant resection, particularly when the arytenoid or paraglottic space is involved. Three weeks of prophylactic, broad-spectrum antibiotics and antireflux agents is initiated. A nasogastric tube is inserted to maintain nutrition in the immediate postoperative period, which may be replaced by a PEG for patients with resection of advanced cancers.

Complications: A complication rate of 4% to 19% has been reported across several studies; the majority and most serious of these complications are postoperative bleeding, aspiration, and laryngeal edema. A few of these complications have been described as life threatening in certain studies, but none of the events have led to a perioperative death in the authors' experience. The complication rates have been significantly associated with the surgeon's experience and extension of the primary cancer.[16] Patients with deep mucosal resection are at increased risk of postoperative hemorrhage so that a tracheostomy is recommended at the end of the procedure to protect the airway. Also, critical in minimizing the risk of bleeding is observance of meticulous hemostasis with clipping and cautery of exposed superior and inferior laryngeal arteries or their branches during TLM.[21] It is also helpful to ligate and divide named vessels during the neck dissection that have been transected at the primary site. Infection and pharyngocutaneous fistula are rare complications of TLM when compared to open surgical approaches.

Endoscopic access can cause pressure-related complications such as dental trauma, tears of the wall of the pharynx, edema of the tongue, and injury to the lingual, glossopharyngeal, or hypoglossal nerves.[22] Laser-related burns or airway fires are particularly rare but are preventable risks with

adequate safety precautions, such as a laser-proof endotracheal tube and an oxygen-depleted anesthetic environment.

Transoral Robotic Surgery

Transoral robotic surgery (TORS) with the da Vinci Surgical System-assisted hypopharyngectomy is an evolving approach, the application of which was first reported in 2010 for resection of early-stage SCC of the PFS and posterior pharyngeal wall.[23]

Technique: The Feyh-Kastenbauer retractor is used to obtain an optimal view of the working space. An 8-mm 30-degree endoscopic camera is inserted into the oral cavity. The two robotic arms on either side of the camera are equipped with 5-mm-sized instruments; one of which is used for tissue retraction or dissection, whereas the other arm carries the unipolar cautery for making incisions. Cancers are resected en bloc. Cancers of the PFS are resected in the shape of a cone with the first incision being made in an anterior to posterior direction along the medial side of the AEF, preserving the arytenoid. This is followed by medial to lateral dissection along the thyroid cartilage where the perichondrium is incised horizontally and the inner perichondrium of the thyroid cartilage is peeled off. The dissection continues along the lateral side of the thyroid cartilage followed by dissection in the posterior part where a portion of the inferior constrictor muscle in the posterior pharyngeal wall is included as a posterior margin.

Postoperative care and complications: Postoperative care is similar to post-TLM resection. The largest published series on outcomes of 23 patients with cancer of the hypopharynx treated with TORS, from Korea, reported postoperative bleeding as the only complication.[24]

TLM versus TORS: A multiangled view of the surgical field, greater mobility of EndoWrist instruments and absence of “line-of-sight” limitation of the microscopic view are cited as advantages of TORS over TLM. However, compared to TLM, TORS can be applied to only select, early cancers of the hypopharynx. Submucosal spread is a common feature of cancers of the hypopharynx, and compared to en bloc resection in TORS, TLM better facilitates oncologic clearance by sequentially following the submucosal extensions while preserving normal structures. Access through the FK retractor may not give exposure of certain anterior and inferior

locations for complete resection of the cancers. These locations can be accessed only by appropriate positioning maneuvers via laryngoscopes (**Fig. 16.5**) through which passage of the currently available TORS instrumentation, let alone creation of working space, is infeasible. Moreover, monopolar cautery, the cutting tool in TORS, causes greater thermal damage and risks electrical damage to the recurrent laryngeal nerve. Cutting with the CO_2 laser fiber has the benefits of precision but with minimal blood loss as it seals vessels smaller than 1mm. Improvement in instrumentation, with added flexibility and miniaturization, may increase the applicability of TORS for resection of cancer of the hypopharynx.

Open Approaches

Conservation Surgery

Open conservation procedures with partial resection of the pharynx and laryngeal preservation for select cancers of the hypopharynx have now been mostly supplanted by transoral approaches, provided the criteria of access are met as described above. The traditional open conservation procedures performed through incisions in the neck are discussed below. A temporary tracheostomy is usually performed at the onset or after these procedures to avert airway complications, which may occur from postoperative mucosal edema.

Partial Pharyngectomy

Partial pharyngectomy for cancer of the hypopharynx through a lateral pharyngotomy approach was first described by Trotter. It can be used safely to extirpate early cancers of the superior aspect of the PFS or the posterolateral wall of the hypopharynx.[25–27] It can also be used in combination with the TLM approach for resection of primary cancers of the hypopharynx that cannot be excised completely transorally due to difficult access or difficulty in approaching the inferior or lateral extensions of the cancer. This approach is contraindicated in the presence of extension below the level of the arytenoids, extension to the postcricoid area, or fixation of cancer to the posterior wall. The exposure to perform the pharyngotomy is usually available through the incision for neck dissection, which is required in most of the patients with hypopharyngeal cancer in order to surgically address the regional lymph nodes. The inferior constrictors are divided at the posterolateral border of the thyroid cartilage, and the posterior surface of the superior aspect of the thyroid cartilage is separated from the pharyngeal mucosa to perform a “pyriformotomy” for approaching the primary cancer. Occasionally, the posterior border of the thyroid cartilage may need to be sacrificed for obtaining complete access. Caution is exercised to preserve the superior laryngeal nerve for better functional outcomes.

A transhyoid approach through the body of the hyoid has been described to perform a pharyngotomy for excision of cancer of the posterior hypopharyngeal wall, but the exposure is limited for achieving complete oncologic resection.

The pharyngotomy defect is usually amenable to primary closure: reinforced by local rotation flaps or acellular dermal graft. Small, <1 cm posterior pharyngeal wall defects can heal by secondary intention; larger defects may require a split thickness graft and, rarely, a pedicled or microvascular free flap.[25] Defects extending to the lateral wall of the hypopharynx may require a local muscle rotation flap.

Partial Pharyngectomy with Supraglottic Laryngectomy

This procedure, described in the early 1960s by Ogura et al.,[28] can be used for resection of cancers in the medial or anterior wall of the PFS or in the posterior wall of the hypopharynx. Poor pulmonary status, restricted mobility of the vocal cord or arytenoid, extension to the base of the tongue, involvement of the apex of PFS or the postcricoid area, and invasion of the thyroid cartilage are contraindications for this procedure. The hypopharynx is entered through the vallecula away from the side of the cancer, and the cancer is resected under direct view while maximally preserving the pharyngeal wall. The ipsilateral supraglottic larynx is included in the resection; the vocal cords are preserved bilaterally.

Closure is achieved by approximating the base of the tongue to the larynx with sutures between the tongue musculature and the thyroid perichondrial flap. It is reinforced by suturing the cut ends of strap muscles without creating any tension on the pharyngeal repair. Reconstruction with a free fasciocutaneous flap may achieve better function for larger pharyngeal defects.

Partial Pharyngectomy with Supracricoid Laryngectomy or Supracricoid Hemilaryngopharyngectomy

Supracricoid laryngectomy or supracricoid hemilaryngopharyngectomy (SCHLP) was first reported in the mid-1960s and later popularized by Laccourreye for treating selected cancers of the PFS with laryngeal preservation. It involves resection of the ipsilateral PFS from the level of the vallecula to the apex, the ipsilateral hemilarynx above the superior border of the cricoid cartilage, and the epiglottis and pre-epiglottic space as required.[29]

This technique provides a better access to resect the cancers of the medial and lateral walls of the PFS and can be performed in the presence of thyroid cartilage invasion or arytenoid fixation, both of which are contraindications for the procedure of partial pharyngectomy with supraglottic laryngectomy. SCHLP is contraindicated in the presence of a fixed hemilarynx, paraglottic space extension, postcricoid and PFS apex involvement, cricoid cartilage invasion, and extralaryngeal spread.

Pharyngeal and laryngeal closure up to the level of the contralateral false cord is achieved with a flap innervated by the contralateral superior laryngeal nerve and comprised of the mucosa of the contralateral posterior pharyngeal wall. The inferior defect is repaired with the musculoperichondrial flap comprised of infrahyoid muscles and thyroid external perichondrium preserved during laryngeal exposure.[29] Postoperatively, these patients may require a tracheostomy and a feeding tube for a longer period compared to patients undergoing a transoral approach.

Radical Surgery

Near-Total Laryngectomy with Partial Pharyngectomy

The technique of near-total laryngectomy was first described by Pearson in 1981.[30] It can be performed for locally advanced cancer of the PFS in the presence of a fixed hemilarynx. The presence of a contralateral, mobile arytenoid, sufficient contralateral disease-free pharyngeal mucosa for the fashioning of a voice shunt, and uninvolved interarytenoid and postcricoid regions are essential for the procedure. The resection specimen consists of the PFS, the hemilarynx including upper tracheal rings, and the thyroid lobe on the ipsilateral side along with the entire epiglottis and the pre-epiglottic space. The contralateral arytenoid and the posterior portions of false and true vocal cords are preserved along with the cricoarytenoid joint and the recurrent laryngeal nerve. Pharyngeal repair with or without regional or free flaps and creation of a tracheopharyngeal shunt facilitate speech and swallowing; the airway is maintained with a permanent tracheostomy.

Total Laryngectomy with Partial Pharyngectomy

Patients with advanced postcricoid cancer and cancer of the PFS with extension to the apex or cricoid cartilage, bilateral arytenoid invasion,

extensive thyroid cartilage, or extralaryngeal invasion are not candidates for laryngeal preservation surgery. Surgery for such cancers requires a total laryngectomy with partial or total pharyngectomy and often a hemithyroidectomy. A tight pharyngeal closure increases the risk of fistula formation and postoperative dysphagia. Hence, primary closure should be performed only if the remnant pharyngeal mucosa is sufficient to close around a 36-French dilator; such defects ideally are less than one-third of the circumference.[31] Larger pharyngeal defects require a “patch” reconstruction with a pedicled myocutaneous or a free fasciocutaneous flap such as radial forearm or anterolateral thigh flap.

Total Laryngopharyngectomy

Total resection of the pharynx with a total laryngectomy is required for SCC of the hypopharynx that are too advanced to be resected with sufficient uninvolved mucosa. Surgery for postcricoid cancers, PFS cancers with extension to the postcricoid area, and cancer of the posterior hypopharyngeal wall with extension below the arytenoids results in circumferential defects, which require a tubed reconstruction of the pharyngeal segment. Resection may also involve portions of the upper esophagus to achieve negative margins. In brief, bilateral sharp skeletonization and blunt skeletonization of the lateral larynx and pharyngeal wall, followed by opening, blunt dissection of the prevertebral space, a suprahyoid pharyngotomy, and transection of the pharynx, and tracheal and esophageal transection inferiorly are the standard surgical steps. A variety of techniques have been described for reconstruction, some of which are only of historic note. Nowadays, the most commonly used techniques are reconstruction with a tubed pedicled flap or a microvascular free flap, the latter being the option of choice. A pedicled regional flap such as a pectoralis major myocutaneous or, less commonly, a deltopectoral fasciocutaneous flap is used in patients unfit for microvascular reconstruction.

A tubed radial forearm free flap (RFFF) provides excellent functional reconstruction with minimal donor site problems and may be modified to incorporate reconstruction with the neck skin (**Fig. 16.6**).[32] In forearm donor sites unfit for RFFF harvest and in patients with a suitable body habitus, the anterolateral thigh flap may be used (**Fig. 16.7**).[33] Free jejunal grafts have been used as one of the reconstructive options because the caliber of the

jejunum closely matches that of the upper esophagus. However, abdominal donor site morbidity, suboptimal quality of swallowing, and tracheojejunal voice[34] do not make it a preferred reconstruction option. Other reported reconstructive options with free tissue transfer include lateral thigh, latissimus dorsi, and gastro-omental flaps.

Total Laryngopharyngoesophagectomy

A total laryngopharyngectomy with resection of the esophagus in continuity is indicated for cancers of the hypopharynx with extension into the cervical esophagus or for a primary cancer of the upper esophagus with or without extension into the postcricoid area. A histopathologic safe resection margin of at least 4 to 7 cm is recommended for primary esophageal SCC.[35] The intrathoracic esophagus has conventionally been mobilized through the transhiatal or open thoracotomy approach, but the newer thoracoscopic mobilization has enabled a more controlled mediastinal dissection with reduced blood loss and morbidity.[7] A gastric pull-up is the reconstruction method of choice if resection of the cancer involves extensive resection of the esophagus. Gastric pull-up includes mobilization and transposition of the stomach into the thoracic cavity for restoring continuity of the alimentary tract. A tensionless anastomosis at the junction between oropharynx and stomach and a pyloromyotomy for efficient gastric drainage are crucial to prevent fistula formation and postoperative regurgitation. Colonic transposition is another reconstructive option for patients undergoing total esophagectomy.

Postoperative Management

Routine care for wound, suction drains, and tracheostomy is instituted along with perioperative antibiotics. Initiation of oral alimentation is avoided until at least 7 days after primary surgery and about 14 days in radiated patients prior to which nutritional status is maintained with nasogastric feeding. Serum protein and calcium levels are assessed and corrected as required. Intensive monitoring of flap viability is required in patients with flap reconstruction. Patients with conservation open surgery may require a PEG insertion if the aspiration is significant in order to prevent serious pulmonary complications. A trial of decannulation is usually initiated in patients with open conservation surgery after two weeks, if the airway is observed to be adequate. Decannulation may be prolonged in patients with SCHLP, as may be removal of the PEG tube.

Complications

The early complications following open surgery include hematoma in the neck, wound infection, pharyngocutaneous fistula, postoperative hypocalcemia, and flap necrosis. The most frequent late complication is varying degrees of dysphagia, which can result from neopharyngeal dysmotility or stricture formation usually at the inferior end of the neopharynx. Stomal stenosis can also occur as a late complication in patients who have had a total laryngectomy. Patients undergoing total laryngopharyngoesophagectomy are at increased risk of hemorrhage, tracheobronchial injury, and pulmonary complications such as chylothorax, atelectasis, and pneumonia. The procedure of gastric pull-up is associated with complications of anastomotic disruption or fistula; pulmonary complications such as mediastinitis, pneumothorax, and hemorrhage; and discomfort from gastric outlet obstruction-like symptoms. Necrosis and anastomotic dehiscence may also occur with jejunal autografts and colonic transposition.

Management of the Neck

A selective or modified radical neck dissection including levels II, III, IV, and VI is performed for patients with clinically positive nodes. Involvement of levels I and V are not common, hence these nodes are only included in the

dissection if indicated by the extent of metastasis to the neck.[36] Cancer of the hypopharynx is associated with a high incidence of bilateral lymph node metastases; hence, the contralateral neck is often treated on an elective basis, especially if the ipsilateral neck is pathologically positive or if the tumor extends to or crosses the midline such as those located in the medial wall of the PFS, postcricoid, and posterior pharyngeal wall. Cancer of the hypopharynx is also associated with higher contralateral occult metastasis in patients with clinically negative necks; rates up to 47% have been reported.[37] Clinically, negative necks are commonly associated with occult nodal metastases even for early (T1 to T2) cancer of the hypopharynx. An occult metastatic rate of ~50% is documented for cancers of the PFS.[38–40] Hence, a selective neck dissection including at least levels II, III, and IV is recommended in clinically negative necks. Level VI nodes should also be explored and dissected in postcricoid SCC and lesions extending to or involving the apex of the PFS and cervical esophagus.

Cancers of the posterior hypopharynx are at high risk of spread into the RPLNs. In a study[41] of 82 patients with hypopharynx and cervical esophagus undergoing RPLN dissection, metastases were reported in 16 patients (20%); 14 of these had SCC of the hypopharynx, of which 57% had involvement of the posterior pharyngeal wall. Though RPLN metastases are usually reported in cN+ necks, 15% of the patients in this study had a cN0 lateral neck. Another study[42] demonstrated that all patients with radiologically evident RPLN metastases had metastases at levels II and III; and RPLN are also strongly correlated with bilateral cervical metastases. Hence, RPLN are addressed using the approach created by resection of the primary if there is presence of radiologic evidence and dissection can be performed safely. Otherwise, they are included in the postoperative radiation field. RPLN metastases in cancer of the hypopharynx have been correlated with poor local control rates. Improved survival and reduced death from RPLN metastases after RPLN dissection has been reported in a few studies[41,43]; however, no improvement was noted in a series of 365 patients undergoing total laryngopharyngectomy with RPLN dissection.[44]

Bilateral neck dissection, including levels II to IV, VI, and the periesophageal nodes, is recommended for patients undergoing surgical resection for cancer of the cervical esophagus. Mediastinal lymphadenectomy may be required for patients with cancer of the cervical esophageal who are

discovered to have a synchronous primary cancer in the intrathoracic esophageal segment during esophagectomy.

Postoperative Therapy

The indications for adjuvant therapy following surgery include adverse pathologic features such as a T4 primary cancer, a positive or close resection margin, extracapsular spread, multiple metastatic nodes, significant extralaryngeal spread, and perineural or lymphovascular invasion. Concurrent cisplatin with postoperative radiation is recommended in patients with extracapsular spread and/or positive margins based on a pooled study of patients from RTOG 9501 and EORTC 22931 trials.[45] The hypopharynx was present as the primary site of cancer in only 10% of the RTOG[46] trial patients and in 20% of the EORTC[47] trial patients. The decision for appropriate adjuvant therapy should be made by a multidisciplinary team considering the disease status, treatment toxicity, and patient preference.

Nonsurgical Treatment

Radiation

Definitive radiation alone provides an alternative nonsurgical therapeutic option for patients with stage I and II hypopharyngeal SCC. A standard fractionation regimen involves administration of 70 to 72 Gy in fractions of 2 Gy each over 6 to 7 weeks, using the intensity-modulated radiation therapy (IMRT) or the classic three-dimensional conformal shrinking field technique. The treatment field extends from the skull base to clavicle and includes bilateral nodal basins. The dose to clinically negative nodal levels may be reduced to 50 to 56 Gy. The use of altered fractionation to intensify radiation such as hyperfractionation or accelerated regimens over conventional fractionation has been reported for stage III and IV disease.[48,49] The radiation doses and field design for primary cancers of the cervical esophagus are similar to hypopharyngeal cancer, which extends to this region; additional lymph nodes in the upper mediastinum are included in the field as required.

Chemoradiation

The two main nonsurgical treatment protocols for cancer of the hypopharynx and cervical esophagus, which use chemotherapy in combination with radiation, are concurrent chemoradiation and induction chemotherapy followed by concurrent chemoradiation. The most common chemotherapeutic agent used in concurrent chemoradiation is cisplatinum administered on days 1, 15, and 23 of radiation. The most common regimen for induction chemotherapy is a combination of taxane, platinum, and 5-fluorouracil (TPF) administered in three cycles following by concurrent chemoradiotherapy. Cetuximab, a monocolonal antibody and epidermal growth factor receptor (EGFR) blocker, is used in patients with known contraindications to cisplatinum. Radiation with cetuximab was shown to improve outcomes compared to radiation alone in a multicenter when SCC of various head and neck subsites were assessed together in a randomized trial[50]; however, the antitumor efficacy was not observed in a subgroup analysis of patients with cancer of the hypopharynx.

Complications

The most common *acute* toxicities with radiation are mucositis, xerostomia, nausea, vomiting, anorexia, dysgeusia, and dermatitis. The radiation-related adverse effects are exacerbated with the addition of cisplatin, which adds toxicities such as cytopenia, febrile neutropenia, sepsis, dehydration, hearing loss, nephropathy, and peripheral neuropathy. The most common adverse events from cetuximab include infusion reactions, acneiform skin rash, and nail disorders.[51,52]Airway edema and malnutrition may require an emergent tracheostomy and PEG insertion during the therapy. Dysphagia and aspiration from pharyngeal stenosis or esophageal stricture are the most common late toxicities of chemoradiation.[53–55] A pharyngoesophageal stricture rate of 21% was documented in a study of 199 patients treated with chemoradiation for SCC of the head and neck, the hypopharynx as the primary site was noted to be a significant predictive factor for stricture formation.[54] In another study, the feeding tube dependency rate for patients treated for cancer of the hypopharynx with concurrent chemoradiation was 31%.[55] Other long-term sequelae include cervical fibrosis, laryngeal chondroradionecrosis, and hypothyroidism. Patients may also be at risk of increased long-term toxicity with a preserved but dysfunctional larynx due to the progressive injury from chemoradiation-related nerve dysfunction,

stenosis, and fibrosis of the mucosa and muscles.[54,56–58] In patients undergoing salvage surgery for recurrent or persistent cancer after radiation or chemoradiation, higher rates of complications such as wound infection or dehiscence, pharyngocutaneous fistula, carotid rupture, and pharyngeal strictures have been observed.[59–62]

Quality of Life and Rehabilitation

Prospective evaluation of QOL outcomes has not been performed for patients with SCC of the hypopharynx who have undergone surgical versus nonsurgical treatment. However, a few studies have assessed the QOL in patients with cancer of either the oropharynx or larynx or hypopharynx treated with surgery and postoperative radiation versus concurrent chemoradiation. In the studies by El-Deiry et al.,[63] minor differences were found in favor of concurrent chemoradiation for esthetics and speech and in favor of surgery for overall QOL and avoidance of depression. In short, the overall QOL was found to be relatively well preserved in both treatment groups. In another study by Major et al.,[64] no difference between the two treatment groups was observed in patients with cancer of the larynx and hypopharynx for eight QOL domains of physical function, bodily pain, energy, health perception, social functioning, or mental health; however, patients who underwent surgery were more likely to be limited in their ability to perform activities of daily living.

For assessing the QOL in patients with cancer of the cervical esophagus, a retrospective study compared 15 patients who underwent total laryngopharyngoesophagectomy and gastric pull-up with 14 patients who received chemoradiation.[35] The posttreatment dysphagia score was significantly better for the operative group. The posttreatment QOL as assessed by a World Health Organization Questionnaire improved in both groups and was better in the operative group: however, the difference was not significant.

Speech and swallowing are critical for a good QOL; hence, rehabilitation of these functions with the assistance of a speech–language pathologist is fundamental to the management of patients with cancer of the hypopharynx, both after conservation and radical surgery as well as nonsurgical therapy. A

primary tracheoesophageal puncture (TEP) is performed for voice restoration in patients having a total laryngectomy. In patients with a total laryngopharyngectomy and tubed flap reconstruction, we recommend creating the TEP through the inlet of the esophageal stump to the infrastomal trachea, before the inferior end of the flap is anastomosed to the esophagus.[34] This maneuver eliminates periprosthesis air leakage, which in turn produces a better voice. Other methods commonly employed for voice rehabilitation include the use of electromechanical devices and esophageal speech. In patients undergoing definitive nonsurgical therapy, initiation of swallowing exercises early during the treatment, dietary modifications, and avoidance of nil-per-os (NPO) periods tend to reduce dysphagia and aspiration.[65]

Outcomes

For early cancer of the hypopharynx, high local control rates and survival have been observed with both conservation surgery and radiation when used as the primary therapeutic modality; however, no prospective comparisons have been made between the two. In a study of 101 patients with T1 to T2 cancers of the PFS treated with radiotherapy and a planned neck dissection in 43% patients, Amdur et al.[66] reported local control of 86% for T1 and 82% for T2 lesions. Late complications were noted in 12% of patients with mortality in three patients, total laryngectomy for chondronecrosis in three patients, and a gastrostomy in seven patients. Other radiation series report 5-year disease-specific survival and laryngeal preservation rates of 85% to 95.8% and 84% to 87% for T1N0 disease and 62% to 70% and 56% to 73%, respectively, for T2N0.[67,68] For T2 lesions, high volume of cancer and cancer at the PFS apex correlate with poorer local control.[69] A study by Pameijer et al.[70] reported significantly reduced 2-year local control rates if cancer volume was >6.5 mL, which roughly correlated with a tumor diameter of >2.5 cm. Survival is reported to be similar in patients treated by conservation surgery, open and transoral, ± postoperative radiation. The transoral approach has the potential to offer good disease control with fewer complications and faster recovery of swallowing.[69] Holsinger et al.[71] reported a 5-year actuarial local control estimate of 79.6% in 30 patients with T1 to T2 cancer of the PFS treated by partial pharyngectomy via lateral pharyngotomy with preoperative

chemotherapy in 8. None of the patients required neither gastrostomy nor completion total laryngectomy for functional reasons. With SCHLP for T2 PFS lesions, Laccourreye et al.[72] reported a 5-year disease-specific survival rate of 56% with a 5-year actuarial local recurrence in 3.4%; 91% of the 34 patients received induction chemotherapy, especially for T1 to T2 cancers. Local control across most TLM studies range from 72% to 90%.[73–77] A series of 23 hypopharyngeal SCC patients (T1 to T2: 70%) resected with TORS reported a 3-year disease-free survival of 84% with 96% of the patients with favorable swallowing results.[24]

For advanced hypopharyngeal SCC, the prognosis is poorer with most studies reporting the 5-year overall survival in the range of 15% to 50%, regardless of the treatment modality.[1,19] Conservation surgery of SCHLP[29] and near-total laryngectomy[78] have been applied to advanced lesions with good local control and survival, but the techniques may be challenging. Five-year actuarial local control of 93% in T3 and 63% in T4 PFS SCC has been reported by Laccourreye et al. using SCHLP; a majority of cases also received induction chemotherapy.[29] Five-year survival of ~66% with high local control has been reported for cancer of the hypopharynx treated with near-total laryngectomy.[78,79] The outcomes with TLM for advanced T3 to T4 cancers is favorable with diligent case selection, although the experience is limited to a few institutions. Vilaseca et al. reported a local control rate of 67% for T3 cancers (*n* = 6/9).[74] Martin et al.[80] reported 5-year Kaplan Meier local control rates of 75% for T3 and 57% for T4 cancers. For the entire series of 172 patients, they reported a 5-year recurrence-free survival of 73% for stages I to II, 59% for stage III, and 47% for IV. Laryngeal function was preserved in all but one. Six patients had permanent gastrostomy tubes.[80]

Randomized trials have been conducted to assess the outcomes of radical surgery versus nonsurgical combined therapy with chemoradiation. The EORTC 24981 multicenter study randomized 194 T2 to T4 patients with cancer of the hypopharynx (T2, 19.5%; T3, 75%; T4, 6%) patients to total laryngectomy or induction chemotherapy followed by radiation and reported similar10-year progression-free survival in the two arms (8.5% in surgery and 11% in induction RT arm) and a laryngeal preservation rate of 8.7%.[81]Another trial of 92 patients with T3 to T4 cancer of the hypopharynx randomized to surgery or radiation alone following neoadjuvant chemotherapy reported better 5-year overall survival (37% vs. 19%) and local

control (63% vs. 39%) in the surgical versus RT arm.[82] In an epidemiologic study of 595 patients (T1 to T2: 46%; T3 to T4: 54%), Hall et al.[83] demonstrated that there was no difference in overall survival or cause-specific survival after surgery ± postoperative radiation or definitive RT ± salvage surgery. These data were analyzed using three techniques: a restricted cohort study (patients with only resectable disease), a matched case study (for the criteria of T stage, N stage, and performance score), and a natural experiment study (based on geographical differences in treatment practices). None of the three methods revealed a difference in survival.[83]

For recurrent cancer of the hypopharynx in patients originally treated with radiation or chemoradiation, salvage surgery can achieve locoregional control if performed as a timely intervention in selected patients, but usually, the recurrent cancer is advanced resulting in low survival with frequent perioperative complications rates. Five-year survival across different studies varies from 18% to 23%.[84–86]

Due to the rarity of cancer of the cervical esophagus, large series reports on treatment outcomes are sparse. The reported 5-year survival outcomes with either radical surgery and adjuvant therapy or nonsurgical therapy in patients treated with curative intent are similar and range from 15% to 40%.[7,87] Dysphagia and aspiration pneumonia are common posttreatment sequelae and have been reported to be more common with nonsurgical approaches, whereas voice is a problem with surgically treated patients.[35]

Thus, based on the available studies reporting disease outcomes with different therapeutic strategies, there is no strong evidence to support one curative treatment over another. Direct comparison of patient function and QOL using uniform validated instruments is also lacking. Therefore, it is important that the therapeutic decision is made by a multidisciplinary team in the best interest of the needs and preferences of the patient in order to optimize the cure, function, and QOL and minimize treatment-related morbidity and mortality.

17 Tumors of the Cervical Trachea

Ralph W. Gilbert Shaf Keshavjee

Primary tumors in the trachea are relatively uncommon, with an estimated 2.7 new cases per million per year. The rarity of these tumors and their subtle clinical presentation require surgeons to have a high index of suspicion particularly with specific clinical presentations. Patients with a tumor of the trachea will present with a range of symptoms, including dyspnea on exertion and inspiratory wheezing, with a normal chest radiograph. Frequently, these patients will be diagnosed and treated as adult-onset asthma long before further investigations determine the presence of an obstructing tumor of the trachea.

This chapter will review the surgical anatomy of the cervical trachea, clinical presentation and diagnostic evaluation of patients with tumors of the cervical trachea, and anesthetic and surgical approaches to both resection and reconstruction of the cervical trachea. It will also review the role of nonsurgical organ preservation approaches and the role of adjuvant therapy in the management of malignant tumors of the upper airway.

The surgical approach to tumors involving the cervical trachea differs from the approach used for tumors of the distal trachea or carina. Although this chapter is directed toward the special problems of the cervical trachea, generalizations must be made from the total experience with tumors of the trachea.

Surgical Anatomy of the Trachea

The trachea begins at the lower border of the cricoid cartilage and terminates where the lateral walls of the right and left main bronchi flare out from the lower trachea. The carinal spur is useful as a definite landmark for the termination of the trachea because it is clearly seen both bronchoscopically and radiologically. The average adult human trachea measures 11 cm in

length with slight variation in proportion to the height of the individual.[1] There are approximately two tracheal cartilaginous rings per centimeter of trachea. With the exception of congenital tracheal stenosis with circumferential rings of the trachea, the cricoid is the only completely circular cartilage in the upper airway.

Direct access to the trachea in the neck is of critical importance both for surgical access and for ease of reconstruction following resection. In young people, hyperextension of the neck frequently delivers in excess of 50% of the trachea into the neck.[2] However, in an aged, kyphotic individual, even the most vigorous hyperextension may fail to deliver any of the trachea into the neck. The anatomic position of the trachea changes from an essentially subcutaneous position at the level of the cricoid to a prevertebral position at the level of the carina; thus, the course of the trachea is normally caudad and dorsal.

The blood supply of the trachea is of critical importance in resection and reconstruction of the trachea. The upper trachea is supplied primarily by branches of the inferior thyroid artery, and the lower trachea is supplied by branches of the bronchial artery, with contributions from the subclavian, supreme intercostal, internal thoracic, and innominate arteries. These vessels provide branches anteriorly to the trachea and posteriorly to the esophagus. They have a perforating pattern that arrives at the trachea from its lateral aspect. The longitudinal anastomoses between these vessels are fine, and transverse intercartilaginous arteries branch ultimately into a submucosal capillary network.[2–4] Excessive division or dissection of these lateral perforators during circumferential dissection of the trachea risks disruption of this network and may lead to devascularization of trachea segments and a failed anastomosis.

The trachea is also intimately related to several critical structures. These include the recurrent laryngeal nerves, the esophagus, and the thyroid gland. Detailed knowledge of these anatomic relationships is essential before attempting any ablative or reconstructive surgery on the cervical trachea.

Evaluation of Patients

Symptoms of a tumor in the trachea, even in the presence of a high degree of airway obstruction, may be insidious. Most commonly, patients with a tumor

in the trachea present with any of dyspnea, hemoptysis, cough, wheezing, dysphagia, change hoarseness, stridor, and pneumonia. In one series, productive cough and shortness of breath were the most common symptoms. A history of slowly progressive dyspnea on exertion is often present.[5] Many patients with a malignant neoplasm will present with hemoptysis often leading to an appropriate bronchoscopic diagnosis. An irritative cough, which may or may not be productive and which may in time be associated with hemoptysis, is sometimes also seen. Change in vocal quality as a result of involvement of one or both recurrent laryngeal nerves is not uncommon and may be insidious in onset. Stridor as a presenting symptom is often reflective of a late presentation of disease. All too often, especially with slowly growing tumors such as adenoid cystic carcinoma, the patient who has developed slowly progressive shortness of breath and wheezing will have an apparently normal chest radiograph. This leads to the diagnosis of adult-onset asthma, with some patients treated with steroids for a prolonged period of time before the slowly growing tumor is discovered.

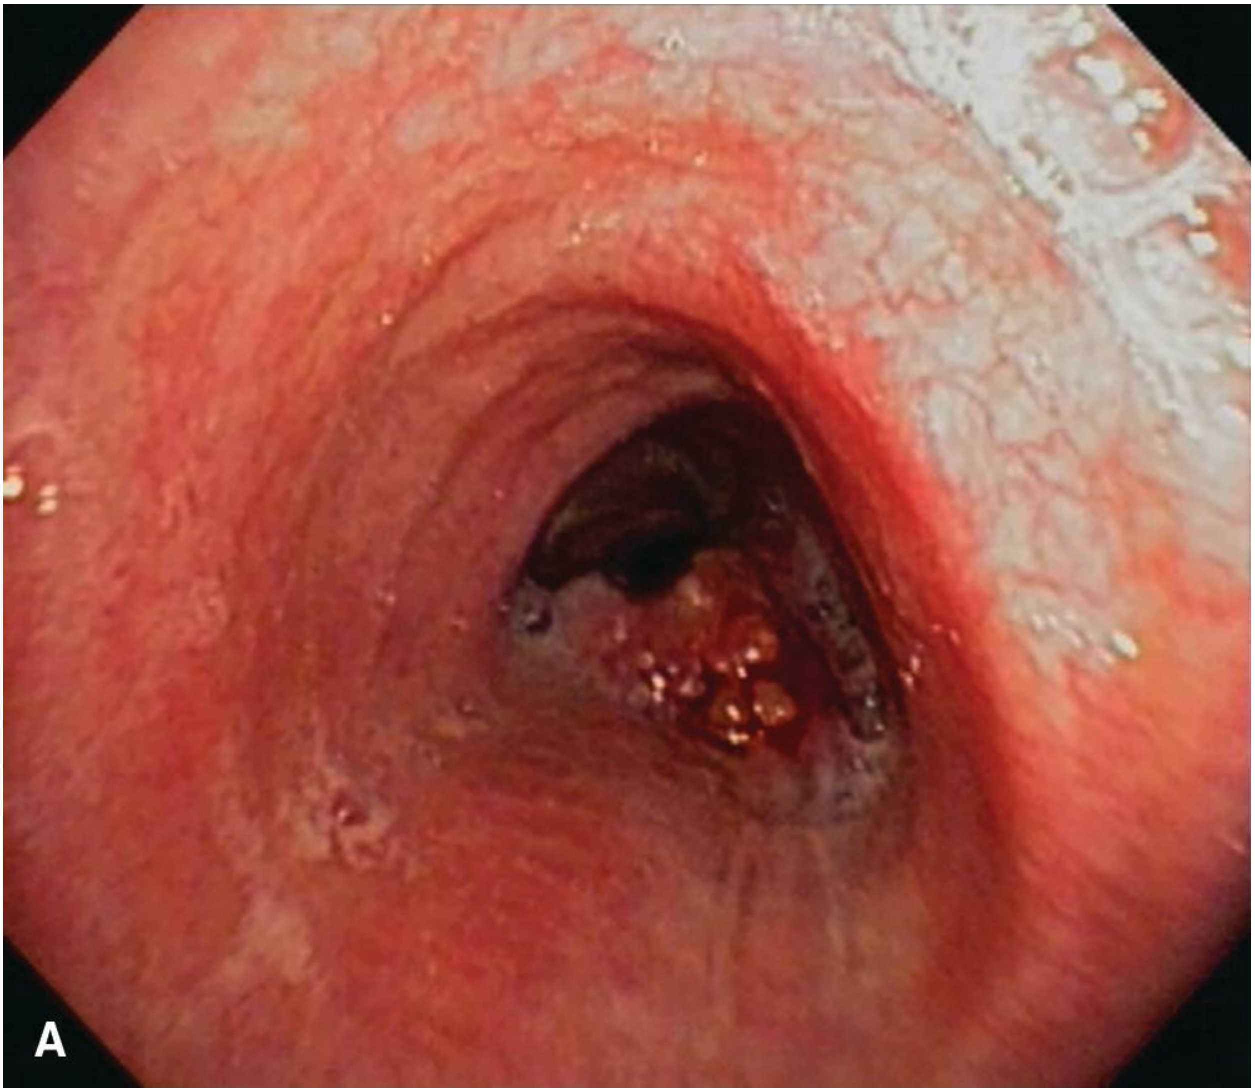
In general, the more aggressive tumors are diagnosed earlier owing to their propensity to present with prominent symptoms, for example, hemoptysis. In one study, the mean duration of symptoms before diagnosis in patients with squamous cell carcinoma (SCC) of the trachea was 4 months, whereas the mean duration of symptoms before diagnosis in adenoid cystic carcinoma of the trachea was 18 months.

Diagnostic Studies

The primary diagnostic modalities for delineating tracheal abnormalities are radiologic studies and laryngoscopy and bronchoscopy.

The following investigations are helpful:

1. Chest radiograph (posteroanterior, lateral, and oblique) centered high enough to obtain good views of the trachea.
2. Computed tomography (CT), with multiplanar reconstruction is the gold standard for assessing extent of disease and defining extratracheal involvement as well as detecting the presence of lymph node involvement[6] (Fig. 17.1A and B).
3. Three-dimensional reconstructions from CT can be useful in visualizing and planning surgery (Fig. 17.2A and B).



A

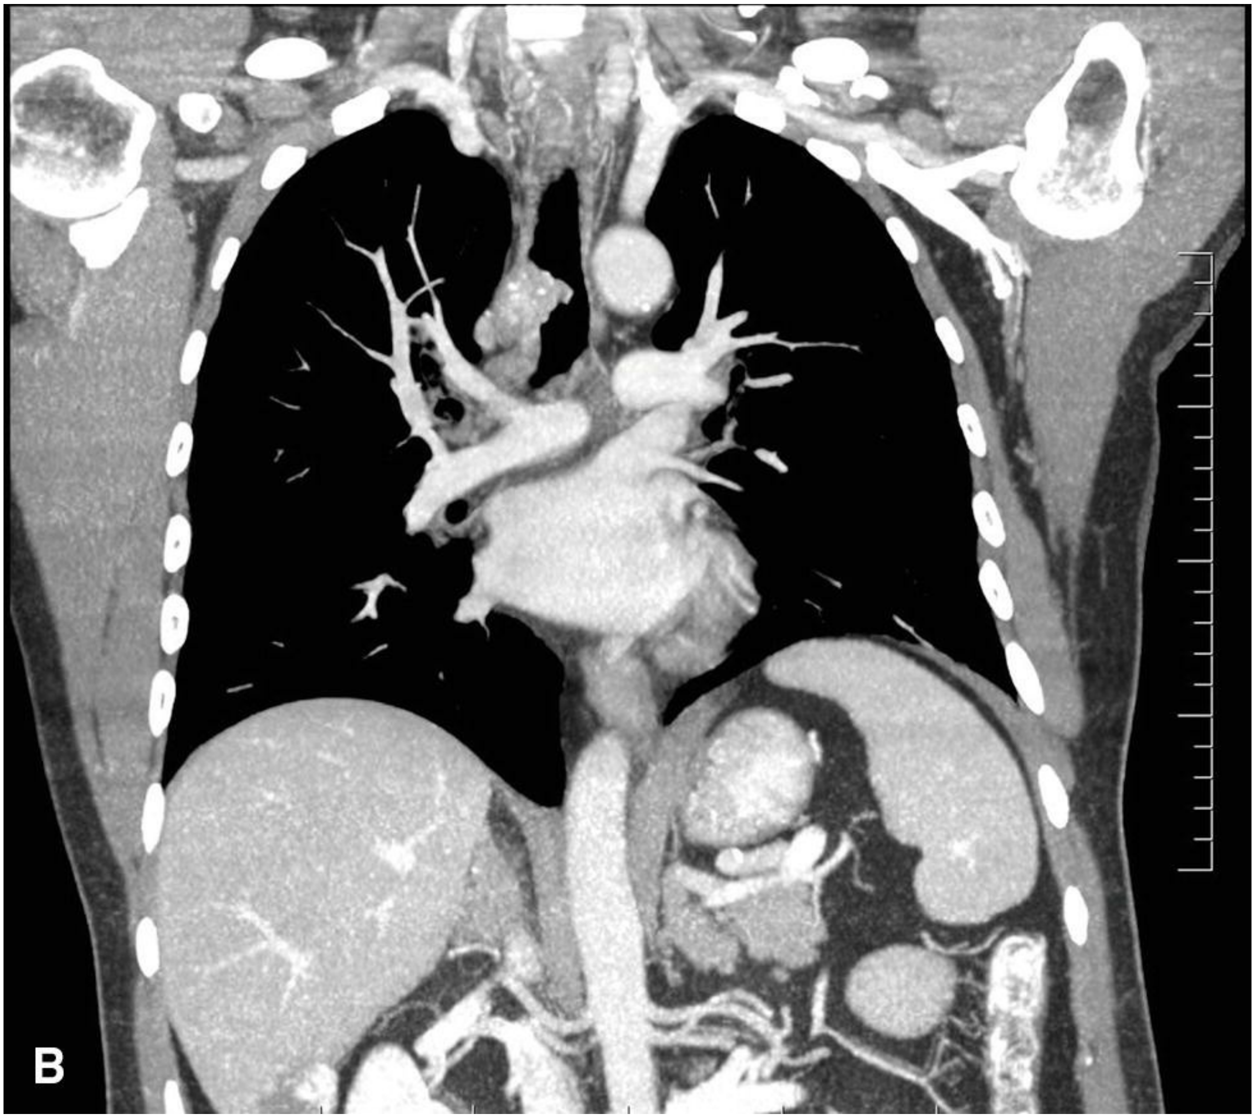


Figure 17.1. CT imaging of tracheal SCC including endoscopic view **(A)** and coronal CT **(B)**.

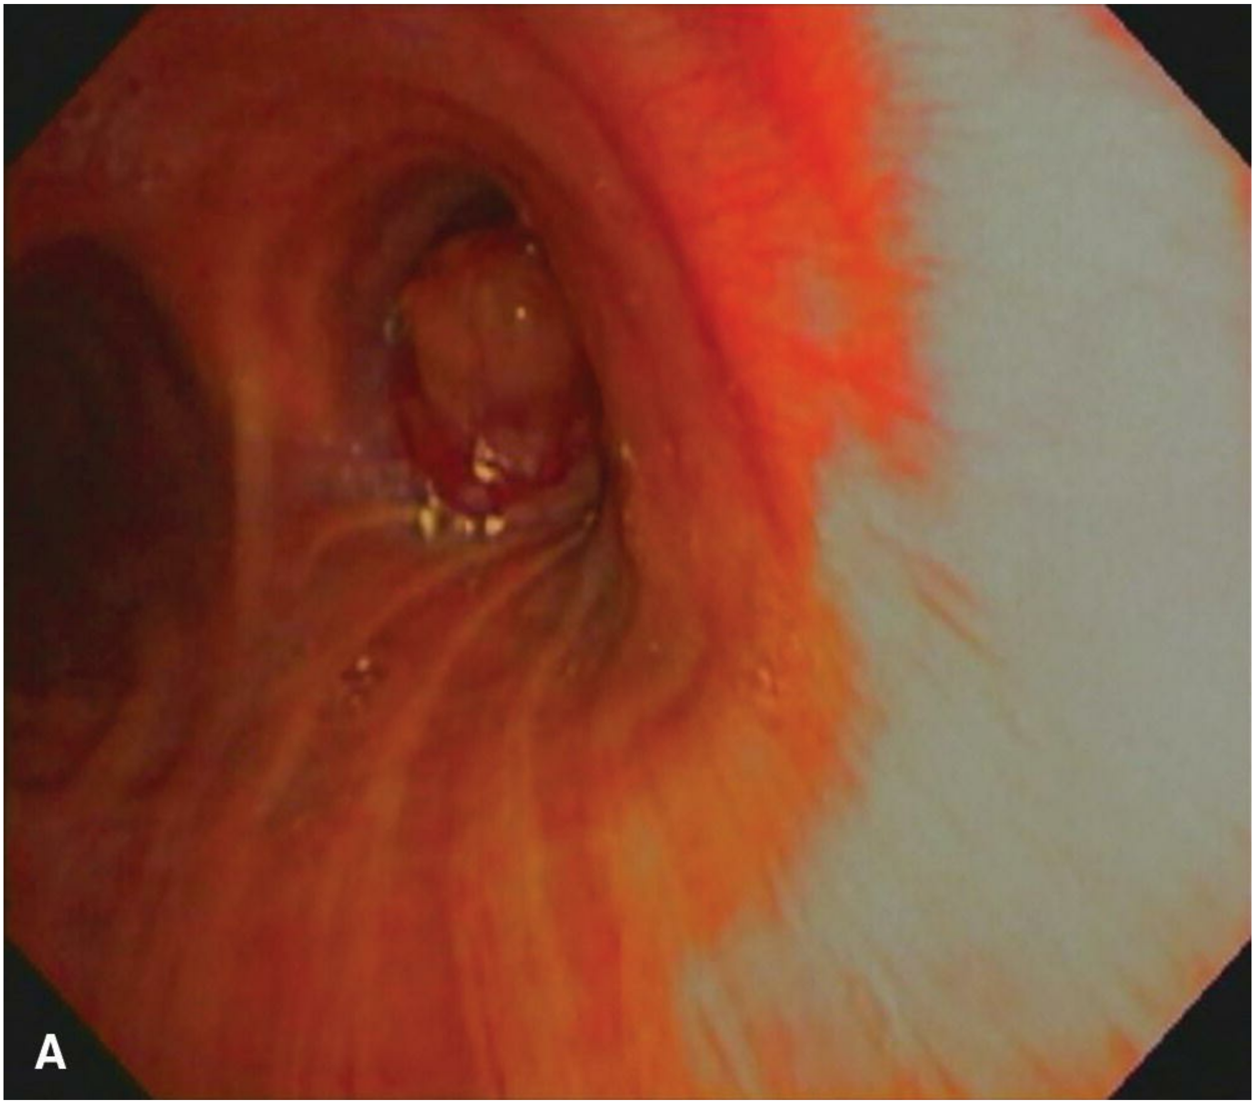

A

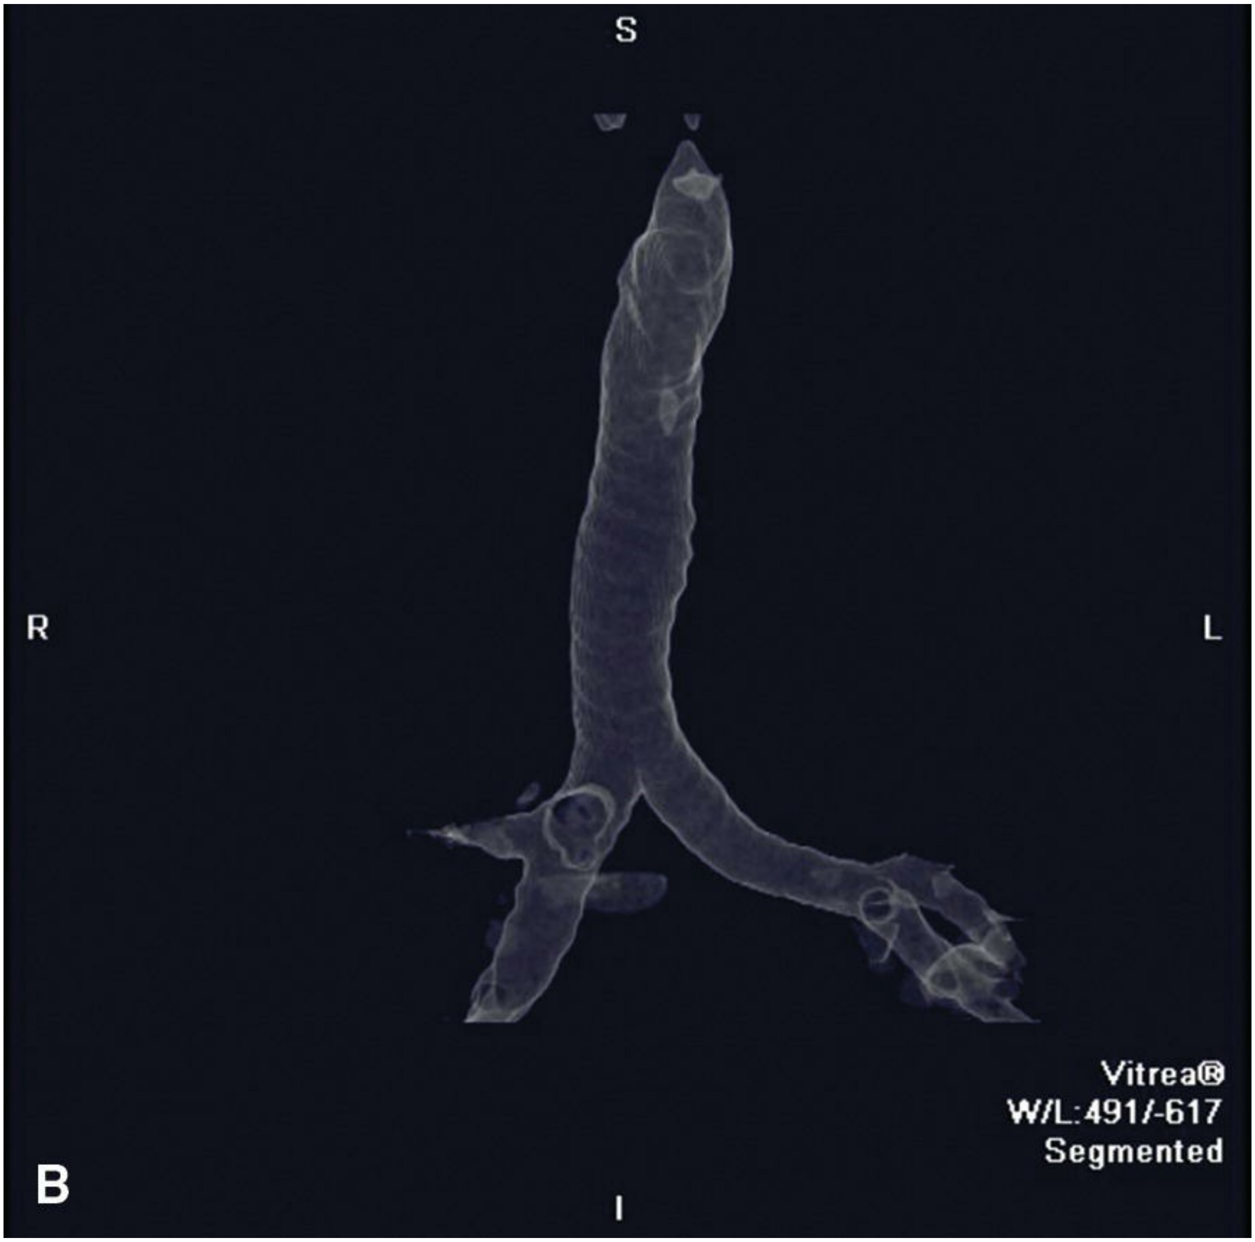

Figure 17.2. Endoscopic **(A)** and virtual endoscopic **(B)** views of tracheal tumor.

Barium esophagram may demonstrate esophageal involvement by extrinsic compression and/or invasion. Magnetic resonance imaging offers the advantage of soft tissue delineation of the trachea; however, it offers little advantage over CT.

Functional studies are of limited usefulness. They may, at times, call attention to an obstructing lesion when clinical signs and symptoms are subtle. Functional studies may also give information about the status of the

lung parenchyma.

All patients suspected of having or known to have a tumor of the trachea require endoscopy at some point during their evaluation. Great caution must be taken with the use of flexible laryngoscopy and bronchoscopy in these patients. Instrumentation of a nearly obstructed trachea may lead to bleeding, edema, or increased secretions that may precipitate sudden airway compromise. No effort should be made to employ instrumentation or to pass beyond a tumor if there is a high degree of obstruction unless preparations have been made to proceed directly with surgical intervention. It is preferable to simply identify the presence of the tumor and to defer any further evaluation and biopsy until appropriate arrangements have been made to manage the airway in the event of problems.

In general, the rigid bronchoscope is preferred when tumors of the trachea are studied. The need to establish an airway by tumor debulking or to obtain more adequate biopsy for diagnosis by frozen section justifies the use of the rigid bronchoscope (with appropriate magnifying telescopes). If necessary, the flexible bronchoscope may be passed through the rigid instrument for the evaluation of disease distal to the main obstruction. Careful measurements must be taken to determine the extent of tracheal involvement as well as to determine the amount of trachea remaining for reconstruction. It is important to establish the distance from the vocal cords to the superior aspect of the tumor, the length of the lesion, and distance from the inferior extent of the mucosal changes to the carina to facilitate surgical planning.

Histology and Staging of TUMORS OF THE TRACHEA

The common primary neoplasms of the trachea are listed in Table 17.1. The majority of tumors are either SCC or adenoid cystic carcinoma with SCC representing ~50% of the histology in most series. Other less common tumors include adenocarcinoma, carcinoid, or neuroendocrine and other rare tumors including sarcoma.

Table 17.1 Histology

Histology	Urdaneta[24]	Regnard[9]	Webb[18]
SCC	45%	52%	46%
ACC	16%	36%	26%
Small cell (neuroendocrine)	9%	5%	8%
Adenocarcinoma	6%	5%	8%
Large cell carcinoma	4%	ns	5%
Sarcoma	4%	1%	2%

Tumors are staged according to the AJCC staging system, which is illustrated in Table 17.2.[10]

Table 17.2 AJCC Staging[6]

	Definition
T Stage	
T1	Primary tumor confined to the trachea; size <2 cm
T2	Primary tumor confined to the trachea; size >2 cm
T3	Spread outside the trachea but not to adjacent organs or structures
T4	Spread to adjacent organs or structures
Tx	Unknown or cannot be assessed
N Stage	
N0	No evidence of regional nodal involvement
N1	Positive nodal involvement
Nx	Unknown or cannot be assessed

Presentation

Primary SCC of the trachea may present as an exophytic mass that is circumscribed or as a spreading lesion that involves a considerable length of the trachea. It may also present as an ulcerative lesion. The cancer may grow into the mediastinum and may be noted radiographically as a bulky extratracheal mass. Metastases to paratracheal and subcarinal lymph nodes as well as direct invasion of mediastinal structures may also occur. This cancer occurs predominantly in males, and the majority of patients will have a smoking history.

Adenoid cystic carcinoma may present as an exophytic mass, frequently with poorly defined margins. A bulky extratracheal mass may be present. In the cervical trachea, the thyroid gland may be directly invaded as well as the

esophagus. It is extremely unusual for adenoid cystic carcinoma of the trachea to present with regional lymph node metastases; if present, it suggests a high-grade subtype of this cancer. This tumor is histologically characterized by submucosal extension and perineural invasion over long distances of the trachea. The submucosal extent is often not visible, even after transection of the trachea. Frozen section control during surgery is critical, and the extent of the cancer may present the surgeon with a problem not predictable preoperatively. The hallmark of this cancer is frequent, and late presentation of metastases to the lungs is sometimes 5 to 10 years following presentation.

The group of miscellaneous cancers includes a wide variety of cancers of varying malignant potential.

Airway Management

Adequate control of the airway is of critical importance in the management of all tumors of the trachea. Tumors of the trachea may present with airway obstruction, and endotracheal intubation may prove impossible. Control of the airway is best accomplished in the operating room, where an assortment of rigid bronchoscopes, dilators, biopsy forceps, and instruments for emergency tracheotomy are available. The key element in safe airway management of these challenging patients is a close collaboration between the anesthesiologist and the attending surgeon. The plan for anesthesia, airway instrumentation, and postprocedural airway management should be discussed prior to the induction of anesthesia.

Anesthesia

Anesthesia for upper airway obstruction remains controversial.[11] Essentially, there are two approaches, inhalation induction with sedation or intravenous induction with administration of neuromuscular blockade. The traditional technique has been an inhalational induction with sevoflurane. Proponents of this technique believe that its major advantage is the maintenance of spontaneous ventilation, theoretically avoiding the risk of sudden loss of the airway. In clinical practice, however, when a patient with a severely obstructed airway undergoes an inhalational induction, the induction is slow, there are periods of apnea, and the patient often becomes hypoxic and hypercarbic. When inhalational induction fails, the anesthetic and surgical

team will have to revert to intravenous induction and neuromuscular blockade to maintain ventilation. The nontraditional technique and the one currently advocated by experienced airway teams are intravenous induction and neuromuscular blockade; these techniques accelerate induction and allow airway instrumentation while maintaining the ability to maintain ventilation. No single technique is perfect, and anesthesiologist faced with an upper airway obstruction need to use both techniques depending on the clinical experience of the team and its ability to instrument the airway.

Clinical Endoscopy

Initial evaluation should be done with a rigid bronchoscope carefully inserted through the vocal cords, stopping just proximal to the level of obstruction. Rigid telescopes may then be inserted through the bronchoscope to assess the degree of obstruction. A rigid bronchoscope can be passed beyond most tumors, even those causing near-complete airway obstruction. Once the status of the distal airway has been assessed, partial removal of the tumor with biopsy forceps can be done in order to determine its consistency and vascularity. For the vast majority of tumors, the tip of the rigid bronchoscope can be used to “core out” most of the tumor; the tumor may then be grasped with the biopsy forceps and removed. If bleeding is noted in the airway, the bronchoscope can be passed into the distal airway, thus ensuring adequate ventilation as well as serving to tamponade the bleeding. Epinephrine irrigation through the flexible or rigid bronchoscope can be effective in producing vasoconstriction and reducing bleeding. Rarely, cautery (with insulated suctions) may have to be used. The use of the YAG laser has become increasingly popular in the management of tumors obstructing the airway, as well as in coagulation of bleeding sites. Endotracheal removal of malignant tumors, either mechanically or by other means, is clearly a temporizing maneuver. However, the use of such techniques in emergent situations may allow for further evaluation of the patient in a relatively elective setting and allow for the appropriate surgery to be performed in an elective manner.

Treatment Selection

Treatment of Benign and Low-Grade Lesions

There is no question that the best treatment for a benign tumor of the trachea is complete surgical extirpation with primary end-to-end reconstruction.[12,13] This is almost always feasible for benign lesions, even if they are relatively extensive. Complete removal by circumferential segmental resection is likely the simplest approach. Occasionally, a surgeon is tempted to consider lateral resections; these may be indicated in selected patients with nonluminal involvement.

Tracheal resection and reconstruction have limited application for tumors that involve the trachea secondarily. When the primary tumor is localized and is a low-grade malignancy (e.g., papillary thyroid carcinoma), tracheal resection is indicated and is highly effective. The detailed management of thyroid cancer is discussed separately in this textbook; however, a recent publication suggests that with a variety of resection techniques and adjuvant radiotherapy, overall survival in this population of patients is 79% and 71% at 3 and 5 years, respectively.[14]

Treatment of Advanced Disease

Numerous options exist in the primary treatment of malignant tumors of the cervical trachea. Investigations and staging will establish whether a tumor is resectable or not. Generally, resectability includes patients with tumor involving <50% of the length of the trachea without significant involvement of extratracheal structures including the esophagus and mediastinal structures. In the setting of a resectable lesion, the primary treatment options include primary surgery alone, surgery and postoperative radiotherapy or chemoradiation, and primary chemoradiation without surgery. Neoadjuvant or preoperative radiotherapy is usually not indicated as it may compromise wound healing, a particularly important issue in the setting of trachea resection.

Whereas the evidence of quality is poor (level III), the consensus of published series suggests that for resectable lesions, primary surgery and adjuvant radiotherapy or chemoradiation in SCC of the cervical trachea and primary surgery and adjuvant radiotherapy in adenoid cystic carcinoma be considered.[8,9,12,15–18] Patients with adenoid cystic carcinoma can be challenging as these cancers may infiltrate submucosally and frequently exhibit perineural extension often making margin status problematic. In

patients with adenoid cystic carcinoma, the degree of radicality needs to be evaluated carefully. This group of patients will have a long survival and a high rate of distant metastases regardless of margin status. Inflicting significant surgical morbidity or risk of perioperative mortality needs to be considered in the context of probability of long-term survival.

In the patients who have unresectable cancer, most advocate primary radiotherapy or concomitant chemoradiation usually with cisplatinum-based chemotherapy protocols. A few series have reported complete responses in advanced cancers; however, the numbers of patients treated is extremely small.[19–22]

Prognostic factors predictive of disease-free survival and overall survival include resectability, margin status, nodal involvement, histology, and the use of adjuvant radiotherapy. Margin status is particularly important in SCC of the trachea along with the presence of nodal metastasis. Controversy exists over the importance of clear margins in adenoid cystic carcinoma with some authors showing significant impact on locoregional control and survival and others suggesting a less dramatic effect.[7,8]

Surgical Technique

The surgeon should have a comprehensive understanding of the techniques of management of the entire upper airway, including experience with flexible and rigid endoscopic techniques, various release maneuvers, and ways to obtain a tension-free anastomosis and an experience and understanding of the stenting options for the upper airway. The surgeon must know the blood supply of the trachea, the course of the recurrent laryngeal nerves, and the options for reconstruction. Each case must be carefully studied and each operation carefully planned before such a procedure is undertaken.

Positioning and Incision

The patient should be positioned to allow full access to the operative field. This usually means neck extension using an inflatable placed as a shoulder bolster. A low-collar incision is used for tumors located in the upper half of the trachea (Fig. 17.3). This incision may be extended through the upper portion of the sternum if access to the mediastinal trachea as required. Exposure of the larynx is obtained by carrying the flap elevation to the level

of the hyoid. If the tumor appears to be extensive, as is sometimes the case with adenoid cystic carcinoma, the patient should be positioned in a manner that allows extension of the incision into the right fourth interspace to the posterior axillary line. Some thoracic surgeons will free drape the right arm so that it can be moved back and forth as necessary.

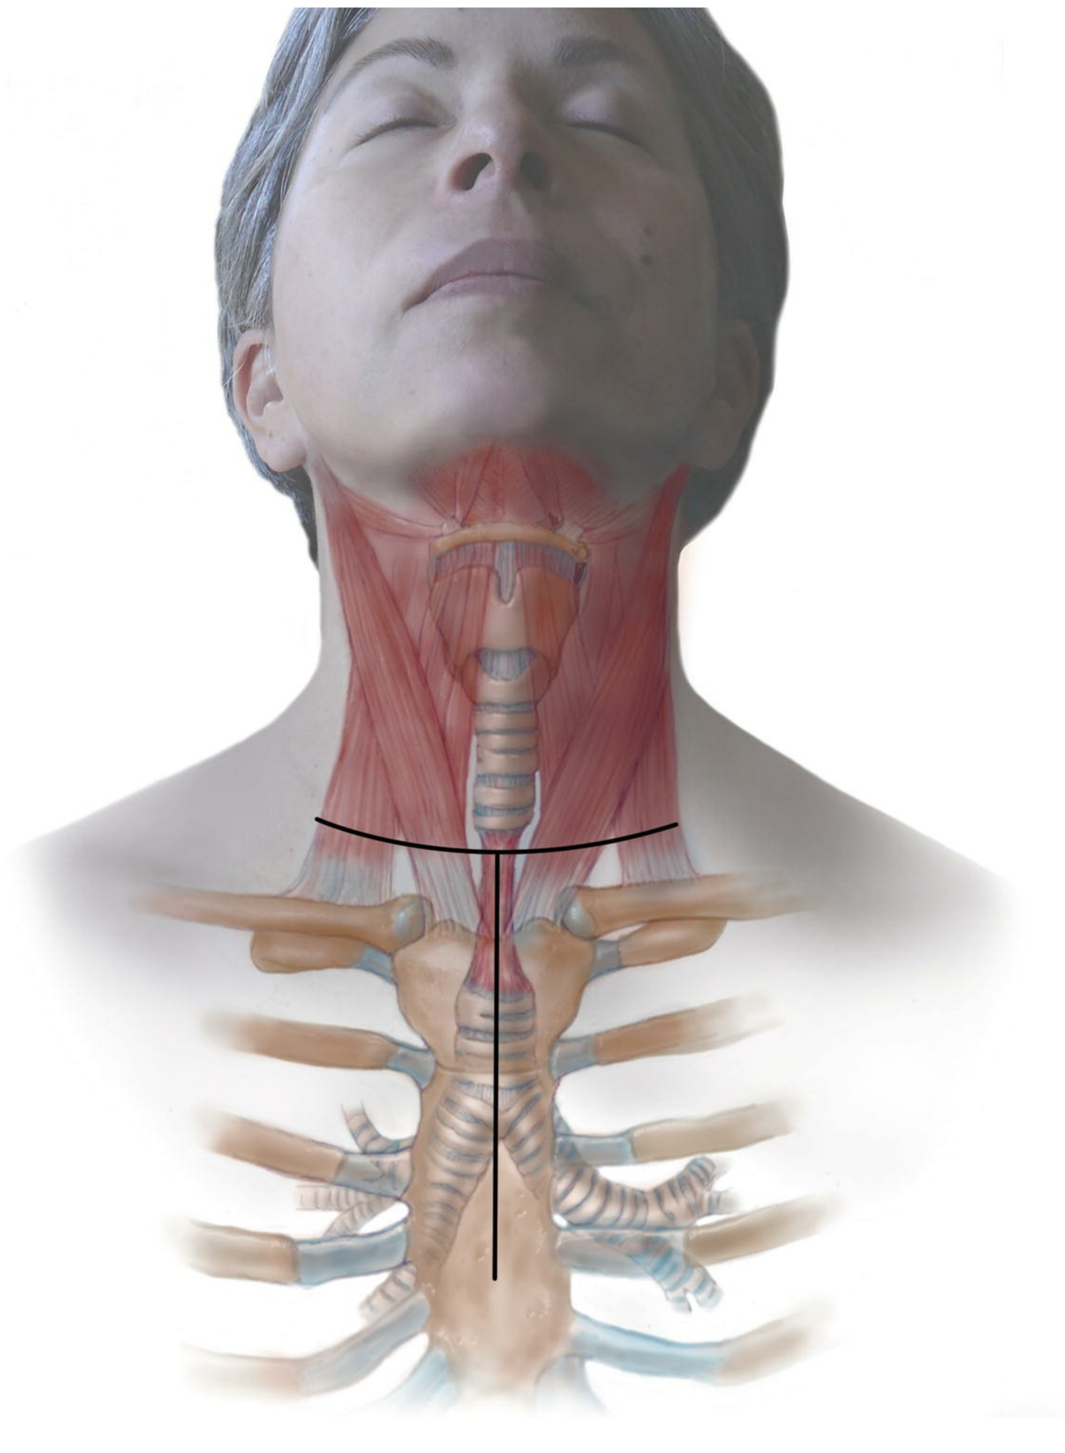

Figure 17.3. Incision design tracheal resection.

Resection

The surgical approach for benign tumors of the trachea varies somewhat more than that for malignant tumors. For benign tumors, dissection is maintained adjacent to the trachea; in this approach, which is similar to tracheal or cricotracheal resection, the recurrent nerves are not visualized. This approach is safe as long as the plane of dissection is maintained directly on the surface of the trachea.

When malignant tumors are resected, the recurrent laryngeal nerves are identified at a distance from the cancer and are followed toward the area of the cancer. It may be necessary to sacrifice a recurrent laryngeal nerve on the side of the tumor due to its involvement with the tumor. Adjacent lymph nodes should be included in any dissection for a malignant tumor. However, such a dissection should be limited because it may endanger the blood supply of the trachea. A compromise must be made between the potential of leaving behind paratracheal tissue that may contain positive lymph nodes and avoiding devascularization of the trachea. Circumferential dissection of the trachea over a great distance should be avoided because this may endanger the blood supply and can lead to problems with healing and/or stenosis. It is best not to circumferentially free more than 1 to 2 cm of trachea from the point at which the trachea is to be transected.

Once the trachea has been identified, the entire pretracheal plane is freed bluntly to the carina and often down the proximal anterior surfaces of the mainstem bronchi. Care is taken to spare the lateral pedicles because these contain the blood supply to the trachea. Isolation of the portion of the trachea containing the cancer is begun on the side of the trachea away from the cancer, and an effort is made to include appropriate lymph nodes. Once the inferior-most extent of the cancer is identified, preparations are then made for transection of the trachea. A sterile anesthetic circuit is passed to the anesthesiologist, and a sterile cuffed endotracheal tube is brought into the operative field. The trachea is then opened in a transverse manner immediately distal to the inferior aspect of the cancer, and the lumen is carefully inspected. If it seems that the division will occur at an appropriate level, the transection is completed; if the level is inappropriate, a more distal level is chosen under direct vision.

After transection of the distal trachea, the airway is intubated across the field with the flexible endotracheal tube. At this point, the orotracheal tube may be withdrawn to a level proximal to the anticipated proximal extent of tumor; it is wise to place a suture to the tip of the tube so that if it is withdrawn above the vocal cords, it may be reintroduced with ease at the end of the case. A small portion of tracheal tissue distal to the line of transection is removed and sent for frozen section analysis so that the adequacy of the distal margin can be determined.

The transected end of the trachea is now grasped with forceps and is placed on gentle traction to facilitate proximal dissection. The esophagus is usually left intact. However, it may be necessary to include a full-thickness segment of the anterolateral wall of the esophagus; at other times, only the muscularis may be excised. Any defect in the esophagus is repaired primarily in two layers with fine interrupted sutures and is reinforced with autologous tissue such as a strap muscle.

With the dissection carried proximally, the proximal extent of the cancer is identified from within the tracheal lumen, and a point of transection is chosen. At times, it may be necessary to bevel obliquely a portion of the inferior aspect of the larynx, such as half or more of the cricoid cartilage, to obtain an adequate proximal margin. Once the proximal point of transection is determined, traction sutures are placed in the proximal trachea in a manner similar to those placed distally, if the transection point is relatively high, the sutures may be placed in the larynx. The trachea is then transected, and a specimen is submitted for frozen section analysis of the proximal margin.

Reconstruction

After removal of the specimen and after establishment of clear margins of resection both proximally and distally, reconstruction can begin. The anesthesiologist is asked to temporarily flex the neck as the surgeon and assistant simultaneously draw together the traction sutures on each side of the trachea. Gentle traction on the sutures should approximate the two ends of the trachea. If excessive tension is noted, release maneuvers will need to be considered. Excessive tension on the anastomosis markedly increases the likelihood of separation or stenosis, both potentially disastrous complications. If further relaxation is deemed necessary to avoid excessive tension, a variety of release maneuvers may be used. The suprahyoid laryngeal release is

particularly effective, especially after resection of the proximal trachea. This maneuver usually obtains an additional 1 to 2.5 cm of tracheal length proximally, but it is of limited use in resection of the distal trachea or carina. Other maneuvers may be performed, but they require entry into the thoracic cavity. These include mobilization of the inferior pulmonary ligament, intrapericardial release of the right hilum, and, rarely, bronchial transplantation.

Once it has been demonstrated that tracheal approximation can be obtained without excessive tension, the neck is again extended and the anastomosis completed. The anastomosis is performed with a absorbable 4-0 monofilament suture. The use of absorbable suture material has dramatically reduced the incidence of suture line granulomas, a problem that was encountered with the use of nonabsorbable suture. Our approach is to place two stay sutures at the posterior edge of the cartilaginous trachea and then close the back wall with a running 4-0 suture. The stay sutures are tied and the back wall suture tensioned and tied to the stay sutures on each side (Fig. 17.4).

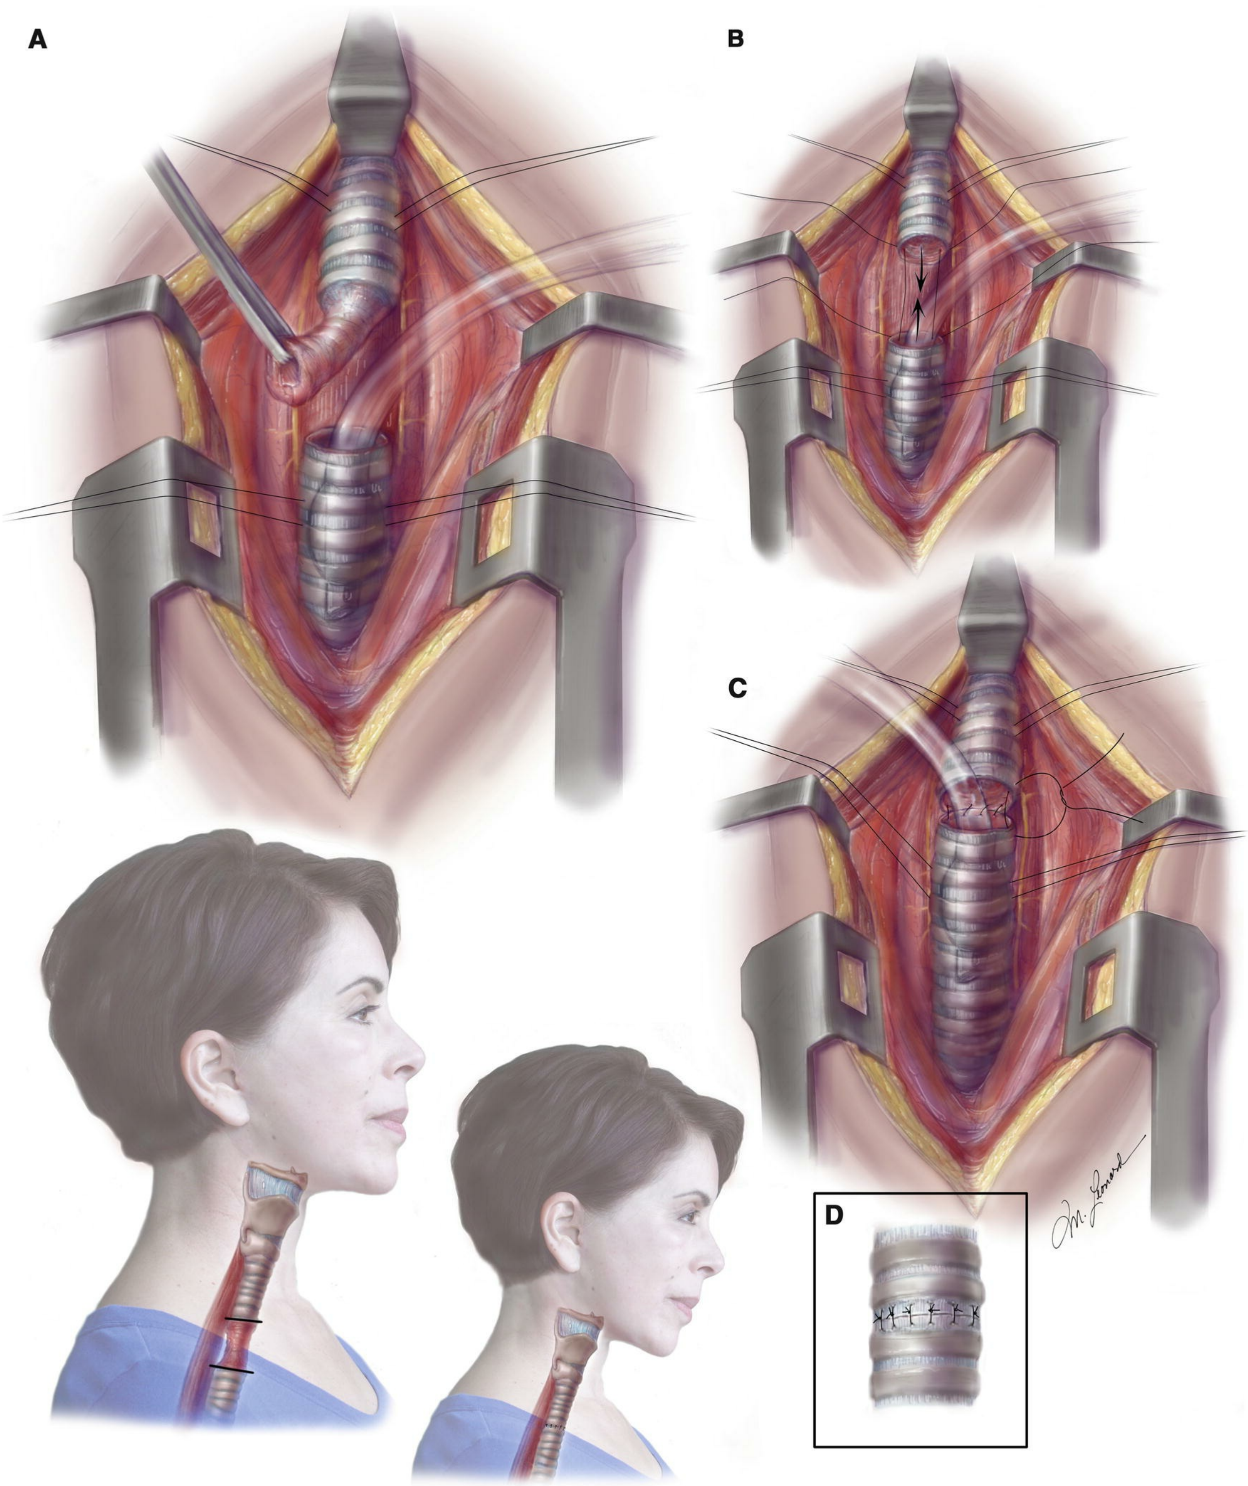

Figure 17.4. A–D: Circumferential cricotracheal resection.

The endotracheal tube is removed from across the operative field, and the orotracheal tube is once again advanced and placed into the distal airway under direct vision. The remaining anterior wall sutures are then placed in an

interrupted fashion. If the thyroid isthmus is intact, the isthmus may be sutured over the anastomosis. Although it is not necessary to interpose a pedicled strap muscle between the innominate artery and the anastomosis, some surgeons may wish to do so to add a measure of security.

Suction drains are placed in the substernal and/or paratracheal areas, and the incision is closed in layers. A heavy suture (Grillo stitch) is placed from the crease below the chin to the presternal skin. This serves as a guardian suture in the postoperative phase, reminding the patient not to suddenly hyperextend the neck. The suture is usually removed on postoperative day 5. Except in rare circumstances, every effort is made to extubate the patient at the conclusion of the operation. In patients with high tracheal or cricoid cancers where a cricotracheal resection has been performed, some authors advocate the use of silastic T-tubes. These tubes are usually positioned with the proximal limb just above the vocal cords with the external limb exiting the trachea one to two rings below the repair through a small tracheotomy. T-tubes have a role in patients at risk of supraglottic edema and potential airway obstruction and where the quality of the proximal or distal trachea is in question. We usually remove the T-tube 4 to 6 weeks postoperatively.

Postoperative Care

Throughout the performance of tracheal resection and reconstruction, care is taken to avoid the entry of blood and secretions into the tracheobronchial tree. This helps to prevent postoperative pneumonitis and shunting, the end result of which may be a requirement for mechanical ventilation, which is an extremely hazardous procedure for a patient with a recently completed tracheal reconstruction. During the operation, the assistant must be vigilant in the clearance of blood and secretions by careful suctioning and must not allow them entry into the airway (even in the presence of an inflated cuff). Postoperatively, the patient is instructed to maintain airway clearance with gentle coughing and other chest physical therapy maneuvers. If these techniques are inadequate, gentle tracheal suctioning is performed. If all of these maneuvers prove unsuccessful, then the flexible bronchoscope is used to clear secretions.

Palliation and the Use of Airway Stents

Patients presenting with advanced unresectable cancers or with locoregional recurrence and airway compromise represent a unique challenge both clinically and ethically. Expandable airway stents can relieve airway obstruction, providing an opportunity for patients to recover from interventions and be actively involved in treatment or palliative decision making. Expandable stents can however be problematic with issues including migration, perforation, and retained secretions in up to 15% of patients.[23] There is little compelling evidence that stents dramatically extend the lives of patients, but they do provide an opportunity to address the issue of acute airway compromise and have an important role in the management of patients with primary or recurrent tracheal tumors.

Outcomes

Treatment-related outcomes for cervical tracheal cancers are dependent on histology, stage of presentation, and resectability. Urdaneta et al.[24] published a SEER review of patients registered between 1973 and 2004 identifying 578 patients with primary tracheal tumors. For the entire dataset, overall survival at 5 years was 27.1%. The overall survival for patients with localized cancer was 46.8% at 5 years and for patients with regional metastasis 25.5% at 5 years. In this series, nodal involvement regardless of histology was associated with a 10.4% 5-year survival. Patients with a primary histologic diagnosis of SCC had a 5-year survival of 12.6%. Patients with a diagnosis of adenoid cystic carcinoma had a 5-year survival of 74.3%, reflecting the more indolent and longer survivals seen in this subset of patients.

The largest single institution series has been reported from the Massachusetts General Hospital with 191 patients treated for primary tracheal tumors between 1962 and 2002.[7] These authors report a series of 90 SCCs with 5- and 10-year survivals of 39% and 18%, respectively. In the same publication, they report a series of 101 adenoid cystic carcinomas with 5- and 10-year survivals of 52% and 29%.

Other series from large institutions include the series from MD Anderson with 5- and 10-year survivals of 20% and 10% for SCC and 5- and 10-year survivals of 45% and 28% for adenoid cystic carcinoma.[18]

Two European series have reported outcomes with adenoid cystic carcinoma with 5- and 10-year survivals of 73% and 57%, respectively, in

one series from France and 77% and 41% at 5 and 10 years from a center in Holland.[9,17]

Novel Reconstructive Approaches

The current standard for reconstruction of cervical tracheal resection is primary end-to-end anastomosis either trachea to trachea or cricotracheal repair. A number of centers have attempted tracheal reconstruction using nontraditional techniques particularly where primary repair is not feasible. The majority of these patients have been previously treated with radiotherapy or have low-grade tumors with a good prognosis such as papillary carcinoma of the thyroid or chondrosarcoma of the trachea or cricoid. A number of centers have reported the use of cutaneous free flaps with either intraluminal or extraluminal stenting.[25] Conceptually, this would seem an appropriate option; however, even when these flaps are thin, they will not maintain a rigid structure. More problematic however is the presence of skin in the upper airway. Long segments of skin lead to airway crusting and an inability to clear secretions from the lower airway as a result of the absence of a ciliated lubricated mucosal surface.

Other authors have considered and used the creation of constructs incorporating vascularized carriers usually fascial free flaps incorporating cartilage or bone with mucosal grafts (Fig. 17.5A–C). These have been used for partial tracheal defects with some success.[26]

D
M. Leonard

Figure 17.5. A and B: Vascularized composite allograft concept, concept for cricoid and upper tracheal reconstruction of partial cricoid or tracheal defects. **C and D:** Concept for reconstruction of central tracheal defect or stenosis.

Delaere and his group have used decellularized allografts vascularized by placing them in the forearm site. Once vascularized, they introduce recipient mucosal grafts from the nasal mucosa to recreate the luminal epithelium and then transfer the construct as a partial tracheal transplant vascularized through the radial artery and its venae commitantes.[27,28] This technique requires a number of months to create the construct and requires short-term immunosuppression as the allograft is introduced to the arm. This technique clearly has no application in high-grade cancer of the trachea but has been used in low-grade tumors with success.

Macchiarini and colleagues[29] have attempted a number of allograft tracheal transplants. In this approach restricted to patients with stenosis and congenital deformities, a decellularized allograft is recellularized in a bioreactor with autologous stem cells to recreate the supported structure and epithelial components. This technique is interesting but currently has no role in the management of malignant tracheal tumors. Early reports have demonstrated the need for continuous stenting putting in question the success and probability of long-term success with this technique of airway reconstruction.

SUMMARY

Primary cancers of the cervical trachea are extremely rare, with many patients presenting with late-stage disease. Two types of histology predominate, SCC and adenoid cystic carcinoma, each with quite different natural clinical courses. Airway management at presentation can be extremely challenging even to the most experienced airway surgeon and require an experienced team including anesthesia. Primary treatment for malignant tumors is multimodal with surgery and adjuvant radiotherapy or chemoradiation advocated for the majority of resectable patients. Primary nonsurgical therapy is reserved for patients with unresectable lesions. Surgical resection is best performed by teams with significant volume expertise in airway surgery.

18 Cancer of the Neck

Jesus E. Medina

Cervical lymph node metastases in patients with squamous cell carcinoma of the upper aerodigestive tract have important prognostic significance; when they are present, survival decreases by ~50%.[1] Detection of lymph node metastases at an early stage, preferably when they are microscopic, is paramount because the prognosis worsens as the extent of the metastases in the neck nodes (N stage) increases[2] (Fig. **18.1**). Depending on the location and stage of the primary tumor and the cervical lymph nodes, management of the neck may require surgery, radiation therapy, or both, and in some instances, it may also require chemotherapy. I begin this chapter presenting basic concepts such as surgical anatomy, staging, and nomenclature, and then, will outline the principles of management of the clinically negative (N0) and positive (N1/N3) neck.

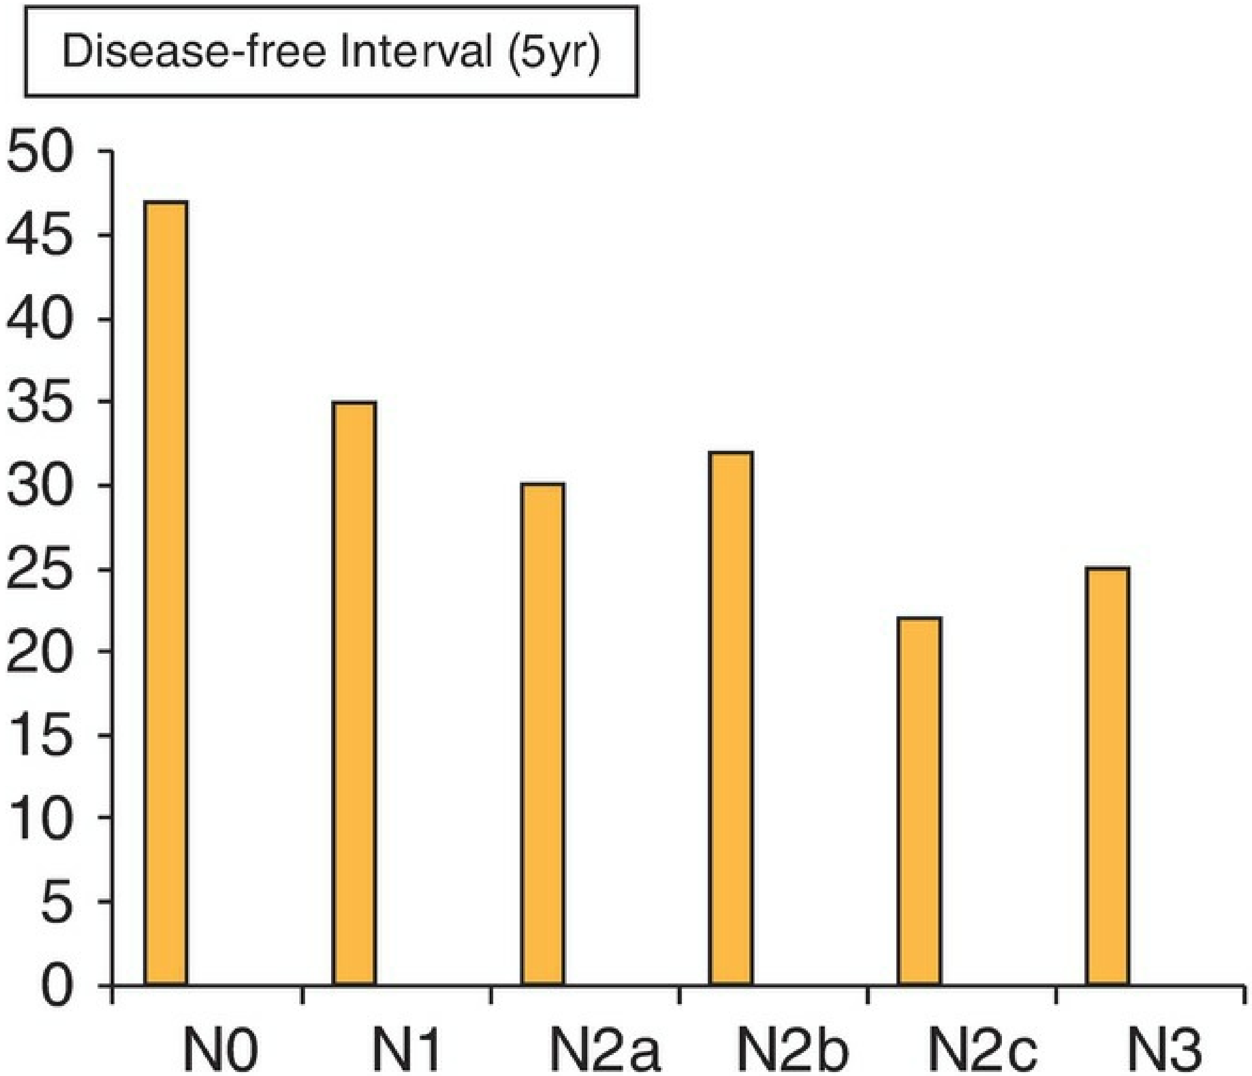

Figure 18.1. Impact of the extent of neck metastases (N stage) on prognosis. Disease-free interval according to TNM staging.

(Modified from Kowalski LP, Bagietto R Lara JR, et al. Prognostic significance of the distribution of neck node metastasis from oral carcinoma. *Head Neck.* 2000;22:207–214.)

ANATOMY

A neck dissection is the mainstay of the surgical treatment of many patients with cancer of the head and neck. A thorough knowledge of the anatomy of the neck is necessary to perform a neck dissection well. Such a discussion of the anatomy of the neck is not within the scope of this chapter. However, it is appropriate to highlight the pertinent surgical anatomy of certain structures that are particularly relevant, in the course of performing neck dissections.

Marginal Mandibular Branch of the Facial Nerve

The inferior division of the facial nerve divides into cervical and marginal branches, a short but variable distance behind the anterior border of the lower portion of the parotid gland (Fig. 18.2). The "lower" cervical branch runs downward and forward and, after exiting the parotid, is located between the anterior border of the parotid and the submandibular gland; it "terminates" in the platysma muscle, a variable distance below the submandibular gland. The marginal branch subdivides further, at about the level of the angle of the mandible, into an "upper" cervical branch and the marginal branch. The upper cervical branch overlies the posterior and then the inferior portions of the submandibular gland, as it curves upward to enter the platysma about 1.5 to 2 cm below the inferior border of the mandible. It is usually not possible to preserve the cervical branches of the facial nerve when performing a neck dissection that includes the submandibular triangle (level I). However, it is often possible to preserve these branches when performing a submandibular gland excision.

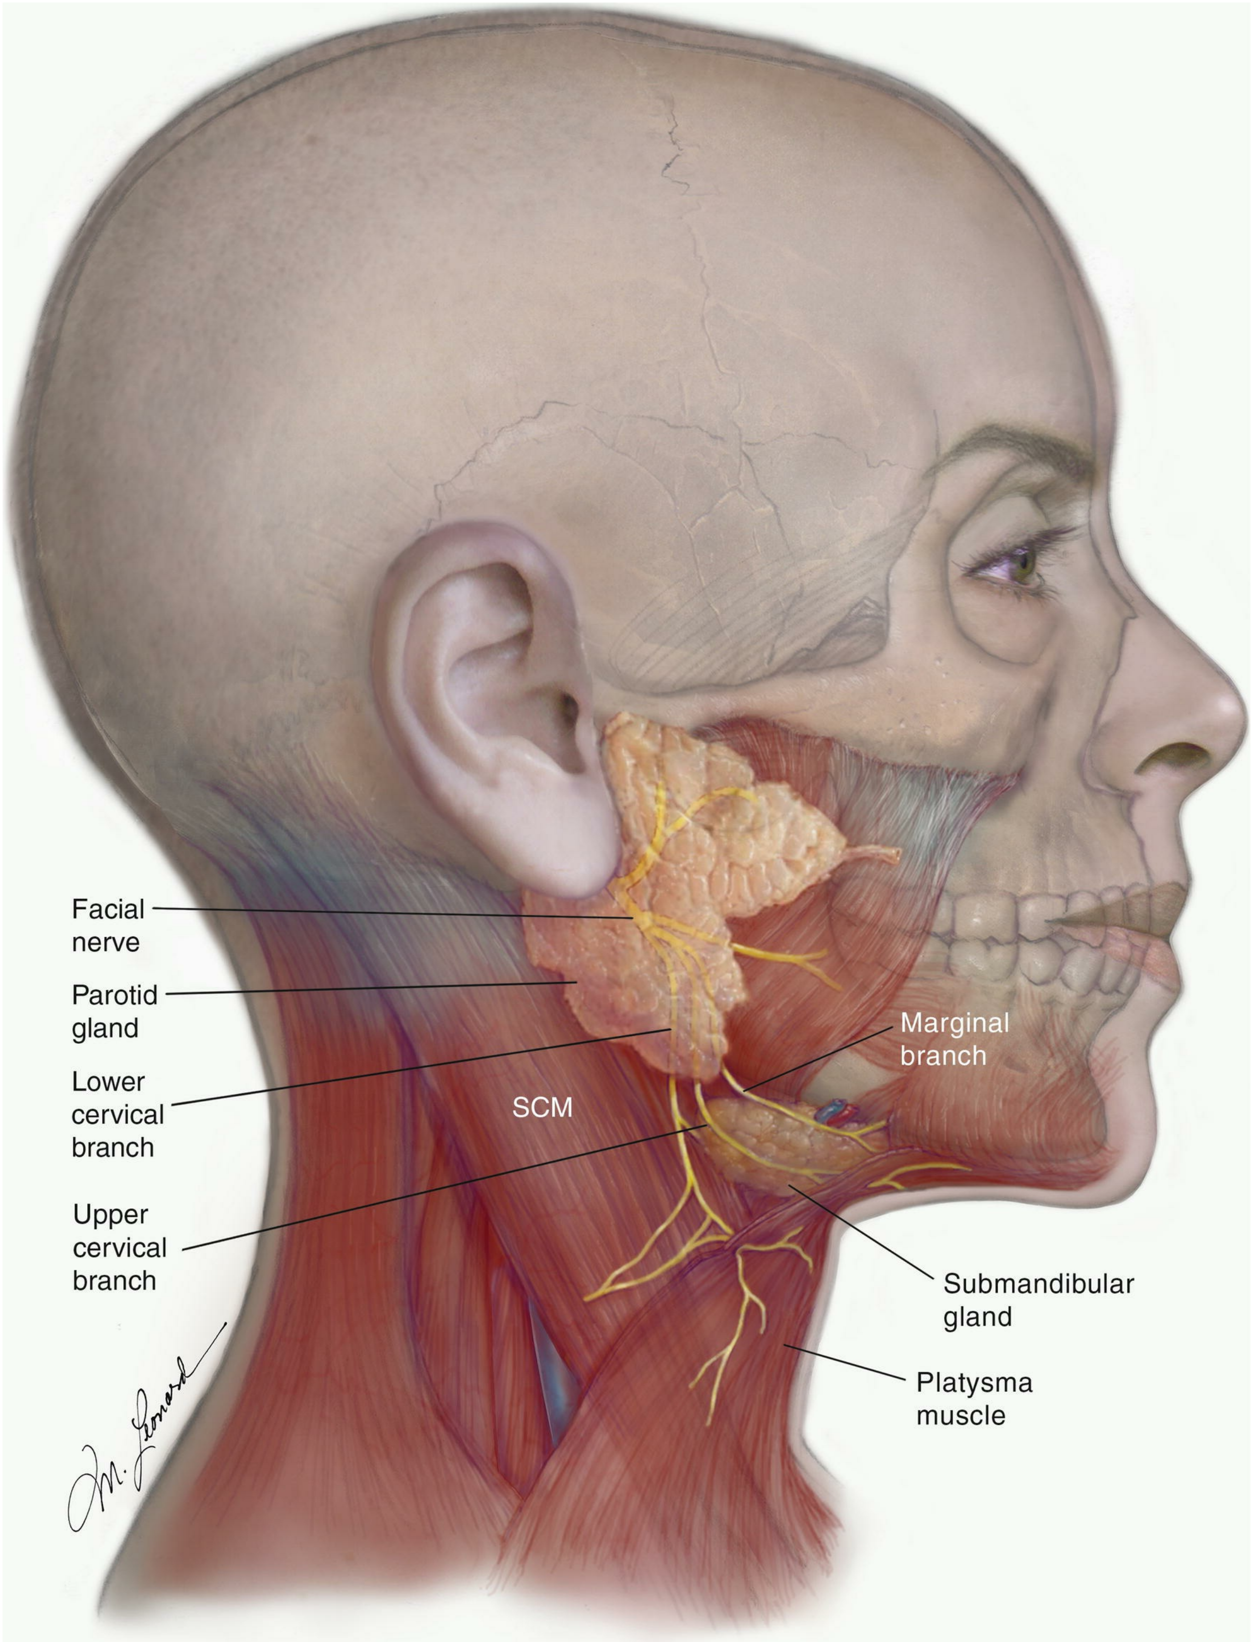

Figure 18.2. Anatomy of the inferior division of the facial nerve: 1. Marginal

mandibular branch; 2. Upper cervical branch; 3. Lower cervical branch.

The marginal branch runs forward, in a slightly oblique, upward direction; it is located deep to the superficial cervical fascia, between the inferior border of the mandible and the superior border of the submandibular gland. When performing a neck dissection, this nerve is usually identified about 1 cm in front of and inferior to the angle of the mandible by incising the superficial layer of the deep cervical fascia that envelops the submandibular gland, immediately above the gland, in a direction parallel to the direction of the nerve. The incised fascia then is gently pushed superiorly, exposing the nerve that lies deep to it but superficial to the adventitia of the anterior facial vein. The submandibular retrovascular lymph nodes are usually in close proximity and medial to the nerve and must be carefully dissected away from it. As this is done, the facial vessels are exposed and can be divided.

Identifying the marginal mandibular branch is essential in performing an adequate excision of the lymph nodes in the submandibular triangle. The practice of ligating the anterior facial vein low in the submandibular triangle and retracting it superiorly to “protect the marginal branch” can also result in elevation of the prevascular and retrovascular lymph nodes, thus precluding their appropriate removal. When indicated, it is preferable to identify the nerve and thoroughly remove these lymph nodes.

Spinal Accessory Nerve

The spinal accessory nerve (SAN) is located medial to the digastric and stylohyoid muscles and lateral or immediately posterior to the internal jugular vein (IJV) (Fig. 18.3). Occasionally, the superior portion of the nerve is posterior–medial to the vein. The nerve then runs obliquely inferior and backward to reach the medial surface of the sternocleidomastoid muscle (SCM) near the junction of its superior and middle thirds (two to three fingerbreadths below the mastoiditis). Although the nerve can continue its downward course entirely medial to the muscle (18%), more commonly, it traverses and appears in the posterior border (82%).[3] Here, the nerve is always located above the point where the greater auricular nerve turns around the posterior border of the SCM, also known as Erb point (Fig. 18.4).[4] The mean distance between the Erb point and the SAN is 10.7 mm, SD ± 6.3. It

then runs through the posterior triangle of the neck and crosses the anterior border of the trapezius muscle. The mean distance between this point and the clavicle is 51.3 mm, SD ± 17.[4] Two anatomic characteristics of this portion of the nerve are relevant to avoid injuring it in the course of a neck dissection. First, the SAN is located rather superficially as it courses through the middle and low posterior triangle of the neck, and it can be easily injured while elevating the skin flaps in the posterior neck. Second, the nerve does not enter the trapezius muscle at the anterior border of it but courses along the deep surface of the muscle in close relationship with the transverse cervical vessels. Therefore, isolating the nerve to the level of the anterior border of the trapezius does not ensure its preservation during surgical dissection below this point, particularly in a bloody operative field.

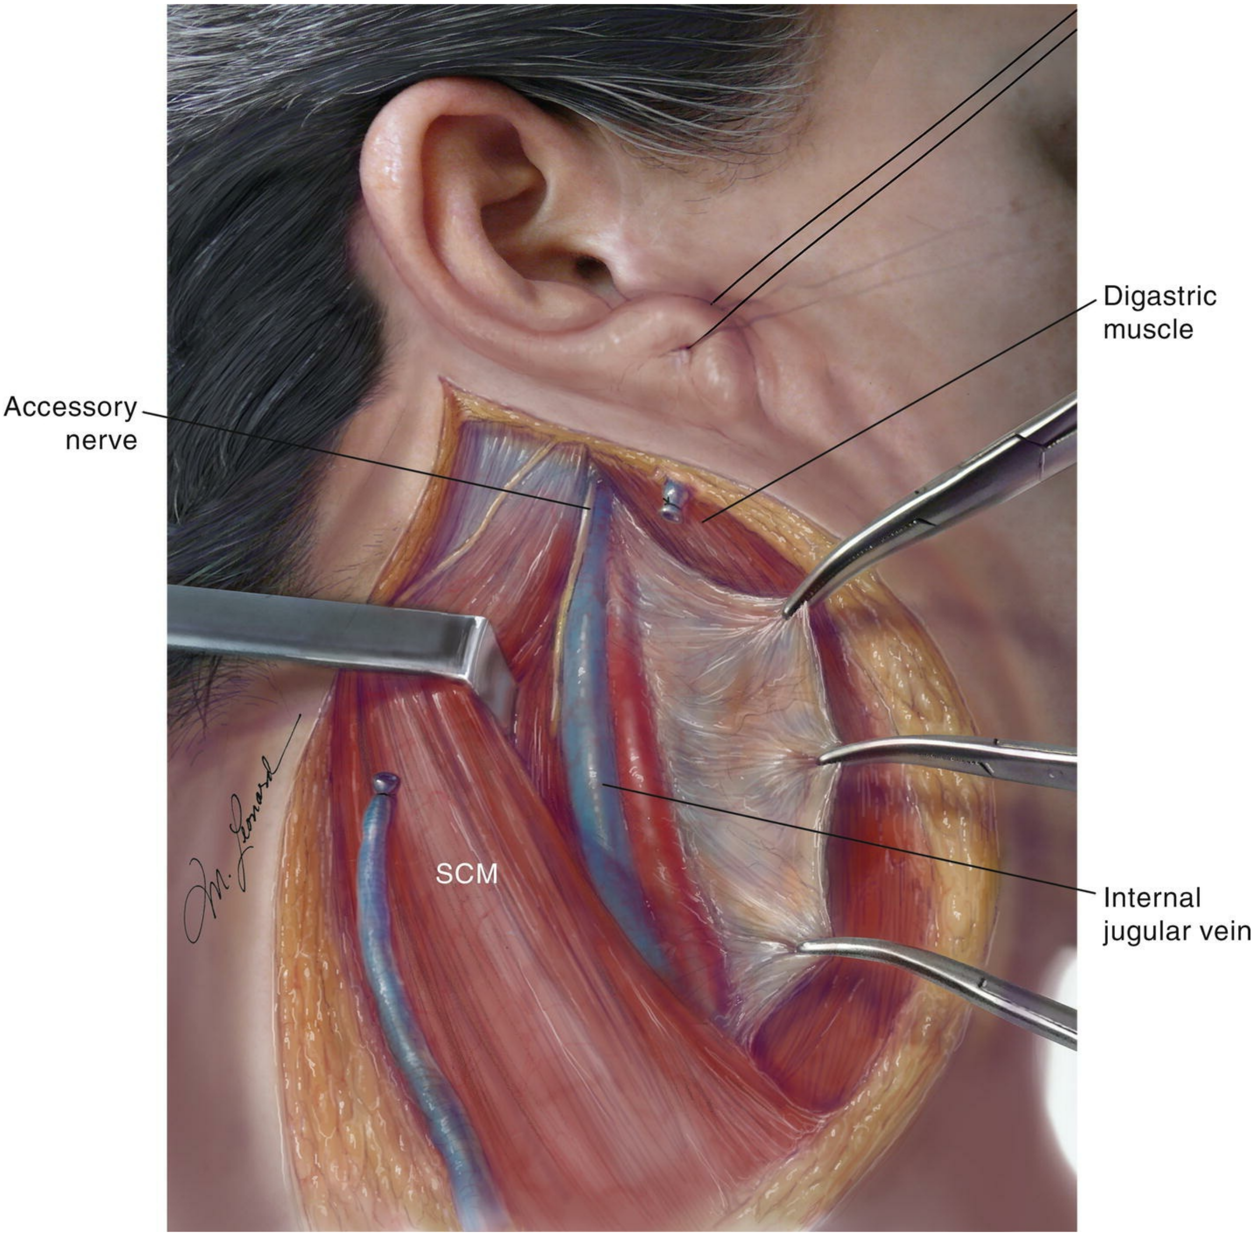

Figure 18.3. The SAN in its most common position in the superior aspect of the right neck: lateral and slightly posterior to the IJV.

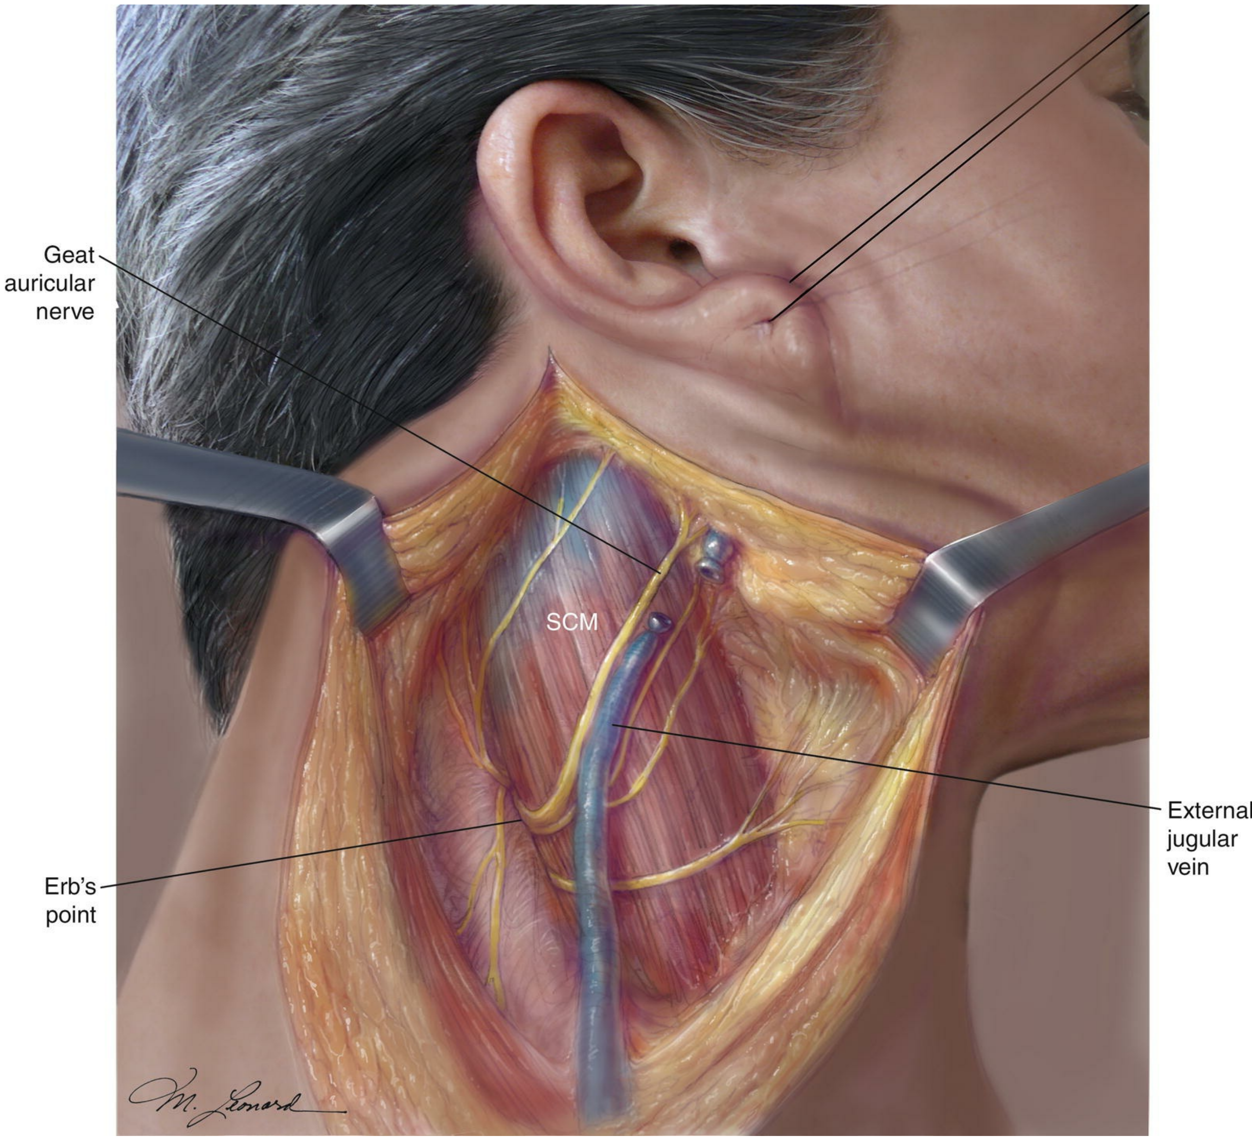

Figure 18.4. The spinal accessory in the posterior triangle of the neck. 1. Erb point; 2. The SAN is usually located about 1 cm above Erb point.

A common sequela in patients who undergo neck dissection is related to the removal of the SAN or to dysfunction of this nerve subsequent to its dissection during surgery. The resulting paralysis or paresis of the trapezius muscle, one of the most important shoulder abductors, causes destabilization of the scapula with progressive flaring of it at the vertebral border, drooping, and lateral and anterior rotation. The loss of the trapezius function decreases the patient's ability to abduct the shoulder above 90 degrees at the shoulder. Paralysis of the trapezius muscle causes a clinical syndrome characterized by weakness and deformity of the shoulder girdle, usually accompanied by

pain.[5] The shoulder pain appears to be secondary to increased supportive demands on and strain of the levator scapulae and rhomboid muscles. Furthermore, adhesive capsulitis of the glenohumeral capsule may result in a “frozen shoulder” leading to a chronic disability and impaired quality of life.[6]

Preservation of the SAN to avoid this cumbersome sequela has been one of the reasons for the development of the modified radical and selective neck dissections (SNDs) that are commonly used today. Interestingly, varying degrees of shoulder dysfunction can occur, even when the SAN is preserved during a neck dissection. Therefore, it is important for the surgeon to understand the anatomy of the SAN and the importance of early diagnosis and rehabilitation when dysfunction occurs.

Nerve to the Levator Scapulae Muscle

The levator scapulae is a triangular muscle located deep in the lateral aspect of the neck, anterior and medial to the splenius capitis muscle. It extends from the transverse process of the atlas and the next three cervical vertebrae to the superior angle and the spine of the scapula. The action of the levator scapulae is to raise the medial angle of the scapula and incline the neck to the corresponding side with rotation of the neck in the same direction. With the trapezius muscle, the levator scapula makes a shoulder shrug possible. Because one of the functions of the levator is to draw the scapula and the shoulder upward and medially, inadvertent or unnecessary resection of the nerves to it during a neck dissection, particularly a radical neck dissection (RND), may accentuate the resulting deformity and functional disability of the shoulder.

The nerves to the levator scapulae, which vary in number from 1 to 3, branch off the 4th and 5th cervical nerves and travel posteriorly and inferiorly. They cross the anterior border of the levator scapulae and remain on the surface of the muscle for a short distance. The nerves to the levator scapulae are deep to the fascia of this muscle; thus, in the course of any neck dissection, but especially in an RND or an modified radical neck dissection (MRND), it is crucial to keep the plane of dissection superficial to the fascia of the levator in order to preserve these nerves. The dorsal scapular nerve is inconsistent in its anatomic relations in the posterior triangle of the neck and contributes to the innervation of the levator scapulae in a minority of cases.[7]

Thoracic Duct

Inadvertent puncture or transection of the thoracic duct at the base of the neck can result in a chylous fistula, a relatively infrequent but potentially cumbersome complication of a neck dissection. Knowledge of the usual location and course of the thoracic duct is paramount whenever a dissection involves the supraclavicular, lower jugular (level IV) region. It is, perhaps, even more important when the surgeon is called on to search for and repair a chyle fistula during or after a neck dissection.

The thoracic duct is located medial to and behind the common carotid artery and the vagus nerve (Fig. 18.5). From here, it arches upward, forward, and laterally, passing behind the IJV and in front of the anterior scalene muscle and the phrenic nerve. It then opens into the IJV, the subclavian vein, or near the angle formed by the junction of these two vessels. The duct is anterior and medial to the thyrocervical trunk and the transverse cervical artery. To prevent a chyle leak, the surgeon also must remember that the thoracic duct may be multiple in its superior aspect and that at the base of the neck it usually receives a jugular, a subclavian, and other minor lymphatic trunks, which must be ligated or clipped individually.

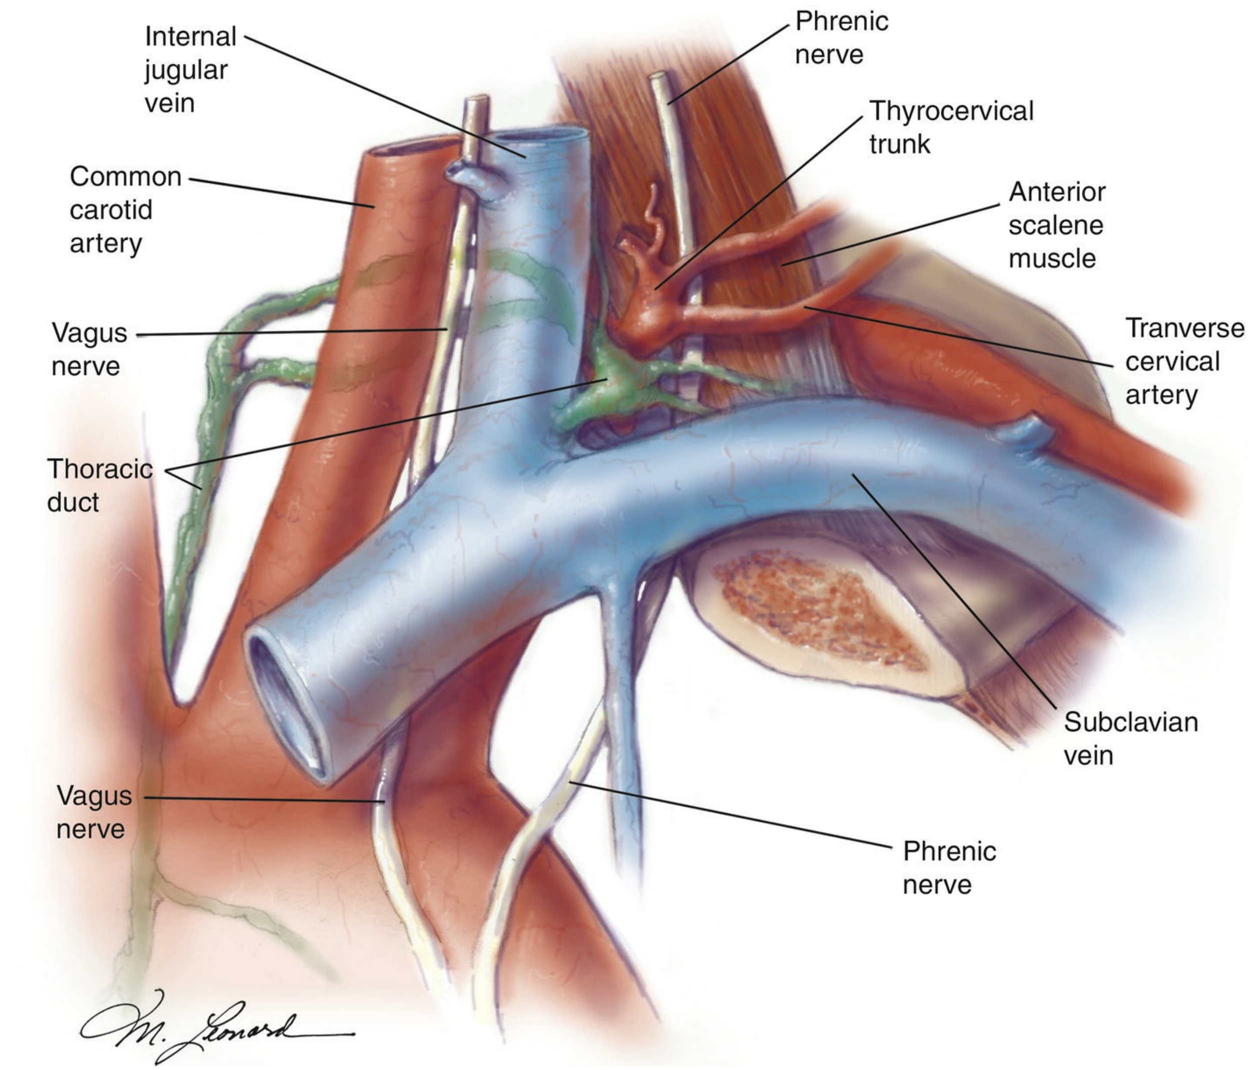

Figure 18.5. Anatomic relations of the thoracic duct. 1. Vagus nerve; 2. Common carotid artery; 3. Internal jugular vein; 4. Phrenic nerve; 5. Thoracic duct draining into the subclavian vein; 6. Transverse cervical artery.

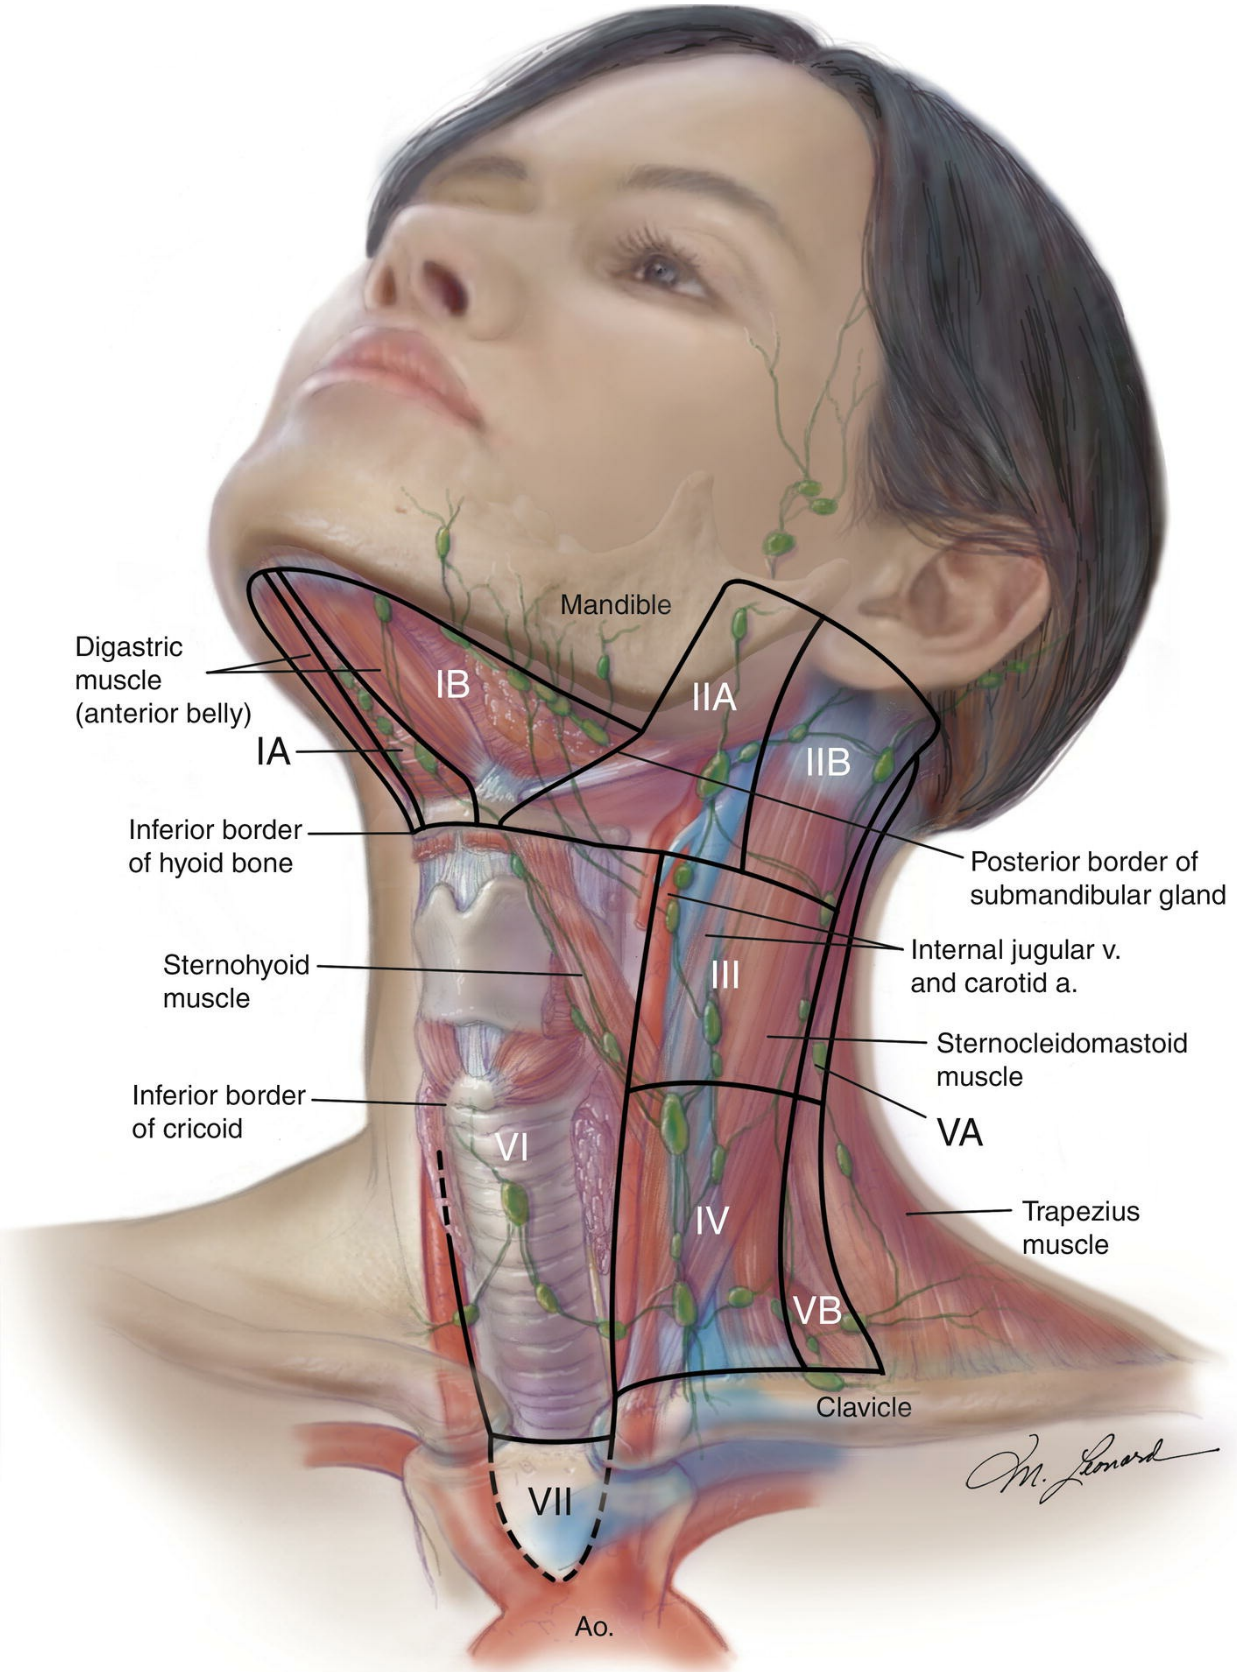
Lymph Nodes of the Neck

The lymph node regions of the neck are shown in Figure 18.6. The six levels currently used encompass the complete topographic anatomy of the neck. The concept of sublevels has been introduced into the classification because certain zones have been identified within the six levels, which may have clinical significance.



Mandible
Digastric muscle (anterior belly)
IA
IB
IIA
IIB
Inferior border of hyoid bone
Posterior border of submandibular gland
Internal jugular v. and carotid a.
Sternohyoid muscle
III
Sternocleidomastoid muscle
Inferior border of cricoid
VI
VA
IV
Trapezius muscle
VB
Clavicle
VII
Ao.
M. Leonard

Figure 18.6. The lymph node regions/“levels” of the neck.

Level I is divided into two sublevels. Sublevel IA (submental) includes the lymph nodes within the inferiorly based triangle bound by the anterior belly of the digastric muscles and the hyoid bone. Sublevel IB (submandibular) includes the lymph nodes within the boundaries of the anterior belly of the digastric muscle, the stylohyoid muscle, and the inferior border of the body of the mandible.

Level II (upper deep jugular) includes the lymph nodes located around the upper third of the IJV and adjacent SAN extending from the level of the skull base to the level of the inferior border of the hyoid bone. The anterior/medial boundary is the stylohyoid muscle (the radiologic correlate is the vertical plane defined by the posterior surface of the submandibular gland), and the posterior (lateral) boundary is the posterior border of the SCM. Two sublevels are recognized in level II: sublevel IIA, nodes located anterior/medial to the vertical plane defined by the SAN, and sublevel IIB, nodes located posterior/lateral to the vertical plane defined by the SAN.

Level III (mid deep jugular) includes the lymph nodes located around the middle third of the IJV extending from the inferior border of the hyoid bone to the inferior border of the cricoid cartilage. The anterior/medial boundary is the lateral border of the sternohyoid muscle, and the posterior/lateral boundary is the posterior border of the SCM.

Level IV (lower deep jugular) encompasses the lymph nodes located around the lower third of the IJV extending from the inferior border of the cricoid cartilage to the clavicle.

The anatomic boundary that separates the medial border of levels III and IV from the lateral border of level VI has traditionally been the lateral border of the sternohyoid muscle, a landmark that cannot be easily discerned on imaging studies. Therefore, the medial aspect of the common carotid artery has been suggested as an alternate boundary to separate these levels in an axial plane in imaging studies.[8]

Level V (posterior triangle) comprised predominantly of the lymph nodes located along the inferior half of the SAN and the transverse cervical artery. The supraclavicular nodes are also included in the posterior triangle group. The superior boundary is the apex formed by convergence of the

sternocleidomastoid and trapezius muscles, the inferior boundary is the clavicle, the anterior boundary is the posterior border of the SCM, and the posterior boundary is the anterior border of the trapezius muscle. A horizontal plane marking the inferior border of the anterior cricoid arch separates two sublevels. Sublevel VA, above this plane, includes the spinal accessory nodes. Sublevel VB, below this plane, includes the nodes that follow the transverse cervical vessels and the supraclavicular nodes with the exception of Virchow node, which is located in level IV.

Level VI (anterior compartment) lymph nodes in this compartment include the pre- and paratracheal nodes, precricoid (Delphian) node, and the perithyroidal nodes including the lymph nodes along the recurrent laryngeal nerves. The superior boundary is the hyoid bone, the inferior boundary is the suprasternal notch, and the lateral boundaries are the common carotid arteries.

Level VII refers to the extension of the paratracheal nodes below the suprasternal notch (the dividing line between levels VI and VII) to the level of the innominate artery.

Other Lymph Node Groups

Lymph nodes involving regions not located within these levels should be referred to by the name of their specific nodal group; examples of these are the superior mediastinal, the retropharyngeal, the periparotid, the buccinator, the postauricular, and the suboccipital lymph nodes.

The retropharyngeal lymph nodes (RPLNs) lie within a pad of adipose tissue located behind the posterior wall of the pharynx and anterior to the prevertebral fascia and the cervical sympathetic trunk and ganglion. This pad of adipose tissue extends from about the level of the carotid bifurcation to just inferior to the skull base. The RPLN are divided into medial and lateral groups; the medial group of nodes lies behind the pharyngeal midline at a level between the first and fourth cervical vertebrae. The lateral group of nodes, better known as the nodes of Rouviere, are contained within a sliver of adipose tissue located immediately medial to the internal carotid artery. The RPLN receive lymphatic drainage from the nasopharynx, tonsil fossa, the walls of the oropharynx and the hypopharynx, and the posterior ethmoid sinuses.

STAGING

After completing the clinical evaluation of a patient with squamous cell carcinoma of the head and neck region, the disease should be classified according to stage. The staging for the lymph nodes proposed by the American Joint Committee on Cancer in 2009[9] is outlined below:

NX: Regional lymph nodes cannot be assessed.

N0: No regional lymph node metastasis.

N1: Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension.

N2: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension.

N2a: Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension.

N2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension.

N2c: Metastasis in bilateral or contralateral nodes no more than 6 cm in greatest dimension.

N3: Metastasis in a lymph node more than 6 cm in greatest dimension.

Staging of the neck in patients with carcinoma of the nasopharynx is different because the distribution and the prognostic impact of regional lymph node metastasis from cancer of the nasopharynx, particularly of the undifferentiated type, are different from that of other cancers of the head and neck mucosa and justifies the use of the following scheme:

NX: Regional lymph nodes cannot be assessed.

N0: No regional lymph node metastasis.

N1: Unilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa.

N2: Bilateral metastasis in lymph node(s), 6 cm or less in greatest dimension, above the supraclavicular fossa.

N3: Metastasis in a lymph node(s) >6 cm and/or to supraclavicular fossa.

N3a: Greater than 6 cm in dimension.

N3b: Extension to the supraclavicular fossa.

CLASSIFICATION OF NECK DISSECTIONS

Several cervical lymph node dissections are currently used for the surgical treatment of the neck in patients with cancer of the head and neck region. To standardize the nomenclature used to refer to these operations, it is essential to adopt a common nomenclature for the groups of lymph nodes in the neck, such as the one outlined above. The current classification of neck dissections recommended by the American Academy of Otolaryngology: Head and Neck Surgery (Table 18.1) takes into account the groups of lymph nodes of the neck that are removed and secondarily the anatomic structures that may be preserved, such as the SAN and the IJV. Analyzing neck dissections from these two points of view, there are essentially four anatomic types of neck dissections: radical, modified radical, selective, and extended. Recently, clinicians from around the world have proposed a nomenclature for neck dissection, which, if recognized internationally, would be "logical, unambiguous, precise, and easy to remember."[10]

Table 18.1 Classification of Neck Dissections

2001 Classification	2010 Proposed Classification
1. Radical neck dissection	1. ND (I–V, SCM, IJV, CNXI)
2. Modified radical neck dissection	2. ND (I–V, SCM, IJV), ND (I–V, IJV, CNXI), ND (I–V)
3. Selective neck dissection (SND): SND (I–III/IV) SND (II–IV) SND (II–V, postauricular, suboccipital) SND (level VI)	3. ND (I, II, II/IV) ND (II, III, IV) ND (II, III, IV,V, postauricular, suboccipital) ND (VI)
4. Extended neck dissection	4. ND (levels removed, nodes or structures removed)

In this classification, the following three descriptors are used to label a neck dissection:

1. “ND” to represent neck dissection, which is prefaced by either “L” or “R” for side. If bilateral, both sides must be classified independently.
2. The levels and sublevels of lymph nodes removed designated by Roman numerals I through VII in ascending order. For levels that contain sublevels (I, II, and V), listing of the level without a sublevel indicates that the entire level (both A and B) was excised.
3. The nonlymphatic structures removed designated by their internationally recognized initials, that is, SCM for sternocleidomastoid muscle and IJV for internal jugular vein.

The advantage of this classification is that it conveys precisely the groups of lymph nodes included as well as the nonlymphatic structures removed in a neck dissection. This will allow a standardized reporting and meaningful comparison of outcomes.

Irrespective of the nomenclature used, it is the responsibility of the surgeon to divide or otherwise orient the neck dissection specimen identifying the different groups of lymph nodes it contains. Only then can the

pathologist render a report that is useful clinically and prognostically. Such a report describes the location and number of lymph nodes examined, the number of nodes that contain cancer, and the presence or absence of extra capsular extension of tumor.

MANAGEMENT OF THE N0 NECK

The initial management of the clinically N0 neck is dictated by the treatment modality that is ideal or is selected for the management of the primary cancer. Therefore, we will discuss the management of the N0 neck when the primary cancer is treated initially with surgery and when it is treated initially with radiation alone or in combination with chemotherapy.

Primary Cancer Treated with Surgery

Most primary squamous cell carcinomas of the oral cavity are treated with surgery. Selected carcinomas of the oropharynx and larynx are increasingly treated with transoral laser excision or robot-assisted surgery. Removing the lymph nodes, that is, performing a neck dissection in every patient with these tumors, is obviously impractical, because not everyone of them would have metastases in the lymph nodes. Ideally, dissection of the lymph nodes would be limited to those patients that are most likely to have metastases. Unfortunately, detection of "subclinical," microscopic metastases in the lymph nodes of the neck in patients without palpable adenopathy (clinically N0) remains a challenge to the clinician.

Clinical Examination

Examination of the neck by palpation is not uniformly reliable. It is commonly accepted that the reported error rate in assessing the presence or absence of cervical lymph node metastases by palpation ranges from 20% to 50%. The factors responsible for this variation are not only the ability and experience of the examiner but also the patient's habitus and previous treatment to the neck with surgery or radiation therapy.

In the quest for a way to identify those patients who harbor "subclinical metastases" in the lymph nodes, clinicians have used a variety of resources spanning from noninvasive methods such as ultrasonography (US) to more

invasive procedures such as sentinel lymph node biopsy (SLNB). However, the decision to recommend elective dissection of the neck is currently based mainly on the probability of lymph node metastases, which is determined on the basis of the location and stage of the primary cancer and several other cancer and patient-related parameters.

Ultrasonography, Computed Tomography, and Magnetic Resonance Imaging

These imaging modalities have a higher sensitivity and specificity than clinical examination in the detection of metastases in lymph nodes. In a prospective study of 48 patients who were to undergo neck dissection, Haberal et al. found that the sensitivity and specificity of palpation for the detection of metastases in the lymph nodes were 64% and 85%, respectively, whereas the corresponding values for US were 72% and 96% and for computed tomography (CT) 81% and 96%.[11] Adams et al.[12] reported similar results for US and CT; in addition, they reported a sensitivity of 80% and a specificity of 79% for magnetic resonance imaging (MRI). However, these imaging modalities failed to detect metastases, in this and other studies, in 19% to 28% of the patients staged clinically N0; thus, a "negative" US, CT, or MRI of the neck cannot be relied upon enough to withhold elective treatment of the cervical lymph nodes.

There are several reasons for the poor performance of current imaging studies in the detection of occult metastases in lymph nodes. First, size is the imaging criterion used most often to consider a cervical node suspicious for metastasis; nodes located in levels I and II larger than 1.5 cm in maximum diameter and nodes larger than 1 cm in other regions of the neck are considered suspicious.[13] Although a correlation exists between the size of a lymph node and the presence of histologic metastasis, not all enlarged lymph nodes contain metastatic deposits, and nodes smaller than 1 or 1.5 cm can contain metastases (Table 18.2). In fact, 33% of all metastases from squamous cell carcinomas of the head and neck are found in lymph nodes smaller than 1 cm.[14,15] Second, 10% of cancer-positive neck dissection specimens contain only metastases <3 mm in diameter, and more importantly, 25% of all clinically occult lymph node metastases are too small to be detected by any of the currently available imaging techniques.[14]

Table 18.2 Nodal Size and Presence of Histologic Metastases

Node Size (cm)	Histologic Status (%)		
	Negative	Positive	Positive with Extranodal Extension
1	67	33	14
2	38	62	26
3	19	81	49
4	12	88	71
5	0	100	76

From Mozzillo N, Chiesa F, Botti G, et al. Sentinel node biopsy in head and neck cancer. *Ann Surg Oncol.* 2001;8(suppl):105S, with permission.

Positron Emission Tomography

Prospective studies using 18-fluorodeoxyglucose positron emission tomography (PET) to assess lymph node metastases from squamous cell carcinomas of the oral cavity have shown a sensitivity and specificity higher than MRI, CT, and US. However, current FDG PET techniques are also limited in the detection of tumor foci smaller than 1 cm.[16–18]

Kyzas et al.[19] performed a meta-analysis of 32 studies that assessed the diagnostic performance of PET scans in patients with squamous cell carcinoma of the head and neck. In patients staged clinically N0, the sensitivity of 18FDG PET scan was only 50% (95% CI = 37% to 63%), whereas the specificity was 87% (95% CI = 76% to 93%). These authors also compared the performance of PET scan with that of “conventional diagnostic methods,” that is, CT, magnetic resonance imaging, and ultrasound with fine needle aspiration by analyzing studies that had used all these diagnostic methods on the same patients. The sensitivity and specificity of PET scan was 80% and 86%, respectively, whereas for the “conventional diagnostic tests,” they were 75% and 79%.

Ng et al.[20] showed that the visual correlation of 18FDG PET with contrast-enhanced CT/MRI was more accurate than 18FDG PET alone for the detection of subclinical lymph node metastases. In 134 patients with squamous cell carcinoma of the oral cavity who were staged N0 clinically, they found a sensitivity of 51.4% for 18FDG PET, which increased to 57.1% after visual correlation with CT or MRI. This increment stemmed from the correction of false-negative 18F-FDG PET results caused by necrotic nodes. Ozer et al.[21] reported a sensitivity of 57% and specificity of 82% for the detection of occult metastasis by 18F-FDG PET/CT in 112 patients with clinically negative necks on physical examination, CT, and/or MRI.

Liao et al.[22] recently reported a meta-analysis comparing CT, MRI, PET, and ultrasound for the detection of cervical lymph node metastasis in patients with clinically N0 necks. They found no significant differences in sensitivity and specificity among these imaging modalities, with the exception that CT had a higher specificity than ultrasound.

Thus, at the present time, the role for PET scan in the evaluation of the N0 neck is limited as it will not detect subclinical metastases in 20% to 50% of the cases.

Ultrasound-Guided Fine-Needle Aspiration Biopsy

In an attempt to overcome the lack of sensitivity of morphologic imaging criteria, US was combined with US-guided fine needle aspiration cytology (US-FNAB). This technique appeared more promising for the preoperative evaluation of the N0 neck as it enabled sampling of lymph nodes as small as 3 mm in diameter and added the advantages of cytologic evaluation.[23] However, the usefulness of this technique is strongly dependent on the skill and time of the ultrasonographer and on the experience of the cytopathologist. Furthermore, the outcomes of a wait-and-see policy after negative US-FNAB have been disappointing. In a study of 92 patients with cancer of the oral cavity, staged T1 and T2, who were observed after a negative US-FNAB, metastases in neck nodes became apparent subsequently in 19 (21%).[24] In a more recent study, Wensing et al. found that palpation and US with or without US-FNAB missed occult lymph node metastases in 22% of the patients with oral cavity squamous cell carcinoma.[25] These figures are troubling because the incidence of lymph node metastases in

patients with such cancers, who are observed without any intervention to the neck, is about 25%.

Sentinel Lymph Node Biopsy

SLNB is feasible and useful as a staging procedure in patients with early cancer of the oral cavity and in particular for patients with cancer of the oral tongue. Proponents of this technique point out that it allows accurate histopathologic staging of the neck by examining the sentinel lymph node (SLN) with serial sectioning and immunohistochemistry, and it avoids unnecessary neck dissection and its possible complications.

The SLNB is based on the principle that cancers metastasize via lymphatics to regional lymph nodes in an orderly fashion, that this process is embolic in nature, and that the lymph node that first receives lymphatic drainage from the primary site can be identified and excised for histologic analysis.[26]

Early studies in patients with squamous cell carcinoma of the mucosal surfaces of the head and neck investigated the methodology and feasibility of SLNB.[26]–[29] In general, the primary cancer should be accessible to infiltration with a radioisotope-labeled colloid to perform a lymphoscintigraphy and a blue dye injection to aid in intraoperative localization of the sentinel node. These localizing methods have been shown to be complementary. In a multicenter study, Ross and associates investigated SLNB in 134 patients with squamous cell carcinoma of the oral cavity and oropharynx, staged T1/T2 N0.[27] Lymphoscintigraphy was performed preoperatively; blue dye and a gamma probe were used intraoperatively to aid in the identification of sentinel nodes. Sentinel nodes were identified in 93% of the cases. The number of sentinel nodes varied, but in a previous series of 48 patients studied by Ross et al.,[30] the mean number of sentinel nodes harvested was 2.4.

Subsequent studies have examined the utility of SLNB in patients with oral cavity or oropharyngeal cancers staged T1/T2 N0. The sensitivity of the procedure is 90% when the histopathology of the sentinel node is compared with that of the neck dissection specimen.[31] It results in histopathologic upstaging of the clinically N0 neck in 36% of the patients when the nodes are examined with routine hematoxylin and eosin staining; serial sectioning and

immunohistochemistry upstage an additional 8% of the cases.[27] The detection of micrometastases can be further enhanced by using highly specific tumor markers and molecular methods.[32,33]

Recently, Civantos et al. reported the results of a North American Multi-Institutional Prospective Study that evaluated the utility of SLNB in T1/T2 oral SCCs.[34] The study included 140 patients (68% oral tongue, 19% floor of the mouth) from 25 institutions who underwent SLNB and SND (levels I to IV). The negative predictive value (NPV) was 94% when the SLNs were examined with hematoxylin and eosin stains and 96% when they were examined with serial sectioning and immunocytochemistry.[34] The NPV among experienced surgeons was 100% versus 95% for less experienced ones. The SLN was the only positive node in 51% of the cases with a positive SLN. The false-negative rate was 9.8% overall. Interestingly, however, the false-negative rate was 10% in patients with cancer of the oral tongue, but was 25% in patients with cancer of the floor of the mouth. In the experience of the University of Miami,[35] the NPV of SLNB was 88.5% in patients with cancers of the FOM and 95.8% when these patients were excluded. Similarly, Ross et al. have reported that the identification of SLNB in patients with cancer of the floor of the mouth was lower (86%) than in patients with cancer in other locations (97%); the sensitivity of SLNB in cancer of the floor of the mouth was also lower (80%), compared with other tumor locations (100%).[28] It appears that lymphoscintigraphy in cancers of the floor of the mouth is not as helpful in identifying the SLN; this is most likely due to the "shine-through" effect of the radioactivity at the primary, which obscures the lymph nodes in level I, the primary echelons of lymphatic drainage for the floor of the mouth and inferior Alvestar ridge. Obviously, this limits the utility of SLNB in patients with tumors in these locations.

Probability of "Subclinical" Metastases

Because clinical examination and current imaging studies cannot reliably rule out the presence of metastases in patients clinically staged N0, therapeutic decisions in these patients are, for the most part, based on the probability of lymph node metastases for a given cancer. There is general agreement that elective treatment of the cervical lymph nodes is indicated when the risk of occult metastases exceeds 15% to 20%.[36] This probability varies with the site of the primary cancer, the stage of it (T stage), and other factors related to the

cancer, the patient, or both.

Carcinomas of the Oral Cavity

The probability of occult metastases derived from clinical and histopathologic data is outlined in Table 18.3.[41] Based on those figures, elective treatment of the neck is indicated in patients with T2, T3, and T4 cancers of the oral cavity, regardless of the subsite of origin. On the other hand, it is not necessary in patients with T1 cancer of the retromolar trigone. However, the probability of metastases is too variable to be dogmatic in cases with T1 cancers of other oral cavity subsites. Thus, there has been a search for other parameters that may be helpful in the decision making in these patients. Some investigators have proposed elaborate scoring systems based on several parameters,[42] but they have not proven practical. The thickness of the primary tumor has been shown to be variably useful in several studies and may be helpful in the decision making regarding elective treatment of the neck.[43,44] A meta-analysis of studies published before 2009 revealed that occult lymph node metastases are significantly more common when the thickness of the primary tumor is >4 mm. A practical advantage of using tumor thickness is that it can be evaluated with frozen section and the decision about neck dissection can be made intraoperatively.[45] Furthermore, recent reports indicate that high-resolution diagnostic intraoral US can be used in the determination of tumor thickness.[46] It should be pointed out, however, that in a recent study that evaluated multiple parameters potentially predictive of lymph node metastases in patients undergoing a thorough search for occult metastases by sentinel lymph node biopsy, tumor thickness failed to achieve statistical significance.[47]

Table 18.3 Oral Cavity Squamous Cell Carcinoma Incidence of Lymph Node Metastases by Stage

Site of Primary Tumor	Percentage of Necks with Node Metastases			
	T1	T2	T3	T4
Oral tongue[37]	18–38	30	57	76.5
Floor of the mouth	8.7–30	29	43.5	53.5
Retromolar trigone[38]	7–11	21	50	50–67.5
Buccal mucosa[39,40]	12–40	20–52	41–80	44–64

We recently conducted a systematic review of the literature dealing with tumor markers possibly associated with cervical metastasis in cancers of the oral tongue over the last 25 years.[48] Sixty-five articles met the inclusion criteria; of these, 51 papers provided adequate data for analysis. A total of 76 unique markers were reported. Adequate data was found for 61 of those markers. Thirteen markers were evaluated in two or more studies. Twenty-two markers had sensitivity >75%. Five markers achieved this in two or more studies; these were MMP-9 (0.80), VEGF (0.94), E-cadherin (0.90), cyclin D1 (0.85), and CD105 (0.82) with a combined sensitivity of 0.86. A total of 13 markers had specificity over 75%. p52 (0.86) and CD105 (0.94) achieved this in more than one study (combined specificity 0.90). Four markers had both sensitivity and specificity over 75%, namely, E-cadherin, CD105, VEGF, and osteopontin (0.87 and 0.97), respectively. Twenty-eight markers had a NPV > 75%. Four of them achieved this in two or more studies with a combined NPV of 0.91 (E-cadherin, VEGF, CD105, and cyclin D1). Two markers achieved an NPV >95%, namely, VEGF and osteopontin (combined NPV of 0.97). At the present time, we are studying five of these biomarkers (VEGF, E-cadherin, cyclin D1, CD105, osteopontin) in a cohort of patients with T1 and T2 cancers of the oral tongue with the purpose of building a predictive model for lymph node metastases.

Cancer of the Larynx

For glottic cancers, the frequency of nodal metastases is <8% for T1 and T2 tumors and varies between 11% and 16% for T3 and T4 tumors.[49–52] For

supraglottic cancers, the reported frequency of nodal metastases is higher, ranging from 14% to 42% for T1 and T2 tumors, 35% to 55% for T3, and 65% to 75% for T4 tumors.[10,53,54]

McGavran et al. found that the incidence of lymph node metastases was significantly higher in patients whose tumors measured more than 2 cm in diameter, were poorly differentiated, exhibited an infiltrating rather than a pushing margin, or exhibited perineural invasion. Unfortunately, these authors did not perform a multivariate analysis. More recently, Kowalski et al. performed a study of 103 patients with carcinoma of the larynx who underwent either unilateral or bilateral comprehensive neck dissection. A logistic regression analysis demonstrated that cancer site (supraglottic origin) and poor histologic differentiation were the only predictors of lymph node metastases. When they considered only cases staged N0, the probability of occult lymph node metastases was influenced significantly only by a supraglottic origin of the primary cancer.

Bilateral cervical lymph node metastases are present in about 6% of the patients with cancer of the larynx.[55] However, the frequency of bilateral metastases is higher in advanced supraglottic cancers that involve the midline and in patients with advanced unilateral/ipsilateral lymph node metastases.[25,56]

The possible predictive role of a number of other factors has been investigated. Mansour et al. studied 171 patients with cancers of the larynx and pharynx and found cervical metastases in 100% of tobacco users and in only 54% of nonusers ($p < 0.0001$). Extracapsular spread (ECS) was observed in 100% of tobacco users and 19% of nonusers ($p < 0.0001$). This study suggests that tobacco use is a possible risk factor for cervical metastasis and extracapsular spread in cancer of the larynx, and thus, it may be helpful information in planning therapy for patients with a clinically N0 neck.[26] In another study, carcinomas of the larynx with a depth of invasion ≥3.25 mm were associated with a rate of cervical lymph node metastasis significantly higher than cancers with a depth of invasion <3.25 mm ($p < 0.05$). Expression of epidermal growth factor (EGFR) is another potentially useful biologic marker. A significant correlation between expression of EGFR and the risk of lymph node metastases was observed by Maurizi et al.,[57] in a study of 140 cases of carcinoma of the larynx. In a similar study, Almadori et al.[58] observed that the 5-year lymph node metastasis-free survival was 66%

for patients with EGFR-negative larynx cancers compared with 15% for patients with EGFR-positive tumors.

Carcinoma of the Oropharynx

The oropharynx contains abundant lymphoid tissue (Waldeyer ring) and has a prominent network of lymphatics, which communicate freely across the midline. This explains the propensity of cancer of this region to metastasize to the regional lymph nodes, as well as the relatively high frequency of bilateral lymph node metastases (Table 18.4). The lymphatic drainage of the oropharynx occurs predominantly toward the upper and midjugular lymph nodes (levels II and III). The retropharyngeal nodes are a less common but important echelon in the lymphatic drainage of the oropharynx.

Table 18.4 Squamous Cell Carcinoma of the Oropharynx: Incidence of Lymph Node Metastases by Stage (Based on Histopathology of Neck Dissection Specimens)

	% of Patients with Lymph Node Metastases			
	T_1	T_2	T_3	T_4
Oropharynx	40%	55%	71%	69%

From Elsheikh MN, Ferlito A, Rinaldo A, et al. Do pathologic and molecular analyses of neck dissection specimens justify the preservation of level IV for laryngeal squamous carcinoma with clinically negative neck? *J Am Coll Surg.* 2006;202:320–323.

When cancer of the oropharynx is treated with surgery (open or transoral), based on the distribution of bilateral lymph node metastases shown in Table 18.5, a bilateral SND (levels II to IV) is indicated except for T1 and T2 cancers of the tonsil and well-lateralized T1 cancers of the base of the tongue and soft palate.

Table 18.5 Squamous Cell Carcinoma of the Oropharynx: Incidence of Bilateral Nodal Metastases[59]

Site of Primary Tumor	Percentage of Necks with Node Metastases				
	T1	T2	T3	T4	All T Stages
Tonsil	3.3	10.7	17.6	8.6	9.4
Base of the tongue	14.3	23.9	27	15.8	21.9
Pharyngeal walls	50	33.3	50	0	31.3
Soft palate	10	25	11	50	20

Treatment

Once it has been determined that the likelihood of metastases warrants elective dissection of the neck, the clinician faces the following decisions:

a. Whether to perform a neck dissection or to observe the neck and intervene only if and when lymph node metastases become apparent.
b. What type of neck dissection is appropriate.

Observation Versus Elective Neck Dissection

A prospective randomized study done in Brazil compared SND versus observation in a mixed cohort of patients with oral cavity cancers involving the tongue or floor of the mouth. This study, reported in 1994, showed significant benefit of elective neck dissection.[60] On the other hand, in the past 5 years, one prospective study and one retrospective study have shown that regional control of cancer and survival when the N0 neck is observed, and is dissected only if metastases develop subsequently, are comparable to those obtained with elective neck dissection. It should be noted that in the prospective study conducted by Yuen et al., 95% of the patients whose neck was observed and in whom lymph node metastases became apparent subsequently were salvaged with surgery and, in most instances, radiation and/or chemotherapy. This remarkable result is probably due to the strict follow-up, which consisted of monthly evaluations for the first year and US examination of the neck every 3 months for the first 3 years.[61,62]

In patients with cancer of the larynx, a study by Gallo et al.[16] retrospectively compared a group of 76 patients who underwent elective neck dissection and were found to have histologically positive nodes with a group of 96 patients, who were initially staged N0, but subsequently developed lymph node metastases and underwent therapeutic neck dissection. After a minimum follow-up of 5 years, they found no statistically significant difference between the two groups of patients in overall, determinant, and actuarial survival rates. Other retrospective studies have found that elective neck dissection decreases the neck recurrence rates significantly in patients with supraglottic carcinoma.[63]

Self-examination by the patient and reliable follow-up are essential for watchful waiting to succeed in the management of the N0 neck. Unfortunately, a significant number of the patients who do not undergo elective neck dissection cannot be salvaged later, when they present with palpable metastases, because the cancer process is too far advanced. In a review of 122 patients with T3/T4N0 cancers of the larynx that were treated by total laryngectomy and observation of the neck at the University of Hong Kong, 36% of the patients who later presented with palpable metastases had inoperable cancer and were amenable to palliative treatment only. Furthermore, of the patients who were operable, 42% eventually died of a recurrence in the neck. These observations, in combination with the idiosyncrasies of character and social background of many patients who have cancer of the head and neck, are the reason why most head and neck surgeons prefer to treat the neck electively, even though the impact of this decision on patient survival remains somewhat controversial.

Type of Neck Dissection

A SND is currently the preferred type of neck dissection for the elective surgical management of the neck in patients with squamous cell carcinomas of the upper aerodigestive tract. These operations consist of the removal of only the lymph node groups at highest risk of containing metastases according to the location of the primary tumor while preserving the SAN, the IJV, and the SCM.

The concept of SND was developed on the basis of the following observations:

1. Patterns of lymph node metastases: Anatomic, pathologic, and clinical investigations[41,64–74] as well as recent prospective studies[75,76] have demonstrated that cervical lymph node metastases occur in predictable patterns in patients with SCCs of the head and neck.

The lymph node groups most frequently involved in patients with carcinomas of the oral cavity are the nodes in levels I and II. The nodes in level Ia are frequently involved in patients with carcinoma of the floor of the mouth and anterior oral tongue. These cancers frequently metastasize to both sides of the neck, and they can skip levels I and II, metastasizing first to the nodes in level III. In a retrospective study of 1,119 RNDs, Shah[71] found that cancers of the oral cavity metastasized most frequently to the neck nodes in levels I, II, and III, whereas carcinomas of the oropharynx, hypopharynx, and larynx involved the nodes in levels II, III, and IV.

It has been demonstrated that in the absence of metastases to the first-echelon nodes, cancers of the oral cavity and oropharynx rarely involve the nodes in level IV and level V. The nodes in level V are not commonly involved, regardless of the site of the primary tumor and whether in the presence or absence of metastases in the jugular nodes,[77] conceivably because there is no retrograde flow from the jugular nodes into the spinal accessory nodes.

Similarly, in a prospective analysis of the prevalence and distribution of histologic lymph node metastases in 100 consecutive neck dissections done as part of the initial treatment of laryngeal and hypopharyngeal cancer, Buckley and MacLennan[76] found that all metastases in N0 and N1 cases were confined to levels II, III, IV, and VI. Metastases to levels I and V were infrequent, even in N+ disease, and occurred only in cases with N2c and N3 disease. These results support the use of dissection of node levels II to IV for N0 and selected N+ cases with laryngeal and hypopharyngeal cancer.

Outcomes: A number of retrospective studies have shown that when SND is used for the elective treatment of the regional lymphatics, regional control and survival rates are similar to those of more extensive neck dissections.[53,78–87] Furthermore, two multi-institutional prospective randomized studies comparing SND to MRND were performed by the Brazilian Head and Neck Cancer Study Group. The first study[88] compared SOHND (SND I to III) with MRND in patients with cancer of the oral cavity and clinically N0 neck. The regional control and overall 5-year actuarial survival rates were 87.5% and 67.0% for the SOHND group versus 89.5%

and 63.0% for the MRND, respectively. The differences were not statistically significant. The second study compared MRND type III and lateral neck dissection (SND II to IV) in patients with supraglottic and transglottic carcinomas. The rates of 5-year overall survival, neck recurrences, and complications were similar in both groups.

Morbidity: SNDs result in less postoperative morbidity. The dysfunction of the trapezius muscle produced by SNDs is minimal and, unlike that produced by the RND, is usually temporary and reversible.[89–94]

The type of SND recommended for the management of the N0 neck depends on the site of the primary cancer.

Oral Cavity

SND of level I to III or ND (I to III) (commonly referred to as "supraomohyoid" neck dissection) (Fig. 18.7) and SND of levels I to IV or ND (I to IV) (also referred to as "extended supraomohyoid" neck dissection) are commonly used in the surgical treatment of patients with SCC of the oral cavity. The lymph nodes removed are those contained in the submental and submandibular triangles (level I), the upper jugular region (level II), and the midjugular region (level III). The posterior limit of the dissection is marked by the cutaneous branches of the cervical plexus and the posterior border of the SCM. The inferior limit is the omohyoid muscle as it crosses the IJV. These operations have been described in detail by Medina and Byers.[95] The procedure is performed on both sides of the neck in patients with cancers of the anterior tongue and floor of the mouth.

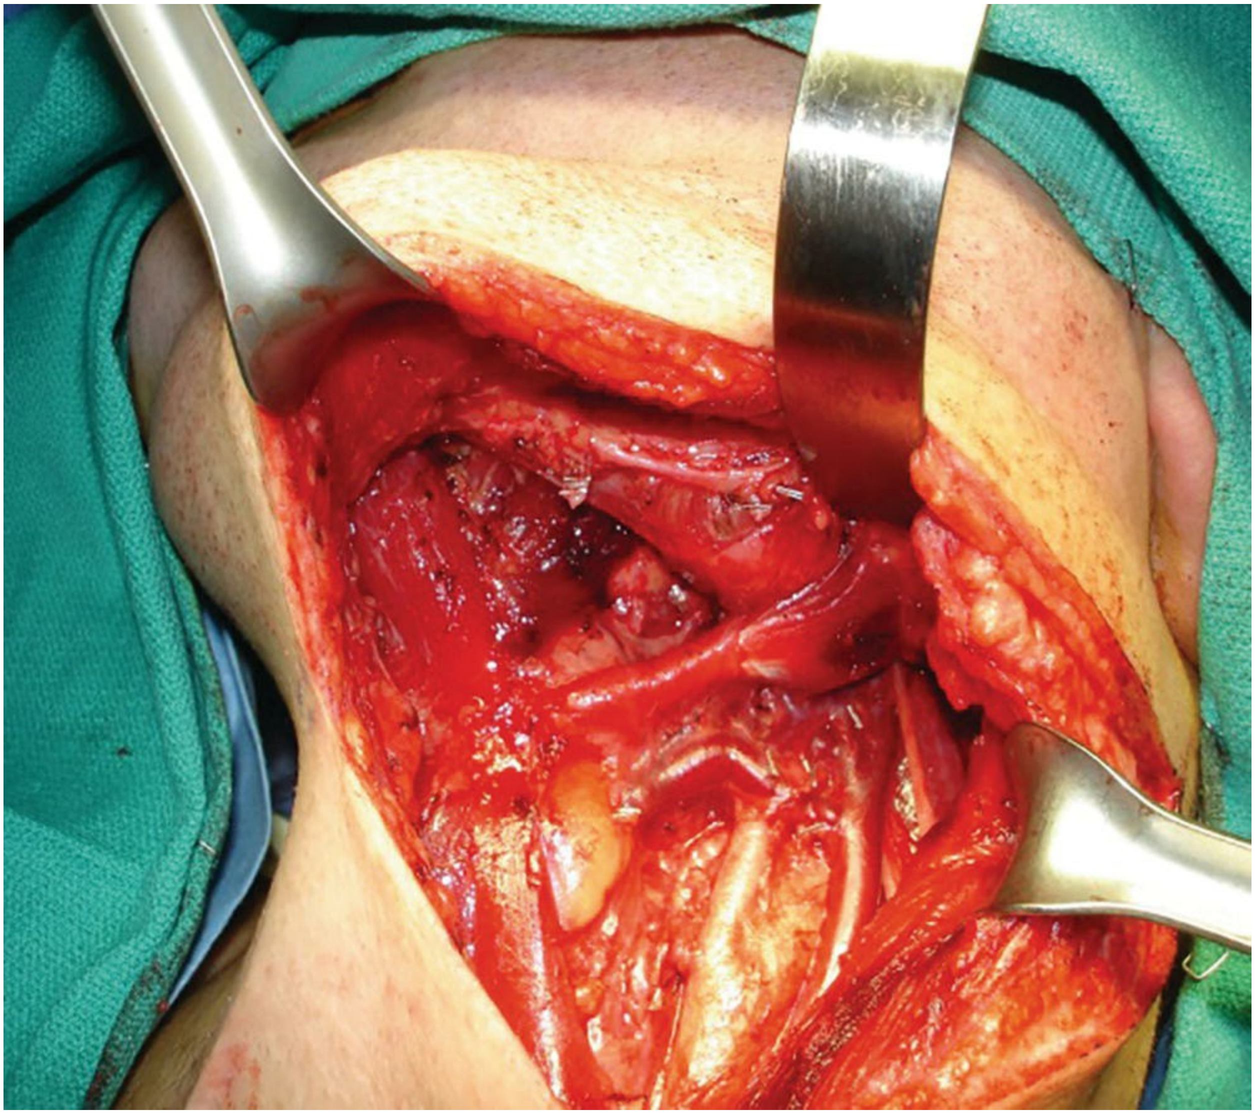


Figure 18.7. Selective neck dissection of lymph node levels I to III (supraomohyoid neck dissection).

The need to routinely remove the nodes in level IV in patients with cancer of the oral tongue is controversial. Byers et al.[64] reported finding "skip metastases" in 15.8% of patients with oral tongue cancer. In these cases, metastases to either level III or IV were the only manifestation of metastasis in the neck. In a similar, more recent review of 119 neck dissections in patients with cancer of the oral cavity, De Zinis et al.[96] found metastases in level IV nodes in 15% of the patients and 28% of them were skip metastases. In another study of 49 patients with cancer of the oral cavity, staged N0, undergoing "extended supraomohyoid" neck dissection, occult metastasis in level IV were found in 10% of the cases.[97] These and other authors contend

that the supraomohyoid neck dissection is inadequate for a complete pathologic evaluation of all the nodes at risk, and they recommend dissecting the nodes in level IV when performing an elective neck dissection in patients with cancer of the oral tongue.

The opposing point of view has been advanced by Khafif et al.[98] whose practice has been to dissect level IV only when a suspicious node is found at level III or there are multiple obviously involved lymph nodes in level II, III, or both. They reported their findings in a cohort of 58 patients with squamous cell carcinoma of the oral tongue (stage T1/T2 N0). The node dissections performed included levels I through III in 42 patients (69%), levels I through IV in 16 patients (26%) and levels I through V in 1 patient (5%). A positive node was found in level IV in only one instance (1/54, 1.8%), and no recurrences were observed in level IV. Ambrosch et al.[78] reported similar observations in a study of 167 patients with cancer of the oral cavity and oropharynx of whom 82 had a clinically staged N0 neck. They dissected level IV only when multiple metastases were suspected during the neck dissection. At a median follow-up of 34 months, the rate of regional recurrence in that series was 5.4%. Shah et al.[72] studied RND specimens performed as elective treatment for cancers of the oral cavity and found metastatic involvement of level IV in 3% of the patients. Li et al.[99] studied 153 patients who had a RND for cancer of the oral cavity (60 therapeutic and 93 elective) and found metastases to level IV in 3.2% of the patients. Wang et al.[100] studied 116 patients with cancer of the oral tongue, staged N0, who underwent comprehensive neck dissections and 5 patients who had SND. Metastases in levels IV or V were found in only one patient each. Interestingly, there were five cases with level III involvement as a first echelon of metastasis. These studies and others[101] have shown that the risk of metastases to level IV in patients with cancer of the oral tongue with clinically negative neck is low; thus, the controversy about the routine inclusion of this level in END in such patients remains.

Cancer of the Larynx and Pharynx

An SND of levels II to IV or ND (II to IV) (Fig. 18.8), commonly referred to as the “lateral” neck dissection, is used in the treatment of patients with cancer of the larynx, oropharynx, and hypopharynx. It consists of the removal of the upper (level II), middle (level III), and lower (level IV) jugular lymph

nodes. For cancers of the supraglottic larynx and posterior pharyngeal walls, the dissection is often bilateral. A recent description of the technique of this operation has been provided by Khafif.[102]

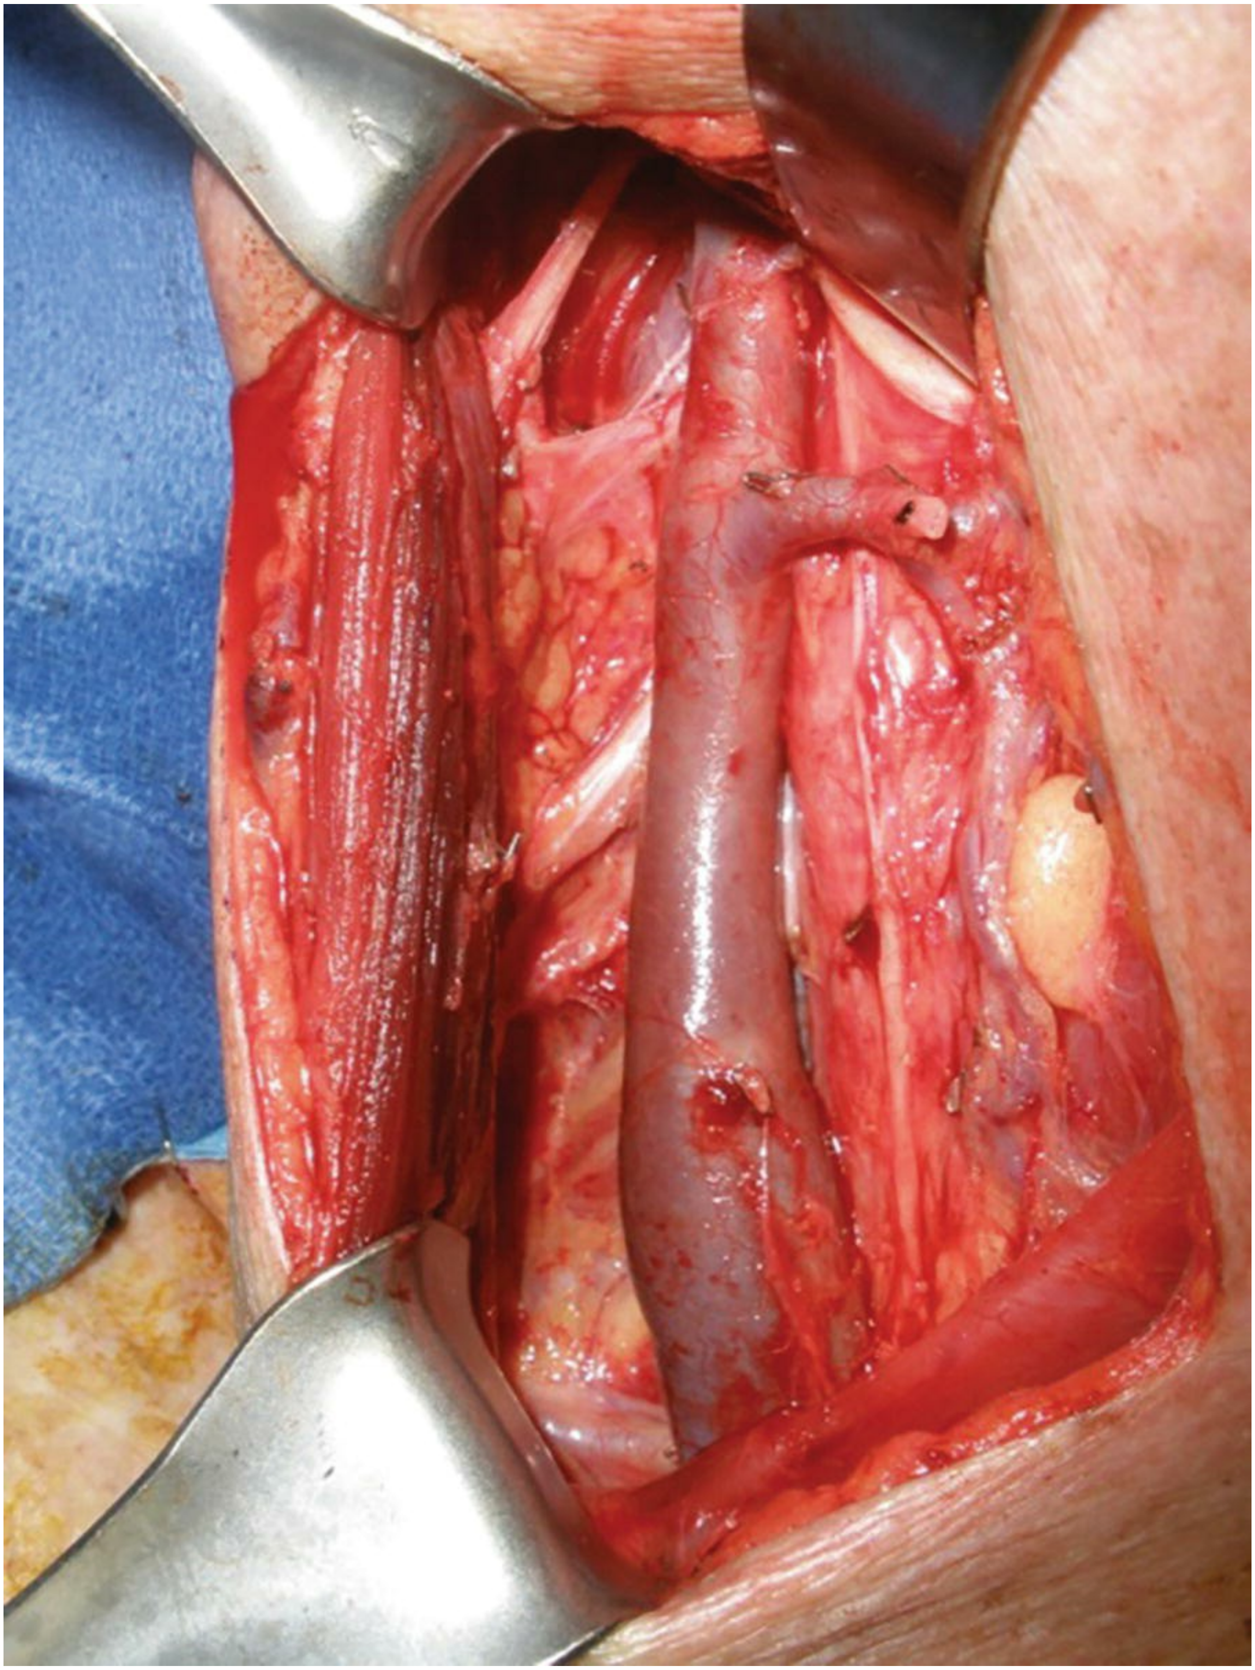

Figure 18.8. Selective neck dissection of lymph node levels II to IV (lateral

neck dissection).

The need to dissect the lymph nodes of sublevel IIB and level IV in every patient undergoing elective SND for cancer of the larynx has recently been questioned. In 2006, Rinaldo et al.[103] collected data from five prospective, multi-institutional studies of neck dissection specimens using pathologic and molecular analysis. These studies included 211 patients with cancer of the larynx and clinically N0 neck. Only three patients (1.4%) were found to have positive lymph nodes at sublevel IIB (one patient had also lymph node metastases to sublevel IIA and level III; the other two patients had also a positive lymph node at sublevel IIA). In a more recent prospective multi-institutional study, metastases in sublevel IIB nodes were found in only 2% of 92 neck dissections done for laryngeal cancer.[104] This and other recent studies have shown that the incidence of sublevel IIB metastases in patients undergoing elective neck dissection for cancers of the hypopharynx and oropharynx is also low, ranging between 5% and 9% for hypopharynx cancer and between 0% and 6% for oropharynx cancer.[50,104,105] These observations strongly suggest that dissection of sublevel IIB is not necessary in patients with cancer of the larynx, oropharynx, and hypopharynx and a clinically N0 neck. Because dissection of this region requires, in most patients, a more extensive manipulation of the SAN, avoiding it can decrease operative time and the risk of postoperative dysfunction of this nerve, as it has been suggested by a recent study using electromyography.[51]

The need to dissect level IV electively in patients with cancer of the larynx has also been questioned recently. In a review of 43 patients with laryngeal SCC who underwent elective ND of levels II to IV, Khafif et al.[52] found that only one patient (2.3%) had metastases in level IV nodes and that patient also had metastases in level II nodes. Others have made similar observations indicating that the prevalence of positive nodes found in level IV in the absence of palpable metastases elsewhere in the neck varies from 0% to 2.3%.[53,106] Furthermore, a recent analysis of the data from three prospective multi-institutional studies of neck dissection specimens, including 175 patients with cancer of the larynx and clinically N0 necks, revealed only 6 patients (3.4%) with positive lymph nodes in level IV.[107,108] Based on a thorough review of prospective multi-institutional studies published to date, Ferlito et al.[109] concluded that dissection of sublevel IIa

and level III appears to be adequate for the elective surgical treatment of the neck in cancer of the supraglottis and glottis. Appropriate outcomes studies are now needed to ascertain that not dissecting these areas of the neck will not have a negative effect on regional control of the disease.

Other lymph node groups that need to be considered when managing cancers of the larynx and pharynx are the retropharyngeal (RPLN) and the paratracheal lymph nodes (PTLNs).[110]

Retropharyngeal Lymph Nodes

In general, the RPLNs do not need to be addressed when managing a neck otherwise staged N0. In a retrospective study designed to assess the frequency of RPLN metastases in 774 patients with SCC of the nasopharynx, oropharynx, hypopharynx, and supraglottis, using enlargement of the RPLN on CT scans as an indicator of the presence of metastases, McLaughlin et al.[111] found an overall incidence of radiologically “positive” RPLN of 9% of the patients. The highest incidence was seen in patients with cancer of the nasopharynx (74%) and the pharyngeal walls (19%). They also noted that in patients with advanced cancer of the walls of the oropharynx and hypopharynx, the incidence of radiologically positive RPLN was higher in patients with cervical metastases (N+ necks) than in those with an N0 neck (pharyngeal wall, N+ 21%, N0 16%; hypopharynx, N+ 9%, N0 0%).[111] Amatsu et al. studied 82 patients who had RPLN dissection for squamous cell carcinoma of the hypopharynx and cervical esophagus and reported finding metastases in the RPLN in 16 patients (20%).[112] Fourteen of these patients had cancer of the hypopharynx, and the posterior pharyngeal wall was involved in 57% of them. In keeping with the studies mentioned previously, the majority of patients with RPLN metastases also had metastases in neck nodes at other levels. However, in 15% of the patients with RPLN metastases, the neck was staged N0.[112]

Paratracheal Lymph Nodes

The paratracheal lymph nodes (PTLN) are a common site of metastases from cancers of the larynx that involve the subglottic region and for cancers of the cervical esophagus. In a study that included 91 patients with carcinoma of the larynx who underwent paratracheal lymph node dissection, Weber et al.

found that metastases to these lymph nodes occurred more often in patients with subglottic cancers (40%) and transglottic cancers (21.4%), but they also occurred in patients with cancer of the glottis (13%) and supraglottis (15.7%). The presence of PTLN metastases had a significant negative impact on survival. Although the survival at 48 months for the entire group of 141 patients was 60%, none of the 29 patients with PTLN metastases survived beyond 42 months (p > 0.0.001).[113] In 2005, Plaat et al. performed a retrospective study of 85 patients who underwent total laryngectomy and PTLN dissection for cancer of the larynx and hypopharynx. The prevalence of PTLN metastases was 30%, 12%, and 67%, in patients with supraglottic, glottic, and subglottic carcinomas, respectively. Among all carcinomas of the larynx with subglottic extension, PTLN metastases were found in 27% of the cases.[114]

Based on the anatomy of the lymphatic drainage of the different laryngeal sites and on the pertinent clinical observations described in the literature, dissection or treatment with radiation of the lymph nodes in level VI is indicated in the following situations[115]:

1. Primary carcinomas of the subglottis. Treatment/dissection in these cases should include the pretracheal and the paratracheal nodes on both sides.
2. Advanced (T3/T4) carcinomas of the glottis particularly those with involvement of the anterior commissure and with subglottic extension. In cancers confined to one side of the larynx, treatment/dissection should include the prelaryngeal, the pretracheal, and the ipsilateral paratracheal nodes. In cancers involving both sides of the larynx, treatment should include the paratracheal lymph nodes on both sides.
3. Advanced (T3/T4) carcinomas of the supraglottis, particularly those with involvement of the ventricle/paraglottic space, the anterior commissure, and those with clinically apparent lymph node metastases in the lateral compartment of the neck. In cancers confined to one side of the larynx, treatment/dissection should include the prelaryngeal, the pretracheal, and the ipsilateral paratracheal nodes. In cancers involving both sides of the larynx, treatment should include the paratracheal nodes on both sides.

In these situations, a neck dissection should be extended to include the paratracheal and pretracheal lymph nodes; failure to do so may predispose to the development of peristomal recurrence. It should also be emphasized that the presence of metastases in PTLN has been found to be associated with

increased tumor recurrence.[115]

Postoperative Adjuvant Therapy

In patients with a clinically N0 neck, the neck dissections also serve as a staging procedure. Information provided by the histopathologic examination of the lymph nodes is used for decision making regarding the need for adjuvant postoperative therapy. If the lymph nodes are histologically negative, no further therapy is indicated and the patient is treated with surgery alone. However, to make this decision with confidence, all the lymph nodes at risk of containing metastases must be evaluated. This evaluation requires dissecting both sides of the neck in patients with lesions of the anterior tongue and floor of the mouth, supraglottic larynx, and most oropharyngeal and hypopharyngeal cancers.

If the histopathology indicates that there is metastases in lymph nodes, adjuvant therapy is considered, and the type of therapy depends on the number of nodes involved and on whether or not the cancer extends beyond the capsule of the lymph nodes.

Pathology Staging N_1 (pN_1)

When a single metastasis is found (pN_1) in a neck dissection specimen, surgery alone has been considered adequate treatment. However, regional recurrence rates from 16% to 25% have been reported with surgery alone, and it has been suggested that postoperative radiation may be beneficial.[53,116]

In a retrospective analysis of 517 SNDs performed in 363 patients, Byers et al. found 51 (17.6%) patients who had metastases in only one lymph node (pathologically N1) with or without ECS. A regional failure occurred in 2 of 36 (5.6%) of these patients who received postoperative radiation and in 5 of 14 patients (35.7%) who did not. All recurrences were within the dissected area of the neck.[53] More recently, Chen et al. analyzed 59 patients with T1–T2/N0–N1 SCC of the oral cavity to determine the effect of postoperative radiation. Of the patients staged pathologically N1, 28 received postoperative radiation and 31 did not. With a mean follow-up period of 46 (12 to 121) months, locoregional recurrences occurred in 14% of the patients that received postoperative radiation and in 39% of the patients who did not. As in the Byers' study, all regional recurrences occurred within the dissected

neck. To characterize further the impact of the N1 status and radiation, the authors excluded from the analysis patients with ECS, positive margins, lymphovascular invasion, and perineural invasion and compared those that had received post-operative XRT with those that did not. The 5-year disease-free survival rate and overall survival were 95% and 92.3%, respectively, for the group that received postoperative radiation and 54.7% and 54.9%, respectively, for the group that did not.[117] However, radiation was found not to be beneficial in an unpublished retrospective review that we conducted of 58 patients with T1/T2 squamous cell carcinoma of the oral tongue treated with surgery, which included an ipsilateral SND and was found to have metastasis in a single lymph node. These patients were treated at 7 institutions and were followed for a minimum of 2 years. Twenty-two (38%) patients were treated with surgery alone, whereas 36 (62%) received postoperative radiation. In the group treated with surgery alone, two patients had recurrence at the primary site and in the neck. Of the remaining 20 patients, 6 (30%) recurred in the neck (5 contralateral and 1 simultaneous ipsilateral and contralateral). In the surgery plus radiation group, 4 (11%) tumors recurred in the neck, all within the operative field. The difference in the rate of recurrence in the neck for the two groups was not statistically significant.

Thus, it appears that a prospective randomized study is necessary to determine in a controlled manner whether or not postoperative radiation is beneficial in patients whose neck is pathologically staged N1. The Radiation Therapy Oncology Group is currently accruing patients to evaluate this question further, in RTOG 0920 Protocol: A Phase III Study of Postoperative Radiation Therapy (IMRT) +/− Cetuximab for Locally Advanced Resected Head and Neck Cancer.

Pathology Staging N2/N3 (pN2-3)

When lymph node metastases are multiple or the cancer extends beyond the capsule of a lymph node, a neck dissection alone is associated with a high incidence of recurrence in the neck.[71,118,119] In these situations, the addition of postoperative radiation therapy results in better regional control of the disease, as demonstrated in numerous studies.[120–123] In addition, it has also been accepted that timing of the initiation of radiotherapy is important, as delays beyond 6 weeks may compromise tumor control.[122] Regarding the

dose of radiation therapy in the postoperative setting, a seminal study by Peters et al.[124] in the early 1990s established that a total dose of 57.6 Gy, delivered to the entire operative bed in daily fractions of 1.8 Gy, is necessary to achieve optimal results; for areas at higher risk for recurrence, such as areas of the neck where extracapsular spread of cancer was found, the ideal dose is 63 Gy.

A prospective, randomized clinical study published in 2004 showed that the concurrent postoperative administration of chemotherapy (cisplatin 100 mg/m^2 on days 1, 22, and 43) and radiotherapy (60 to 66 Gy in 30 to 33 fractions over 6 to 6.6 weeks) significantly improved the rates of local and regional control and disease-free survival in patients with high-risk–resected cancers of the head and neck.[125] The high-risk criteria included any or all of the following: histologic evidence of metastases in two or more lymph nodes, ECS, and microscopically involved margins of resection. Although the subjects of the study were stratified according to the presence or absence of microscopically positive margins, the published results did not include an analysis of outcomes with and without concomitant chemotherapy in the cohort of patients with microscopically negative margins, which would have helped to understand whether or not the addition of chemotherapy was beneficial to patients with high-risk neck metastases. A similar study by the European Organization for Research and Treatment of Cancer, published at the same time, included patients with various clinical (primary cancer and nodal volume and nodal site) and pathologic (involved margins of resection, ECS, perineural involvement, and vascular embolism) high-risk factors related to neck metastases.[126] It also showed that concomitant postoperative chemoradiation was significantly more efficacious than radiation alone in these high-risk patients. However, resection margins were positive in 30% of the patients included in the study, and the design did not include an analysis focused on the neck disease factors. Nonetheless, both of these studies suggested that the addition of chemotherapy may be beneficial to patients with resectable cancers of the head and neck who have advanced metastases to the neck (N2/N3) and to patients with N0 or N1 disease who are found to have multiple histologically positive nodes or extracapsular spread.

In a subsequent analysis of both the EORTC and RTOG studies, Bernier et al. found that chemoradiation improved overall survival in patients with ECS and/or positive margins in the EORTC study ($p = 0.0019$), but the

improvement did not reach statistical significance in the RTOG study (p = 0.0.63).[127,128] Thus, in regard to adjuvant treatment of neck metastases following neck dissection, the presence of extracapsular spread is currently considered an indication for postoperative concurrent chemoradiation.

Primary Cancer Treated with Radiation with or without Chemotherapy

In many centers today, cancers of the oropharynx, larynx, and hypopharynx are initially treated with either radiation alone (T1 and T2 cancers of the oropharynx, larynx, and hypopharynx) or combinations of radiation and chemotherapy (T3 cancers of the oropharynx, larynx, and hypopharynx). In these patients, the likelihood of subclinical metastases in the lymph nodes is sufficiently high to warrant elective treatment of the neck. Several studies have shown that elective radiation results in a >90% control rate of micrometastasis.[129] In a more recent study of a large cohort of patients with carcinoma of the oropharynx treated at MD Anderson Cancer with intensity-modulated radiation therapy (IMRT), which included 88 patients with N0 neck staging, only 4 patients (4.5%) developed a recurrence in the neck.[130]

MANAGEMENT OF THE N+ NECK

As with the N0 neck, the initial management of the neck when lymph node metastases are clinically apparent is also dictated by the initial treatment modality chosen for the primary cancer.

Primary Cancer Treated with Surgery

When surgery is the initial treatment of the primary cancer, initial management of the “positive” neck consists of a neck dissection. The purpose of the operation is to adequately remove the disease present in the neck. Decades ago, surgeons performed only one operation when managing the “positive” neck, for example, a RND. Today, the extent of the operation, that is, the type of neck dissection, is dictated by the extent of the metastases to the neck.

ND (I to V, SCM, IJV, XIN) (Radical Neck Dissection)

A RND is indicated when there are multiple clinically obvious cervical lymph node metastases, particularly when they involve the lymph nodes of the posterior triangle of the neck and are found to surround or to be tightly adherent to the SAN. A RND is also indicated when there is a large metastatic tumor mass or when multiple matted nodes are present in the superior aspect of the neck. In such instances, it is unwise to preserve the sternocleidomastoid or the internal jugular or to dissect the SAN and risk entering the cancer (Fig. 18.9). A similar situation can be created by the inflammation, hematoma, or ecchymosis that follow ill-advised excisional biopsies of neck metastases. A RND may be the safest option in such patients. Currently, RNDs represent <20% of all neck dissections done at many institutions.[131] A comprehensive description of the surgical technique of this operation was recently provided by McCammon and Shah.[132]

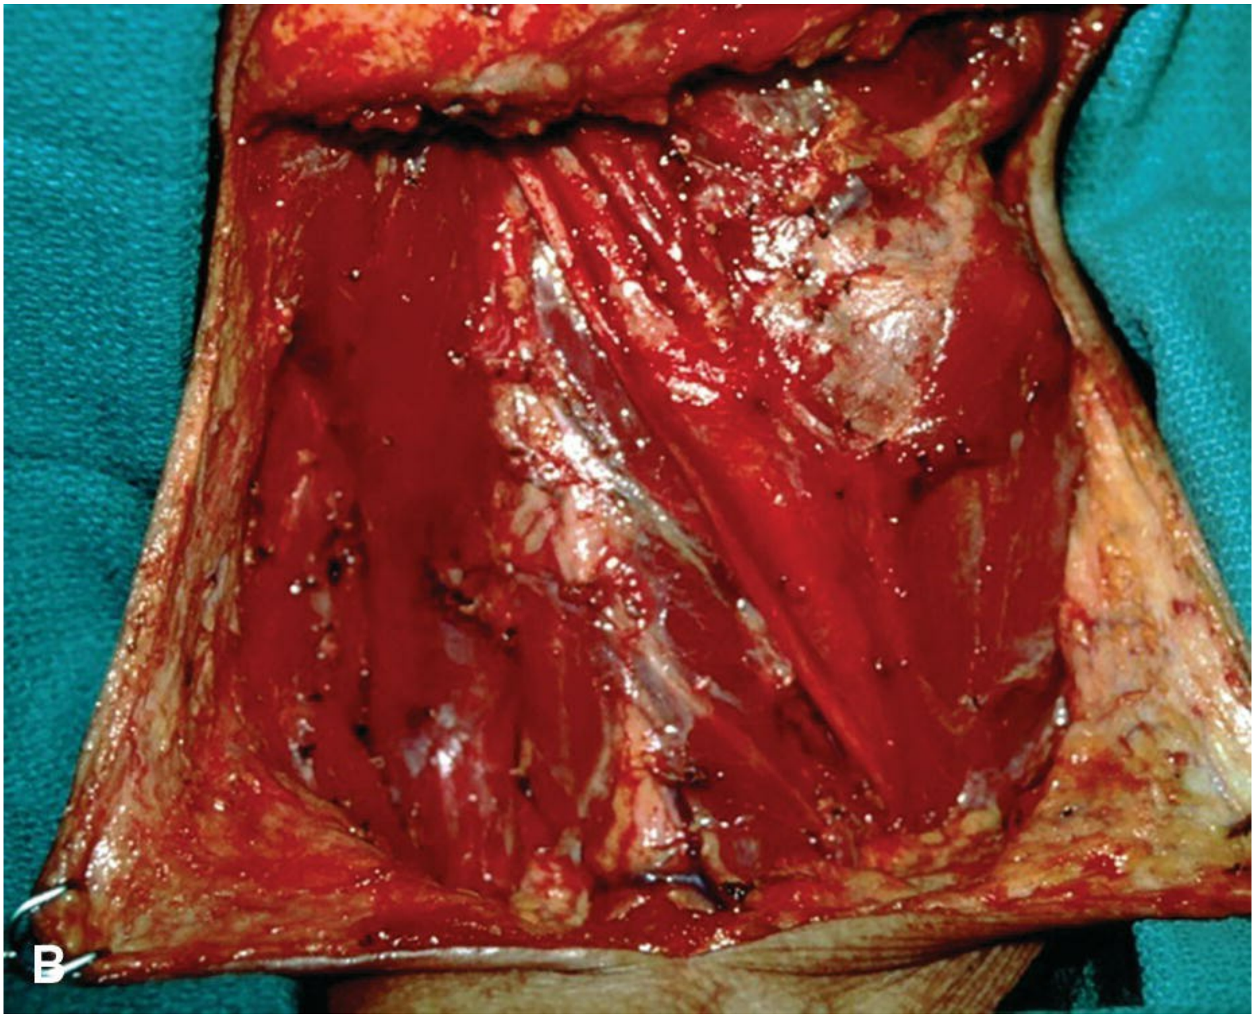

Figure 18.9. A: Patient with multiple matted nodes in the upper and midportions of the neck. **B:** Radical neck dissection.

ND (I to V, SCM, IJV) (Modified Radical Neck Dissection with Preservation of the Spinal Accessory Nerve)

When the metastatic lymph nodes grossly involved by cancer are not in close proximity to the SAN, preserving the nerve does not compromise the oncologic soundness of the operation and may prevent shoulder morbidity associated with resection of the nerve.

This type of neck dissection (Fig. 18.10) is used in the surgical treatment of the neck of patients with clinically obvious lymph node metastases when the SAN is not directly involved by cancer, regardless of the number, size,

and location of the involved lymph nodes. The decision to preserve the SAN is, therefore, a delicate intraoperative surgical decision. Much like the philosophy about preservation of the facial nerve during surgery for parotid tumors, the SAN can be preserved whenever there is a clearly identifiable, not an artificially created, plane of dissection between the tumor and the nerve knowing that the patient will be treated with radiation or chemoradiation postoperatively. The reported rate of recurrence in the neck when used for the treatment of the N+ neck in combination with postoperative radiation is 8.1%.[133]

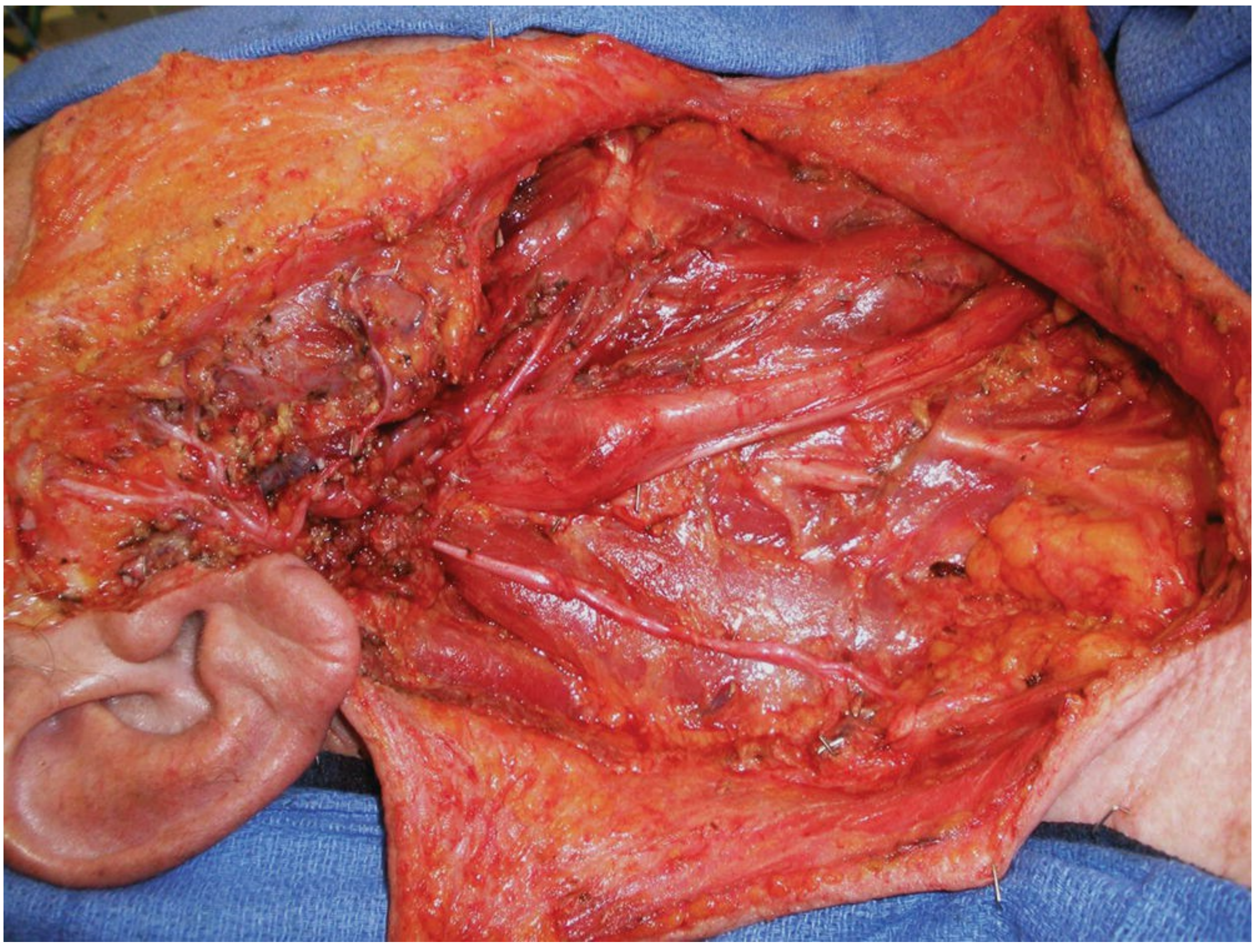

Figure 18.10. ND (I to V, SCM, IJV) (Modified radical neck dissection with preservation of the SAN).

ND (I to V, SCM) (Modified Radical Neck Dissection with Preservation of the Spinal Accessory Nerve and the

Internal Jugular Vein)

In this type of dissection, the lymph node–bearing tissues of one side of the neck are removed en bloc, preserving the SAN and the IJV (Fig. 18.11). This operation is seldom planned. It is done occasionally when, in the course of a neck dissection, the metastatic cancer in the neck is noted to be adherent to the SCM but not directly involving the accessory nerve and the jugular vein. This situation occurs occasionally in patients who have cancer of the hypopharynx or larynx with metastases deep to the middle third of the SCM.

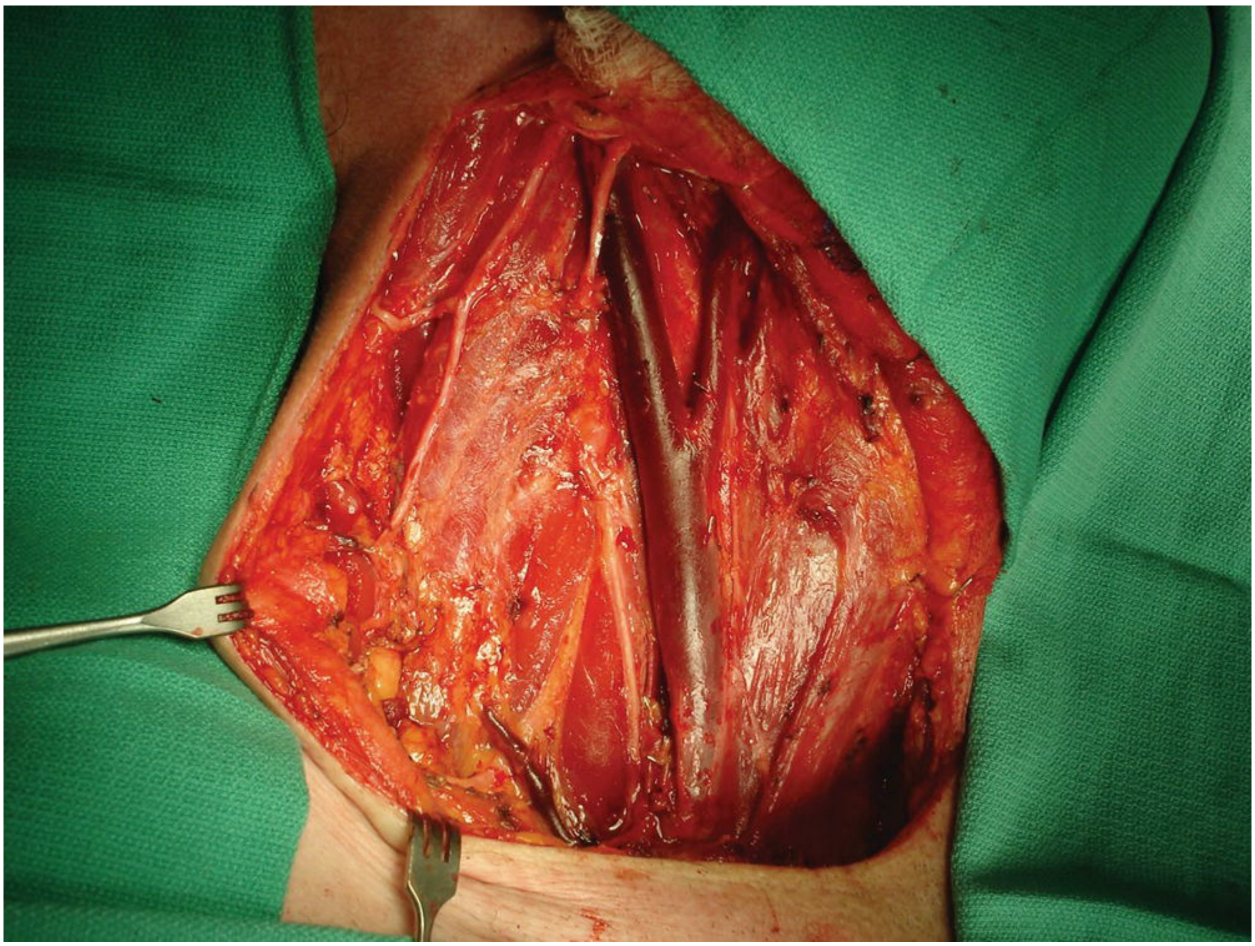

Figure 18.11. ND (SCM) (Modified radical neck dissection with preservation of the SAN and the IJV).

ND (I to V, SCM, IJV, CN XI) (Modified Radical Neck Dissection with Preservation of the Spinal Accessory Nerve, the Internal Jugular Vein, and the

Sternocleidomastoid Muscle)

In the early 1960s, Suárez[134] observed that the lymph nodes of the neck are not located within the muscular aponeurosis of the SCM and do not form part of the adventitia of nearby blood vessels, particularly veins. He also demonstrated that it was technically feasible and oncologically sound to perform a comprehensive removal of the lymph node–bearing tissues of one or both sides of the neck without removing the SCM, the submandibular gland, and the IJV. It should be pointed out that the nerves of the neck do not follow the aponeurotic compartment distribution, except for the vagus nerve, which is contained within the carotid sheath. The phrenic nerve and the brachial plexus are partially within a compartment; the hypoglossal and the SANs run across several compartments. Unless these nerves are directly involved by cancer, they can be dissected free and preserved (Fig. 18.12).

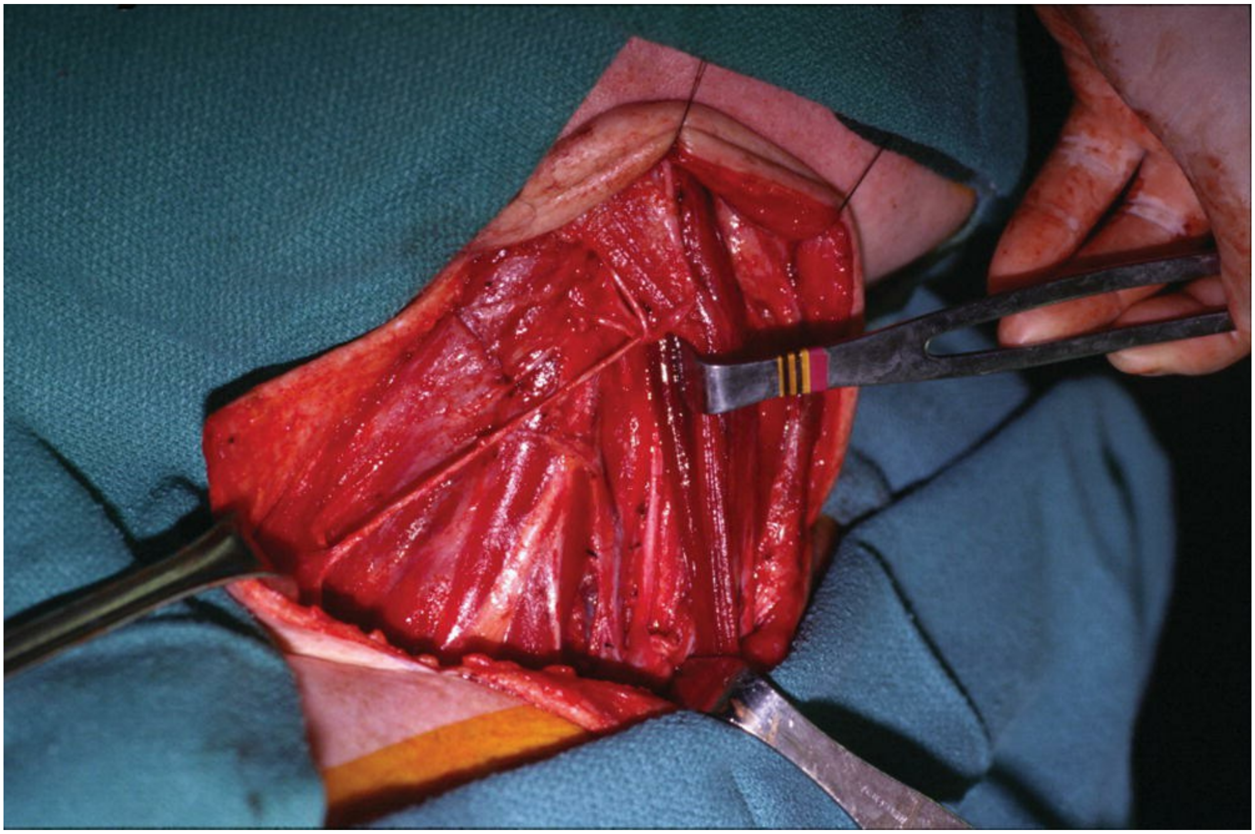

Figure 18.12. ND (I-V, SCM, IJV, CN XI) (Modified radical neck dissection with preservation of the SAN, the IJV, and the SCM).

A description of this operation, as it is currently advocated by most

European surgeons, can be found in a publication by Gavilan et al.[135] According to some surgeons, this operation is indicated for the treatment of the N1 neck, when there are multiple metastatic nodes that are mobile and no >2.5 to 3 cm. The reported rates of recurrence in the neck with this type of neck dissection range between 3.7% and 25% for the N+ neck.[134–139]

Selective Neck Dissection

SND is being used with increasing frequency in the management of selected patients with clinically obvious lymph node metastases (N+). In order to determine the feasibility of doing a supraomohyoid neck dissection in patients with carcinoma of the oral cavity who have a single clinically metastatic lymph node smaller than 6 cm (N1 and N2a), Kowalski and Carvalho[69] studied a series of patients with cancer of the oral cavity with clinical stage N1 or N2a cancer submitted to RND. Interestingly, metastases were found in any level IV lymph nodes in only one patient (0.6%), and metastases were not found in level V nodes. The authors concluded that in patients with clinical stage N1 in whom the metastasis is at level I, a supraomohyoid neck dissection (extended or not to level IV) is feasible instead of a RND.[74] Andersen et al.[136] reported a 10-year multi-institutional retrospective review of pooled data from 106 previously untreated clinically and pathologically node-positive patients who went under 129 SNDs and followed for a minimum of 2 years or until death. The neck was clinically staged N1 in 58 patients (57.7%), N2a in 5 (4.7%), N2b in 28 (26.4%), N2c in 14 (13.2%), and N3 in 1 (0.9%). Extracapsular extension of tumor was present pathologically in 36 patients (34.0%), and postoperative radiation therapy was administered to 76 patients (71.7%). Overall, nine patients had recurrence in the neck. Six of these recurrences were in the areas of the neck that had been dissected during the SND, for a regional recurrence rate of 5.7%. The recurrence rates reported by others using SND in the N+ neck ranges from 5.5% to 11.1% (mean recurrence rate of 8.3%).[137,138]

The recurrence rates following SND are comparable to those reported after MRND or RND.[133,139–144] Patel et al.[145] reported the results of a comparison of outcomes following therapeutic SND and comprehensive neck dissections. This study involved a retrospective review of 232 therapeutic neck dissections with a minimum of 2 years follow-up. Patients having SND had fewer adverse prognostic factors compared with patients having

comprehensive dissection ($pN_{2\text{-}3}$, $p = 0.001$; and extracapsular spread, $p = 0.001$). In spite of this, there was no significant difference between the two groups in regional control in the dissected neck (96% vs. 86%, $p = 0.06$), and disease-specific survival (59% vs. 43%, $p = 0.06$).

These observations suggest that SND can be used to effectively treat the clinically positive neck in selected patients with squamous cell carcinoma of the upper aerodigestive tract.

Extended Neck Dissection

Sometimes, the extent of the metastatic cancer in the neck is such that adequate removal requires the neck dissection to be "extended," to include either structures that are not routinely removed (i.e., skin of the neck, carotid artery, levator scapulae, vagus or hypoglossal nerve) or lymph node groups that are not routinely removed (i.e., retropharyngeal, paratracheal, upper mediastinal).

Skin, Muscles, and Nerves

In a review of 106 cases of extended neck dissections, the largest review on record in the literature, involvement of the skin occurred in 18% of cases.[146] Involvement of the skin did not have a significant prognostic implication.

Involvement of muscles requiring extension of the neck dissection may include superficial, prevertebral, and paraspinal muscles. The superficial group is composed of the strap muscles (sternohyoid, sternothyroid, and omohyoid), the mylohyoid, and the digastric/stylohyoid muscle complex. Removal of one or more of these muscles was the reason for extending neck dissections in as many as 62% of the cases studied by Carew and Spiro,[146] the digastric muscle being among the structures sacrificed in 51% of cases. The functional deficit resulting from removal of these muscles is of little consequence functionally, and their removal usually does not typically require reconstruction. The dissection was extended to include the prevertebral muscles in only 3% of the cases. The muscles deep to the sternocleidomastoid that may be involved by a cancer are the splenius capitis, the levator scapulae, and the semispinalis capitis muscles. Involvement of these muscles occurs most commonly just lateral to the carotid artery. It was the reason to extend a neck dissection in 14% to 18% of cases.

Cancers may be adherent to or involve several important nerves in the neck. Because the lymph nodes in level II are the most common site of metastases, the nerve most commonly involved is the hypoglossal nerve (41%). This is followed by the sympathetic chain (8%), the lingual nerve (7%), the vagus nerve (4%), the superior laryngeal nerve (3%), the phrenic nerve (3%), and the glossopharyngeal nerve (2%).[146] When a nerve is resected, it is advisable to obtain an intraoperative frozen section of the margins of resection even if the appearance of the nerve is normal; perineural tumor spread is initially axial and may not result in thickening of the nerve until late.[147]

The Carotid Artery

Controversy still exists about the advisability of extending a neck dissection to resect the common or the internal carotid artery. Initial reports on resection of the carotid artery showed very poor results, with ~50% of patients suffering either a severe stroke or death. Recent reports have shown a decrease in these events to ~25%, with modest improvement in survival compared to those who did not undergo resection. This is epitomized by the recent report by Freeman et al.[148] of their experience with 58 patients with metastatic lymph nodes adherent to the internal or common carotid artery. Angiography was used in patients who demonstrated fixation of tumor to the carotid artery on examination or imaging, followed by balloon test occlusion and single photon emission computer tomography (SPECT) brain scanning. In most patients (70%), the carotid was reconstructed with a vein graft, especially if there was insufficient collateral cerebral circulation. In addition, these patients were given 15 to 20 Gy of intraoperative radiation. In their more recent cases, the carotid was permanently occluded preoperatively when possible. Unfortunately, in spite of such aggressive treatment preceded by a systematic, "state-of-the-art" preoperative assessment, the median disease-specific survival was 12 months and 11 patients (19%) suffered a stroke.[148] The mean 1-year disease-free survival rates reported in the literature after resection and reconstruction of the carotid varies between 0% and 44%.[149]

When considering resection of the carotid artery, the surgeon must make critical preoperative, intraoperative, and postoperative decisions. Preoperative evaluation of these patients requires a clear understanding of the methods available for assessment of the cerebral circulation. Several tests are available

that involve occlusion of the carotid artery with either digital pressure (Matas test) or using a balloon during arteriography. The objective of each method is to determine a "critical point" that indicates when reconstruction of the artery is necessary. With the transcranial color Doppler method, the "critical point" is reverse flow from the external carotid artery to the internal carotid. Technetium-99m hexamethylpropyleneamine oxime brain SPECT measures cerebral perfusion. A 19% to 29% reduction in radioactivity is considered the "critical point." Unlike some of the other methods, this is not a real-time measurement, but requires delayed imaging. Another method uses Xenon in an aerosolized mixture that is inhaled by the patient, and then cerebral perfusion is measured by CT scan. Xenon is concentrated in areas of the brain that are well perfused, correlating with blood flow. Two CT scans are obtained to assess cerebral blood flow, the first one during balloon occlusion and the second after the balloon is released. The "critical point" is a 25% reduction in the degree of enhancement on the first occlusion scan compared to the open study. Electroencephalography (EEG) has a distinct disadvantage compared to other methods. It does not evaluate blood flow volume to the brain directly. However, it has the advantage that it can be used intraoperatively. The "critical point" is a 50% attenuation of the somatosensory-evoked cortical potential in relation to the preoperative examination. Finally, stump pressure measurements can be taken during angiography to determine the pressure on the distal side of the balloon when it is occluded. The critical point is a measurement of <50 mm Hg. There is significant individual variability with this measurement, as it is affected by systemic blood pressure.

Intraoperatively, patients with obvious involvement of the wall of the carotid artery whose preoperative evaluation indicates intolerance to carotid ligation should have the artery reconstructed. Saphenous vein grafts are preferred over prosthetic grafts for reconstruction, and if the skin has been heavily radiated or a portion of skin over the carotid artery is resected, an appropriate flap should be used to cover the graft. There is still considerable debate regarding the routine use of intraoperative shunts, and to date, there has not been a prospective study to prove their usefulness. However, shunting is clearly indicated when there is angiographic evidence of inadequate flow through the circle of Willis.

Postoperatively, delayed strokes can occur in as many as 25% of patients

who have undergone carotid artery resection without reconstruction, even if they “passed” the balloon occlusion test.[150] Flow from the contralateral side through the circle of Willis prevents a stroke initially. However, the resection creates an arterial stump that begins at the takeoff of the middle cerebral artery and continues down to the level of the resection. This can be a site for thrombus formation, which can then propagate up into the circle of Willis. Alternatively, the thrombus may produce emboli that can travel into the distribution of the middle cerebral artery. Although these mechanisms have not been conclusively proven, many surgeons advocate the use of heparin postoperatively to prevent delayed strokes following resection of the internal carotid artery. Recommended doses range from 5,000 units subcutaneously twice a day to full therapeutic anticoagulation.[151] The benefit of anticoagulation has not been demonstrated in a prospective controlled study.

Primary Cancer Treated with Radiation with or without Chemotherapy

The management of patients treated with “organ preservation” strategies using radiation and, more recently, combinations of radiation and chemotherapy, who present with clinically obvious lymph node metastases, particularly those with advanced metastasis to the neck (N2/N3) is evolving and remains somewhat controversial.

The first controversy is whether or not a planned neck dissection (PND) should be performed, irrespective of the response of the cancer in the neck to the treatment with radiation or chemoradiation. Some clinicians argue that a neck dissection should be carried out as part of the treatment plan, irrespective of the response of the cancer in the neck, because the clinical and pathologic responses of the tumor in the neck correlate poorly with each other. In a study by Brizel et al.,[152] a planned neck dissection appeared to confer a disease-free survival and overall survival advantage in patients with N2/N3 disease undergoing chemoradiation and had acceptably low morbidity. This was a retrospective study of a cohort of 108 patients with advanced squamous carcinoma of the head and neck, who presented with lymph node metastasis and were treated with hyperfractionated radiotherapy and concurrent cisplatinum and 5-fluorouracil. A “modified neck dissection” was performed in 65 patients, whereas 29 patients did not undergo neck dissection because of “physician and/or patient preference.” The 4-year

disease-free survival was 70% for patients with N1 disease, irrespective of the clinical response or whether a neck dissection was performed. For patients with N2/N3 disease who had a complete clinical response to chemoradiation, the 4-year disease-free survival rate was 75% for those who had a neck dissection and 53% for those who did not. This difference was not statistically significant ($p = 0.08$). However, the 4-year overall survival rate was significantly better (77% vs. 50%) for the group treated with neck dissection ($p = 0.04$). These authors and others have suggested that a planned neck dissection be considered for all patients with N2 and N3 disease.[152,153]

On the other hand, some clinicians argue that it is not necessary to perform a “planned” neck dissection when the cancer in the neck undergoes a complete response to the treatment.[154,155] This position is based on the observation that less than a third of the patients with clinically positive nodes before therapy have histologic evidence of metastases at neck dissection,[156] even when there is residual clinical or radiologic “adenopathy” in the neck after completion of (chemo)radiation.[157,158] Furthermore, when the cancer in the neck undergoes a complete response to the treatment, the probability of an isolated recurrence in the neck is low (0% to 11%); therefore, the patients may simply be observed.[154,159–161]

The controversy over whether or not a PND is needed is in large measure due to the inability to determine, preoperatively, when a complete clinical response is associated with the presence or absence of viable tumor cells. PET scanning has been found useful in identifying the subset of patients who need a neck dissection, because this imaging modality has been shown to be more accurate than others in the evaluation of patients following treatment.[162] However, the timing of posttreatment PET scanning appears to be important. In a series of 12 patients studied prospectively by Rogers et al.,[163] a positive PET scan 1 month after radiation therapy accurately indicated the presence of residual disease in all cases; however, a negative PET scan indicated absence of disease in only 14% of the cases. Other studies have also shown that a PET scan obtained 1 month after completion of treatment with radiation was inaccurate in predicting the presence of residual cancer.[164] In contrast, a PET scan done 12 weeks after completion of treatment with radiation or chemoradiation may be more useful. Porceddu et al.[165] evaluated the utility of PET imaging in 39 patients with N+ neck who achieved a complete response at the primary site but had a residual mass in the neck, 8 weeks or

more after definitive (chemo)radiotherapy. The PET scan was performed at a median of 12 weeks (range 8 to 32 weeks) after treatment. Interestingly, the PET scan showed no metabolic activity in the residual mass in 32 patients. Five of these patients had a neck dissection and were all pathologically negative. The remaining 27 patients were observed for a median of 34 months (range 16 to 86 months), and only one of them had a locoregional recurrence. Thus, the NPV of PET for viable disease in a residual anatomic abnormality in the neck was 97%. These authors concluded that a neck dissection is not necessary in patients who have achieved a complete response at the primary site but have a residual abnormality in the neck that is PET negative ~12 weeks after treatment and that these patients can be observed safely. Others have reported similar results. Rabalais et al. in a retrospective analysis of 52 patients treated with CRT found that 10 (19.2%) had a positive PET scan an average 11.8 weeks after completion of treatment.[166] Three of the 10 underwent neck dissection of which 2 partial responders had residual disease and the 1 complete responder did not. The remaining 7 (70%) patients were observed only. One of these patients was shown to have residual cancer on FNA but was not a surgical candidate for neck dissection and another had cancer in the neck in addition to persistent cancer at the primary site. Of the five remaining patients with positive PET/CT results who did not undergo PND, all five had gradual resolution of the cancer on serial PET/CT scans with no failures in the neck. Of the 42 (81%) that had a negative posttreatment PET finding, 2 underwent neck dissection for palpable lymphadenopathy and 3 had neck dissections as a component of salvage surgery for the primary cancer. None of the five neck dissection specimens demonstrated residual cancer. There were no isolated recurrences in the neck in the remaining 37 patients (average follow-up 60.4 weeks). Recently, Corry et al.[167] reviewed their experience with N2/N3 disease following CRT in 102 patients. Of the 28 patients in whom there was a CR within the primary and a PR in the neck, 11 patients demonstrated resolution of their adenopathy with continued observation, 1 was diagnosed with metastatic cancer prior to any further therapy and 16 patients had a neck dissection of which 9/16 (65%) were pathologically negative. In another study, patients with a clinical complete response to chemoradiation who were observed rather than having a neck dissection demonstrated a regional failure rate of 3% to 8%, and if negative PET imaging was included as part of the definition of a complete response, the regional failure rate decreased to 0% to

3%.[168] Thus, it appears from this information that observation with a PET/CT obtained at least 12 weeks after completion of chemoradiation is a reasonable alternative to a "routine" planned neck dissection.[168]

The second dilemma regarding "planned" neck dissections is the extent of the operation. Traditionally, surgeons performed comprehensive neck dissections (levels I to V) with or without preservation of nonlymphatic structures.[169] Recently, however, surgeons have reported performing SNDs with recurrence rates below 4%.[170] Robbins et al. performed 33 selective neck dissections in patients treated with targeted intra-arterial high-dose cisplatin infusions combined with radiation therapy (RADPLAT).[160,170] There was only one recurrence in the neck. Stenson et al.[171] reported the results in 69 patients who had planned neck dissections after various concomitant chemoradiation protocols. The majority of them (56/69) underwent a selective neck dissection, and only one patient had a recurrence in the neck. These studies suggest that selective neck dissection may be an appropriate option for some patients with an N+ neck who are treated with organ preservation regimens.

Robbins et al.[172] in 2005 reported the results of 106 neck dissections performed in 84 patients with advanced N stage cancer (N2/N3) that were treated with the RADPLAT protocol. Fourteen neck dissections were radical or modified radical, 81 were selective and 11 were dissections of levels II and III and were labeled as "super selective neck dissections" (SSND). Interestingly, there were no recurrences in the neck in the group that underwent SSND. The authors outlined the indications for the different types of neck dissection as follows: in general, a radical or modified RND was performed in patients in whom the residual lymphadenopathy involved multiple levels, a selective neck dissection was performed when the residual cancer was confined to two levels involving the lymph node groups at greatest risk, and an SSND was performed when the residual lymphadenopathy was confined to one level.

Vasan et al., at the University of Oklahoma, investigated the feasibility of performing a "single-level dissection." To that end, they studied a cohort of 51 patients, treated between January 1999 and March 2005, who underwent a total of 55 "planned" neck dissections for clinically or radiologically apparent residual cancer in the neck, after definitive treatment of the primary tumor

and neck with radiation therapy alone or with chemotherapy.[157] The primary cancer was in the tonsil in 20 (39%) patients, the base of the tongue in 12 (23%), the supraglottic larynx in 10 (20%), the hypopharynx in 4 (8%), the faucial arch in 3 (6%), and “unknown” in 2 (4%). The neck was staged N1 in 19 (38%) patients, N2A in 8 (16%), N2B in 10 (20%), N2C in 6 (12%), and N3 in 7 (14%). All patients were treated with radiation therapy with curative intent. The mean radiation dose was 7,077 cGy and 5,814 cGy to the primary cancer and neck, respectively. Twelve patients also received chemotherapy. The neck dissections performed included lymph node levels II to IV in 32 (58%) of the cases, II to III in 16 (29%), I to IV in 4 (7.1%), and one each of I to IV, II to V, and II only. In 19 dissections (34%), nonlymphatic structures were removed, including the IJV (19/34%), a portion or all of the SCM (14/25%), the digastric (5/9%), and the XI cranial nerve (4/7%). Interestingly, Robbins et al.[160,170] also reported the need to remove one or more of these nonlymphatic structures in 24% of “planned” selective neck dissections. The pathologists found histologically “viable-looking” cancer in one or more lymph nodes in 15 of the 55 neck dissection specimens; thus, the yield of histologically positive nodes was 27.2%. In the analysis of the distribution of the positive nodes, five patients had clinical or radiologic evidence of metastases of one or more nodes in level II only; in all of them (5/5), histologically positive lymph nodes were found only in level II. Eight patients had clinical/radiologic evidence of metastases in one or more nodes in levels II and III (one patient also had a node in level V); histologically positive nodes were found in level II in one instance, in level III in four, and in levels II, III, and IV in three. Two patients had clinically/radiologically positive nodes in levels I and II; histologically positive nodes were found in levels I and II in one of them and in levels I and III in the other. Over a mean follow-up time of 25.9 months, there were only two recurrences in the neck (4%).

These findings confirm the effectiveness of selective neck dissection in the management of residual cancer in the neck. In addition, they suggest that it may be feasible to perform a single-level dissection in patients whose cancer is confined to level II nodes, before, during, and after treatment with radiation with or without chemotherapy. Boyd et al.[173] noted a predictable pattern of residual metastases following irradiation and suggested that a lateral (II to IV) neck dissection may be appropriate in the majority of

patients. In this study of nine positive specimens, six revealed malignant cells in a single nodal echelon. Obviously, such an approach must be investigated further in prospective studies.

More recently, investigators have used CT scans of the neck following chemoradiation to determine the extent of neck dissection. Goguen et al.[174] and Yeung et al.[175] noted the NPV for CT for the posttreatment neck was 95%. They noted that an SND or superselective neck dissection guided by posttreatment CT would have captured all residual cancer in 95% and 93% of the cases, respectively.

SEQUELAE OF NECK DISSECTION

The most notable sequelae observed in patients who have undergone a RND are related to removal of the SAN. The resulting denervation of the trapezius muscle, one of the most important shoulder abductors, causes destabilization of the scapula with progressive flaring at the vertebral border, drooping, and lateral and anterior rotation. The loss of trapezius function decreases the patient's ability to abduct the shoulder above 90 degrees at the shoulder. These physical changes result in the recognized shoulder syndrome of pain, weakness, and deformity of the shoulder girdle commonly associated with the RND. It should also be noted that preserving the cervical plexus contributions to the SAN may not decrease shoulder morbidity significantly.[176] Furthermore, shoulder disability after neck dissection results not only from the SAN dysfunction but also from secondary glenohumeral stiffness caused by weakness of the scapulohumeral girdle muscles and postoperative immobility.

A number of studies have demonstrated that when compared with the RND, neck dissections that preserve the SAN are associated with less shoulder pain,[177] better shoulder function and overall quality of life.[5,90–92,178,179] However, these studies also provide evidence that even procedures that involve minimal dissection of the SAN can result in shoulder dysfunction. Although this dysfunction is often reversible, it behooves the surgeon to make every effort to avoid undue trauma to the nerve, particularly stretching, during any neck dissection in which the nerve is preserved. In addition, every patient who undergoes neck dissection must be questioned about the function of the shoulder and must be evaluated by a physical

therapist early in the postoperative period. If any deficit is detected, the patient should be properly counseled and coached to ensure proper rehabilitation of the shoulder. Physical therapy aimed to early recovery of passive motion and to avoid the occurrence of joint fibrosis has been shown to be beneficial.[180] It has also been suggested that progressive resistance exercise training may be a useful adjunct to standard physical therapy.[181] It should be kept in mind, as mentioned earlier, that shoulder pain after neck dissection may not be the result of dysfunction of the SAN. Consequently, if a patient experiences shoulder pain after neck dissection, the trapezius muscle and active bilateral abduction of the shoulder should be examined to determine if the SAN is involved.[93]

COMPLICATIONS OF NECK DISSECTION

In addition to the medical complications that can occur after any surgical procedure in the head and neck region, several surgical complications can be related solely or in part to neck dissection.

Infection

Following clean neck dissections, those in which the upper aerodigestive tract is not entered, wound infections are uncommon. Interestingly, however, a recent prospective study, designed to evaluate the effects of a prophylactic antibiotic regimen (ampicillin–sulbactam for 24 hours) on the incidence of infection after clean neck dissection, showed that the infection rate in patients that were treated with the antibiotic was 1.7% compared to a significantly higher rate (13.3%) among patients who did not receive antibiotic (p = 0.02).[182]

Chylous Fistula

The reported incidence of chyle fistula following neck dissection varies between 1% and 2.5%. In most patients who develop a postoperative chylous fistula, a chylous leakage is identified and apparently controlled intraoperatively.[183] Given these observations, it behooves the surgeon to avoid injury to the thoracic duct proper and to also to ligate or clip any

visualized or potential lymphatic tributaries in the area of the thoracic duct, which may be accomplished with relative ease if the operative field is kept bloodless when dissecting in this area of the neck. Furthermore, as soon as the dissection of this area is completed and again before closing the wound, the area is observed for 20 or 30 seconds while the anesthesiologist increases the intrathoracic pressure.

Even the smallest leak of chylous drainage must be pursued seriously until it is no longer leaking. Direct clamping and ligating may be difficult and sometimes counterproductive as a result of the fragility of the lymphatic vessels and the surrounding adipose tissue. Hemoclips are ideal to control a source of leakage that is clearly visualized. Otherwise, it is preferable to use suture ligatures with pliable material, such as 5-0 silk, that are tied over a piece of hemostatic sponge to avoid tearing. In the immediate postoperative period, serum and drainage levels of triglycerides and cholesterol obtained on the first postoperative day may be useful parameters to predict early the occurrence of a chyle fistula.[184]

Management of a chyle leak noted postoperatively depends on the time of onset of the leak, on the amount of chyle drainage in a 24-hour period, and on the presence or absence of accumulation of chyle under the skin flaps.[183,185] When the daily output of chyle exceeds 600 mL or 200 to 300 mL/day for 3 days, especially when the chyle fistula becomes apparent immediately after surgery, conservative closed wound management is unlikely to succeed.[186] In such cases, it is preferable to explore the wound early, before the tissues exposed to the chyle become markedly inflamed and before the fibrinous material that coats these tissues becomes adherent, obscuring and jeopardizing important nearby structures such as the phrenic and the vagus nerves. Surgical exploration is also warranted when chyle accumulates under the skin flaps either because of inadequate drain size or because of the volume or consistency of the chyle causes partial or complete obstruction of the drains.

On the other hand, chylous fistulae that become apparent later in the postoperative period, after enteral feedings are resumed, or those that drain <200 to 300 mL of chyle per day, are initially managed conservatively with closed wound drainage, pressure dressings (which are cumbersome to secure in this area of the neck), repeated aspirations, and diet modifications aimed at decreasing chyle drainage while maintaining nutritional support. Usually,

nutrition can be provided enterally using elemental diets supplemented with medium-chain triglycerides, which are absorbed directly into the portal circulation bypassing the lymphatic system. In some patients, parenteral nutrition may be necessary.[187] If these measures fail, the neck is surgically explored and the leak is identified and dealt with appropriately. Sometimes, this intervention is unsuccessful and the leak persists. The use of fibrin glue and a clavicular periosteal flap may be useful to control the leak in such cases.[188] Percutaneous lymphangiography-guided cannulation and embolization of the thoracic duct is an effective minimally invasive alternative to open surgical intervention.[189] Success with this technique has been reported in as many as 45% to 70% of the cases.[186] In a recent report, Nyquist et al. described a case in which a chylous fistula stopped draining 24 hours after the administration of octreotide (100 μm given subcutaneously three times a day). These authors postulate that the effect of octreotide on chylous fistulae may be due to its ability to reduce gastrointestinal and pancreatic secretions, decrease hepatic venous pressure, and reduce splanchnic blood flow, which may decrease thoracic duct flow and relative concentration of triglycerides.[190]

Ipsilateral chylothorax can occur following neck dissection. Bilateral chylothorax as a complication of neck dissection is extremely rare, but it is potentially serious and sometimes fatal.[191,192]

Facial or Cerebral Edema

Synchronous bilateral RNDs, in which both IJVs are ligated, can result in the development of facial edema, cerebral edema, or both. The facial edema sometimes can be dramatically severe. It appears to be a mechanical problem of venous drainage, which resolves to a variable extent with time as collateral circulation is established. It appears to be more common and more severe in patients who had previous radiation to the head and neck and in those patients in whom the resection includes large segments of the lateral and posterior pharyngeal walls. We have been able to prevent massive facial edema by preserving at least one external jugular vein whenever a bilateral RND is anticipated. The external jugular usually is separated from the tumor in the neck by the SCM and can be dissected free between the tail of the parotid and the subclavian vein. Others have reconstructed one internal jugular using various techniques including vein with saphenous vein grafts or by using a

segment of one of the resected jugular veins, distal to the site of tumor involvement.[193,194] The development of cerebral edema may be at the root of the impaired neurologic function and even coma that can occur after bilateral RND. Following neck dissection, a syndrome of inappropriate secretion of antidiuretic hormone (SIADH) occurs in 8% to 30% of patients. This is a disorder in which release of antidiuretic hormone is independent of plasma osmolarity, resulting in fluid retention and development of dilutional hyponatremia. It occurs significantly more often in patients who have history of smoking, and it has been noted to resolve within 72 hours.[195] It is commonly believed that synchronous, bilateral RND causes the SIADH, presumably as a result of increased intracranial pressure. This belief is based mainly on the results of an experimental study published in 1978 in which occlusion of the superior vena cava in dogs resulted in increased intracranial pressure and SIADH. Using an animal model that more closely resembles the clinical condition of bilateral RND, Khafif et al. found that bilateral synchronous IJV ligation and bilateral RNDs did not result in SIADH in dogs.[196] As these results contradict a commonly held belief in clinical practice, a prospective evaluation of the physiologic changes after bilateral RNDs is warranted. Nevertheless, it is possible that an expansion of extracellular fluids and dilutional hyponatremia that occurs in some patients after neck dissection could aggravate cerebral edema, creating a vicious cycle. In practice, this behooves the surgeon and the anesthesiologist to curtail the administration of fluids during and after bilateral RNDs. Furthermore, perioperative management of fluid and electrolytes in these cases should not be guided solely by the patient's urine output but also by monitoring central venous pressure, cardiac output, and serum and urine osmolarity.

Carotid Artery Rupture

The most feared and most commonly lethal complication after neck surgery is exposure and rupture of the carotid artery, the so-called carotid blowout syndrome (CBS). Therefore, every effort must be made to prevent it. Prevention of CBS begins with an understanding and avoidance of the circumstances that predispose to CBS; these include:

1. Previous treatment with radiation or chemoradiation, malnutrition, and diabetes impair healing capacity and compromise vascular supply that

may lead to wound breakdown, skin flap necroses, and fistula formation.

2. Neck incisions with trifurcations over the carotid: small areas of necrosis of the tips of flaps at the trifurcation can result in exposure of the carotid. If the skin incisions are designed properly, the carotid seldom becomes exposed in the absence of a salivary fistula.

Faced with any of these risk factors, the surgeon must (1) use flawless surgical technique in the closure of oral and pharyngeal defects, (2) perioperative antibiotics, and (3) use free and pedicled vascularized flaps, which provide skin for closure of mucosal defects and muscle that can protect the carotid. These measures have rendered obsolete the use of “protective” measures such as dermal grafts, levator scapulae muscle flaps, and controlled pharyngostomes.

Fortunately, CBS has become less frequent; however, its frequency may increase again as more salvage procedures are done in patients whose tumors fail to respond to chemoradiation regimens. Therefore, it is essential for all head and neck surgeon to be familiar with presentation and current management of CBS.

A patient may present at different stages of CBS that range from exposure of the carotid artery to hemorrhage from the carotid artery system and management varies accordingly.

Stage I or threatened CBS, when exposure of the carotid artery is found on clinical examination or imaging studies (i.e., air surrounding the vessel, adjacent abscess, or tumor associated with a fistula or areas of arterial wall disruption, found on vascular imaging studies). At this stage, the patient may be asymptomatic.

Stage II or impending blowout, when bleeding episodes occur that resolve temporarily with pressure and wound packing. In many cases, these are self-limiting, single incidents that may cause little suspicion to those unaware of the patient’s history and risk factors for CBS. Sentinel bleeding can occur moments to months before hemorrhage.

Whenever the carotid is exposed, it is advisable to take the following precautions:

- Warn and instruct nursing personnel and house staff about the possibility of a carotid rupture, the site of potential rupture, and the steps

to be taken in the event of bleeding.

- Have compatible blood available.
- Keep appropriate surgical instruments at the bedside.

Management of the exposed carotid depends on the likelihood of rupture, based on the length of the exposed segment, the condition of the surrounding tissues, and the size of the oropharyngocutaneous fistula. Large cutaneous defects or large high-output fistulae in previously radiated patients are not likely to heal by secondary intention in a timely manner. The likelihood of rupture of the carotid in these conditions is extremely high. Therefore, an attempt should be made to repair the defect and to cover the carotid using well-vascularized tissue early, before the vessel has been irreversibly damaged.

Identification and appropriate management of the early stages of CBS are crucial, as these patients have a lower complication rate than do those who wait until hemorrhage develops.

Stage III or hemorrhage from the carotid system. This can be rapidly fatal especially when it occurs outside the hospital setting. Bleeding can occur externally through a neck wound or “internally” into the pharynx/mouth. In the latter case, the possibility exists for airway compromise. When a carotid rupture occurs, it is usually possible to stop the bleeding with manual pressure while blood and fluids are given to restore and maintain the patient’s blood pressure. Often, in emergency situations, medical staff place multiple dressings over the wound, which will not apply focused pressure over the bleeding site, and the patient may continue to exsanguinate around them. It is more effective to place a gloved finger for pressure to temporarily control the bleeding until definitive treatment is undertaken. Blood pressure must be addressed aggressively with proper resuscitation. Only then is the patient taken to surgery or the radiology suite, because the risk of morbidity with ligation increases significantly in the setting of hypotension, which is the greatest predictor of a poor outcome in the acute treatment of CBS. Attempts to repair the area of rupture are futile. Introducing Fogarty catheters through the area of rupture help control the bleeding temporarily while the artery is exposed and ligated proximally and distally to the area of rupture.

Endovascular embolization—whether it be with balloons, coils, or other

materials—is more precise than ligation, as it targets the exact location of the arterial defect. It also decreases the hospital stay and causes less of the collateral morbidity that is sometimes associated with emergent open ligation procedures, such as injury of cranial nerves or ligation of the incorrect trunk or branch of the carotid system. Endovascular embolization also has the ability to help predict cerebrovascular complications with temporary balloon occlusion and collateral cerebral blood flow analysis. Carotid artery embolization is associated with 15% to 20% long-term neurologic morbidity rate and a much lower incidence of associated mortality.

More recently, constructive endovascular management of CBS became available for patients who have risk factors for neurologic sequelae after embolization. Constructive methods using intravascular stents to control vascular wall instability while allowing adequate cerebral perfusion. Some indications used for arterial stenting include an incomplete circle of Willis, significant contralateral carotid artery atherosclerosis or narrowing, inability to perform balloon occlusion tests (proximal atherosclerotic stenosis or unstable clinical scenario), and failure to tolerate balloon test occlusion on either clinical or cerebral blood flow criteria (decrease of cerebral blood flow of more than 20%).

Regardless of the treatment used, anticoagulation therapy may be required to prevent thrombosis distal to the ligation or endovascular occlusion site or to prevent stent thrombosis. Patients with an exposed carotid artery require wound management with flap placement to cover and protect these vessels.

Although endovascular treatment within the carotid system can have a significant risk of mortality and neurologic morbidity, it has become the treatment of choice for CBS.

Jugular Vein “Blowout”

This complication is seen more often because the IJV is preserved more frequently during neck dissection. Rupture of the jugular vein should be considered in patients undergoing primary excision of cancer with a modified RND complicated by a pharyngocutaneous fistula. In a recent study of six patients who experienced rupture of the IJV, Cleland-Zamudio et al.[191] found that patients who have a complete circumferential dissection of the IJV low in

the neck and go on to have fistulas develop may be more prone to this complication.[197] Typically, bleeding occurs repeatedly. Treatment consists of surgical exploration and ligation of the jugular vein above and below the level of rupture.

Jugular Vein Thrombosis

Preservation of the IJV during neck dissection does not ensure its patency after surgery, particularly when radiation therapy is also used. Cotter et al.[198] used preoperative and postoperative CT or MRI on 69 patients undergoing 79 vein-sparing neck dissections. Sixty-eight veins (86%) were patent postoperatively. Capiello et al. studied the patency of the IJV following selective lateral neck dissection in a cohort of 34 patients. A preoperative baseline study of vein patency and flow by US was obtained followed by postoperative evaluations at 1 week, 1 month, and 3 months. At 1 week postoperatively, 50% of the IJVs did not present any alteration in patency, 46% had reduced flow, and 4% showed absent flow. However, at 3 months, none of the patients showed evidence of IJV occlusion. Postoperative radiotherapy did not have a statistically significant impact on IJV patency ($p = 0.09$).[199]

A recent report describes the rate of complications after planned posttreatment neck dissections in patients enrolled in organ preservation protocols. The authors conclude that the rate is similar to that previously reported for neck dissections (37%) and that the rate increases when higher preoperative radiation therapy doses are used.[200]

19 Thyroid Cancer

Jennifer R. Cracchiolo Ashok R. Shaha

The incidence of thyroid cancer is rapidly rising in the United States and around the world.[1] This is largely related to the routine use of ultrasound and imaging studies including CT scan, MRI, and PET scan in the evaluation of other conditions, which leads to the early identifications of thyroid nodules many of which after further analysis prove to be thyroid cancer. The incidence of thyroid cancer has almost quadrupled in the United States in the last quarter of a century from ~8,000 cases per year in 1975 to the current incidence of 66,000 new thyroid cancers per annum. A much steeper rise in incidence has been seen in Korea where ultrasound of the neck is performed in a routine health check. The vast majority of these incidentally identified thyroid cancers are papillary carcinomas <2 cm in size, for which the 5-year survival exceeds 99.5%. However, the finding of thyroid cancer in each patient leads to intense concern about the diagnosis of cancer, often leading to aggressive treatment that is costly and, at times, morbid.

There is a current debate as to whether relatively more aggressive treatment will make a difference in long-term outcome, given that the outcome in patients with small papillary carcinomas is excellent. Thus, questions remain as to whether the routine use of total thyroidectomy with such patients is more likely to lead to improvements in survival that would justify the risk of laryngeal nerve palsy and temporary or permanent hypoparathyroidism. There is now a considerable interest both in Japan and in the United States to conduct observation studies on patients with microcarcinoma similar to prostate cancer to determine whether treatment of thyroid cancer is needed in all patients. Given the vast numbers of patients diagnosed and treated for thyroid cancer each year, the prognostic factors and risk group analysis are extremely well defined for patients with thyroid cancer that helps with the selection of how aggressively patients should be treated and which patients could potentially be observed closely rather than treated.

The majority of thyroid cancers are papillary carcinoma with follicular, Hurthle cell, anaplastic, and medullary carcinoma representing the remaining histologies that are most commonly seen (Fig. 19.1). Significant advances in the molecular biology of thyroid cancer have contributed to the way in which thyroid cancer is understood, diagnosed, and managed, as molecular testing now aids in predicting malignancy and prognosis in cytopathology samples. In addition, three drugs recently approved by the FDA for the treatment of advanced thyroid cancer are currently being used. With all of these new technologic developments currently available, it is important to continue to adhere to the principles of management of patients with thyroid cancer to avoid treatment-related complications both medical and surgical.

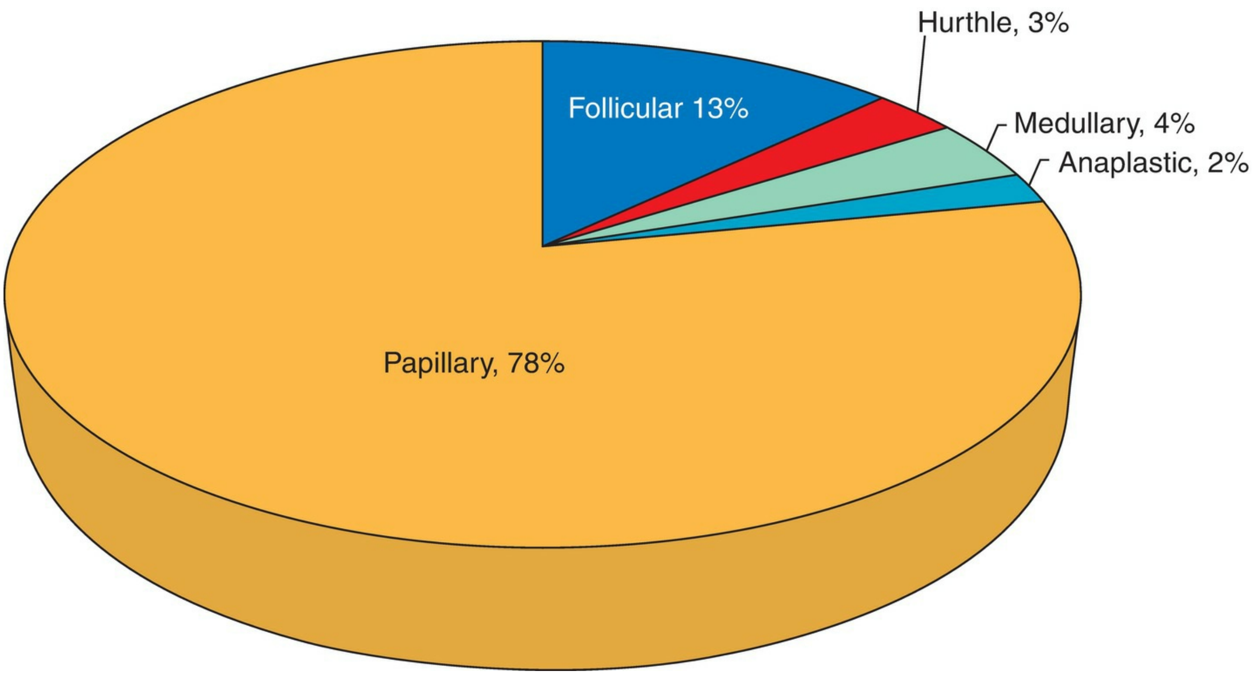

Figure 19.1. Histologic distribution of thyroid tumors.

In this chapter, we will discuss the current understanding of thyroid cancer, pathology, prognostic factors and risk group analysis, available treatments, and overall outcomes. Current recommendations for evaluation, treatment, and surveillance are based on the wide experience of practitioners, investigators, and organizations such as the American Thyroid Association (ATA) and have led to publication of guidelines for the management of thyroid cancer first in 2006 and most recently in 2015.

THYROID CANCER: A UNIQUE HUMAN NEOPLASM

Thyroid cancer is a unique human neoplasm as the overall biologic behavior of thyroid cancer is characterized by slow-growing tumors with progression of disease over many years. Furthermore, this is the only human neoplasm where age is included in the staging system (Tables 19.1 and 19.2). In fact, here is no stage III or IV thyroid cancer in patients below the age of 45, which reflects the excellent outcome of these patients even in the setting of distant metastases. Age is an important prognostic factor, and even though age 45 is used as the general threshold in the staging system, it appears that the better age threshold is at 55.[2] The presence of microscopic or “laboratory cancer” has very little clinical significance. It is not uncommon to find laboratory microscopic cancer in a thyroid gland removed for other medical issues. Such microscopic papillary cancers have an excellent prognosis and do not have any implication in the long-term outcome and do not require additional treatment. The presence of nodal metastasis in thyroid cancer is fairly common and is seen in almost 60% to 80% of younger individuals diagnosed with the disease. It has no major bearing in the overall outcome except in selective aggressive thyroid cancers or in older individuals.

Table 19.1 AJCC Staging of Thyroid Cancer

Definition of TNM	
Category	**Definition**
Primary tumor (T)[a]	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 2 cm or less in its greatest dimension, limited to the thyroid
T2	Tumor more than 2 cm, but not more than 4 cm in its greatest dimension, limited to the thyroid
T3	Tumor more than 4 cm in its greatest dimension limited to the thyroid or any tumor with minimal extrathyroidal extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues)
T4a[b]	Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
T4b[b]	Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels
Regional lymph nodes (N)[c]	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
N1a	Metastasis to level VI (pretracheal, paratracheal. and prelaryngeal/Delphian lymph nodes)
N1b	Metastasis to unilateral, bilateral, or contralateral cervical or superior mediastinal lymph nodes
Distant metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	Mo distant metastasis
M1	Distant metastasis

[a]All categories may be subdivided: (I) solitary tumor, (ii) multifocal tumor (the largest determines the classification).

[b]All anaplastic carcinoma are considered T4 tumors: T4a—intrathyroidal anaplastic carcinoma (surgically resectable); T4b—extrathyroidal anaplastic carcinoma (surgically unresectable).

[c]Regional lymph nodes are the central compartment, lateral cervical, and upper mediastinal lymph nodes.Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. An understanding of the histologic variations of thyroid carcinoma such as tall cell insular or poorly differentiated tumors and aggressive features is critical in the selection of treatment for patients in order to assure that they have the best possible outcome. In addition, these factors are important for the selection of adjuvant treatment and follow-up testing. The number of mitoses seen per high-power field on histologic examination is also important as a major prognostic feature, as are the findings of extrathyroidal extension and invasion of surrounding structures. It is critically important that the operating surgeon appreciate these clinical features and perform adequate and appropriate surgery including resection of the surrounding involved structures to achieve a complete resection in order to avoid future locoregional recurrence.

Despite all that is known about the biologic behavior of differentiated thyroid cancer, there are several controversies that remain regarding its management. One major area of controversy has been a subject of debate in national and international conferences and the literature abounds with publications describing the extent of thyroidectomy and whether treatment with thyroid lobectomy versus total thyroidectomy is the most appropriate way to manage patients with early-stage differentiated cancer. Two additional areas of controversy are (1) the use of radioactive iodine ablation in patients with low-risk thyroid cancer and (2) whether prophylactic central compartment dissection should be performed in patients with low-risk thyroid cancers. These controversies generate considerable debate, and this has been reflected in the evolution of the ATA guidelines for thyroid cancer treatment from 2006 to 2015.

EPIDEMIOLOGY

The National Cancer Institute has reported that 62,980 people will be diagnosed with thyroid cancer, and 1,890 people will die of this disease in the United States this year. The risk for thyroid cancer is three times more

prevalent in women than men and more common in Caucasians. The probability of being diagnosed with thyroid cancer peaks between 35 and 44 years of age. Although the diagnosis of thyroid cancer affects young patients, the percent of thyroid cancer deaths is highest among older patients with the median age of death being 73 years. Rates for new thyroid cancer cases have been rising on average 5.5% each year over the last 10 years. This increase in incidence is not isolated to the United States as the rise in thyroid cancer has been observed over the last three decades all over the world. The exception to this trend is in Africa, where detection may be insufficient. Importantly, death rates have also been rising on average 0.8% each year over 2002 to 2011.[3] Many have hypothesized on the reasons behind the rising incidence of thyroid cancer, and explanations for the worldwide increase in thyroid cancer incidence are a source of controversy. The recent advances in imaging studies such as ultrasound, CT scan, MRI, and PET scan have identified exceedingly high number of incidental thyroid cancers, which are generally microcarcinomas. This is directly related to the increased usage of ultrasound and other imaging studies of the neck in the evaluation of other conditions including carotid vascular disease, cervical spine problems, and trauma. Many institutions have routine health checks with ultrasound of the neck as well as ultrasound of the breast. This practice of performing routine ultrasound of the neck has led to an exceedingly high incidence of thyroid cancer in South Korea where the incidence has risen almost 15-fold in the last 15 years.[1] Although it is generally accepted that early detection of cancers is generally associated with better outcomes and has led to screening for prostate and breast cancer, the impact of the early identification of papillary microcarcinomas on patient survival remains unclear at this time, and further studies are needed to determine the most appropriate management that will lead to good survival, low morbidity, and appropriate utilization of health care resources.

INCIDENTALLY DIAGNOSED THYROID CANCER

Many thyroid cancers are identified as an incidental finding during the evaluation of other conditions or during screening tests, and these otherwise asymptomatic cancers can therefore be referred to as “incidentalomas.”

Incidentalomas are fairly common in the thyroid gland. This terminology was previously used routinely for adrenal lesions, and it is now commonly used for thyroid nodules found “incidentally” without clinical symptoms or suspicion. Approximately 5% to 10% of individuals have thyroid nodules; however, many of these may remain clinically silent in the lifetime of the individual.

Clinical incidentalomas are commonly noted in routine clinical examination either by a primary care physician or during an ENT examination. Imaging incidentalomas can be divided into ultrasound of the neck, CT scan, MRI, or PET. These are more common when a patient undergoes routine imaging of the neck for other medical problems such as trauma, neck pain, or neurovascular conditions. Once a thyroid nodule has been identified by one of these studies, further evaluation including an ultrasound and needle biopsy may lead to the diagnosis of cancer.

We are seeing more and more incidentalomas related to the use of PET, which raises a suspicion of cancer in the mind of the radiologist and the oncologist. Incidentalomas identified by PET need to be divided into those with diffuse and those with focal uptake. Diffuse uptake is more likely related to nodular hyperplasia and Hashimoto thyroiditis, although the latter condition may also have areas of focal uptake, suggestive of malignancy.

Once a focal incidentaloma is noted on PET, it is important to proceed with ultrasound and based on the findings of the ultrasound consider ultrasound-guided needle biopsy. Katz and Shaha[4] have described their experience and review of PET-associated incidental neoplasms (PAIN) and have noted that the incidence of malignancy in selectively operated patients is ~50%, whereas a large number of these patients have aggressive histology such as tall cell tumor, Hurthle cell tumors, or oncocytic malignant tumors. Figure 19.2 demonstrates a thyroid nodule indecently found by PET scan. In summary, the focal PET hypermetabolic thyroid nodule needs to be further evaluated with ultrasound and possible ultrasound-guided needle biopsy.

Figure 19.2. PAIN (PET-Associated Incidental Neoplasm). Lesions found incidentally on PET scan have a higher rate of malignancy.

ANATOMY

The thyroid gland includes two lateral lobes, connected by a central isthmus. Often, a vestigial remnant of the thyroglossal duct tissue extends as a finger-like projection superiorly from the thyroid isthmus to make up a third, “pyramidal lobe” of the gland. Two ligaments “attach” the thyroid from the cartilaginous airway. The anterior suspensory ligament arises from the anterior aspects of tracheal rings and inserts on the posterior aspect of the thyroid isthmus. Condensation of the thyroid capsule forms the posterior suspensory ligament (ligament of Berry) and connects the posteromedial aspect of the gland to the tracheal rings and cricoid cartilage. In contrast to the avascular plane characteristic of the anterior suspensory ligament, an arterial and venous plexus course through the posterior suspensory ligament and can be a source of bleeding during thyroidectomy.

The arterial and venous supply to the thyroid must be meticulously dissected and ligated during thyroid surgery. Arterial anatomy includes paired superior thyroid arteries arising as the first branch of the external carotid artery and paired inferior thyroid arteries arising from the thyrocervical trunks. An unpaired thyroid ima artery may arise from the innominate artery, carotid artery, or directly off the aortic arch. Attention to hemostasis and keen attention to vascular structures associated with the thyroid gland are important in avoiding postoperative hematoma.

Identification and preservation of the nerves arising from the vagus nerve during thyroid surgery require a thorough knowledge of the anatomy as well as surgical skill. The recurrent laryngeal nerve (RLN) innervates all intrinsic muscles of the larynx except the cricothyroid muscle. The left RLN branches from the vagus nerve and then descends into the chest passing inferior and posterior to the aortic arch. In contrast, the right RLN leaves the vagus nerve at the base of the neck and loops around the subclavian artery. This results in the more lateral location of the right RLN versus the left RLN in the neck as both nerves ascend in tracheoesophageal groove before entering the larynx at the cricothyroid joint (Fig. 19.3). The nerve may be split into multiple branches or into two major branches anterior and posterior. It is the anterior

branch that carries motor fibers and is more functionally important for the mobility of the vocal cord.

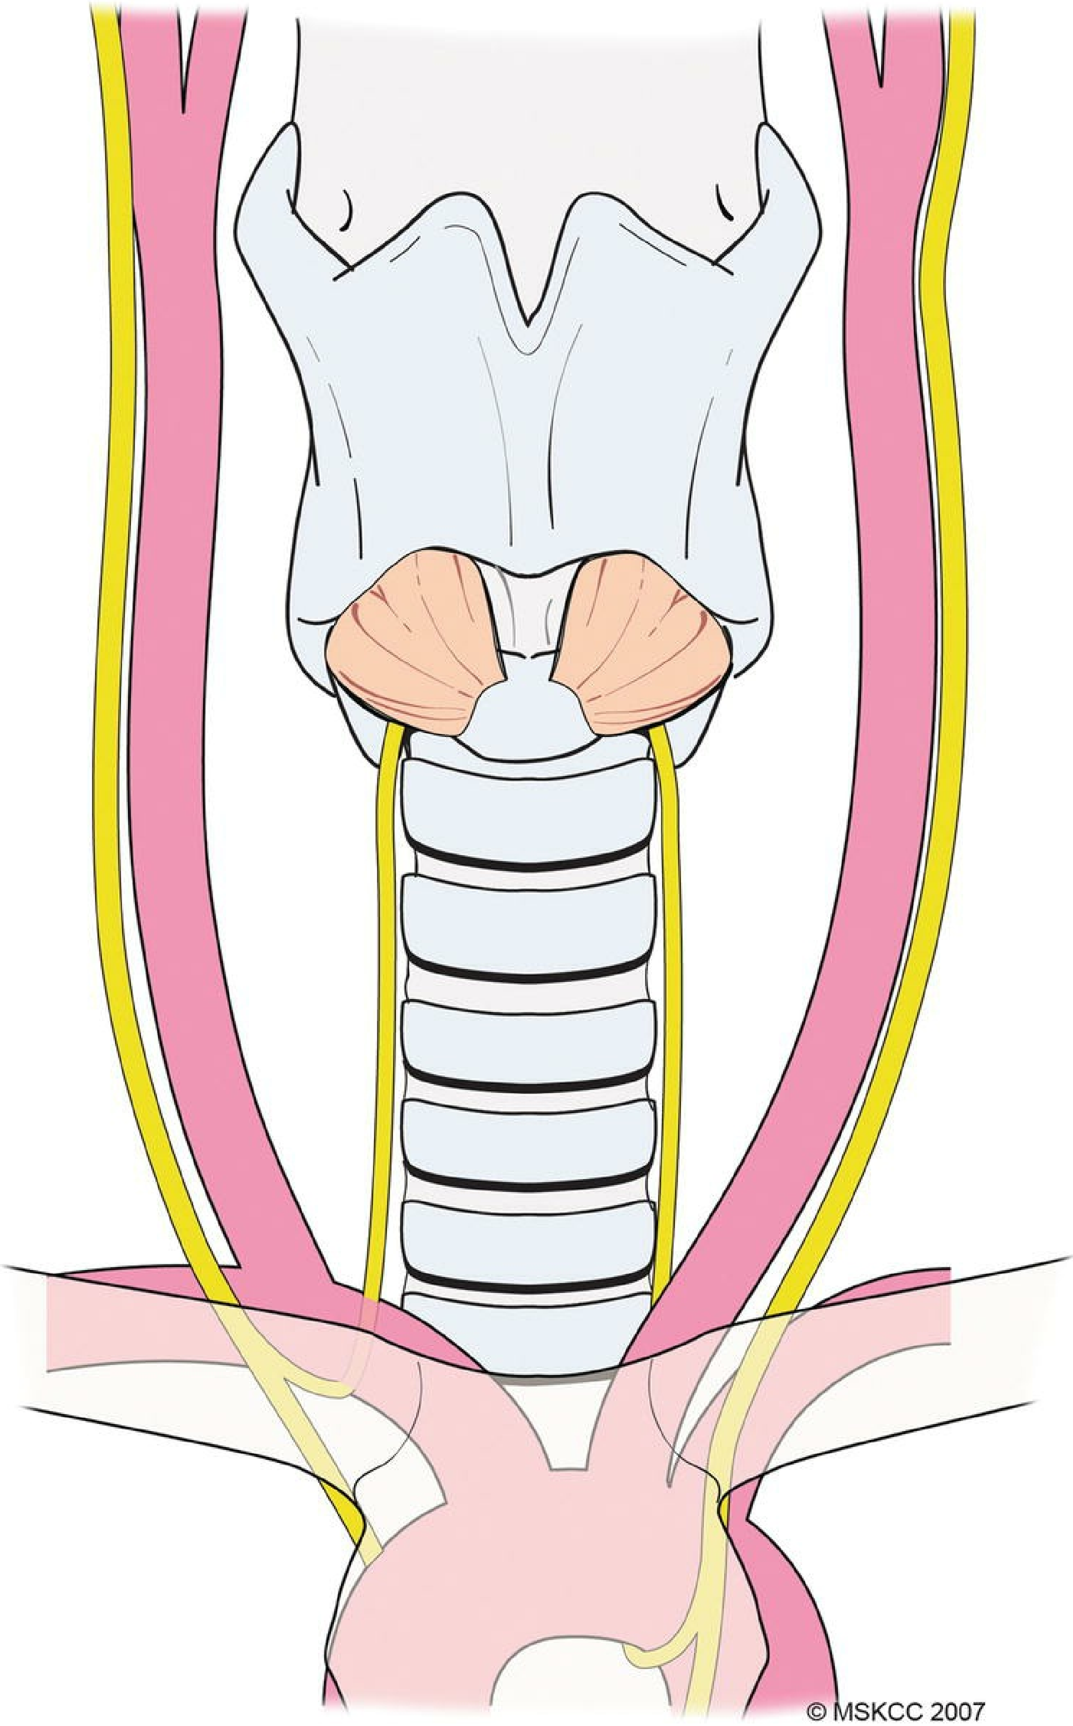

Figure 19.3. The left RLN branches from the vagus nerve and then descends into the chest passing inferior and posterior to the aortic arch. The right RLN leaves the vagus nerve at the base of the neck and loops around the subclavian artery. This results in the more lateral position of the right RLN.

Most of the time, nerve injury is related to thermal injury or traction injury rather than direct transection of the nerve. It is also important to recognize that the entry point of the RLN is a fixed point, and therefore, stretch injury when retracting the thyroid medially during surgery can also occur. The anatomical identification of the tuberculum Zuckerkandl can aid in the identification of the RLN. This anatomic structure is present in majority of the patients with thyroid pathology. It is a small outpouching of the thyroid tissue, which forms a tiny tubercle near the ligament of Berry. Often, the nerve is posterior and slightly medial to the tuberculum Zuckerkandl and is a good landmark for identification of the RLN (Fig. 19.4A and B). Occasionally, the tuberculum of Zuckerkandl may displace the RLN laterally around it, placing the nerve at risk for injury if this variation is not recognized (Fig. 19.4C). The nerve may be intimately adherent to this region, which could also predispose it to injury.

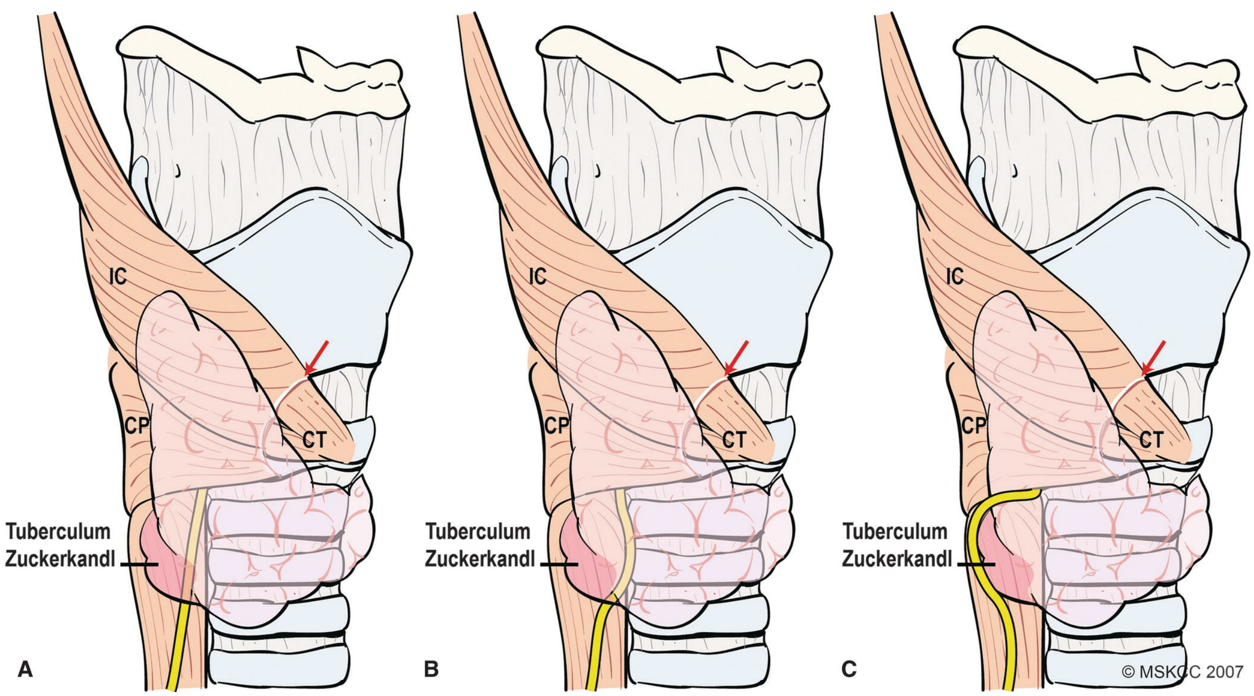

Figure 19.3. A and B: The RLN lies posterior and slightly medial to the tuberculum Zuckerkandl and is a good landmark for identification of the

RLN. **C:** Occasionally, the tuberculum of Zuckerkandl may displace the RLN laterally around it, placing the nerve at risk for injury.

There are three areas where the RLN can be injured. The first is in the tracheoesophageal groove, which is often encountered during the dissection of the lymph nodes in the tracheoesophageal groove. This is the same area where the nerve may be traumatized due to adherence of the lymph nodes or more importantly while dissecting the nerve off the lymph nodes. The nerve may also be injured at the crossing of the inferior thyroid artery. In the majority of the time, the nerve crosses behind the inferior thyroid artery; however, in ~25% of patents, the nerve may be superficial to the inferior thyroid artery where the identification of the nerve may be difficult and inadvertently traumatized. The most common injury to the RLN occurs near the ligament of Berry. The most common reason for injury to the RLN in this region is that small blood vessels travel through the ligament of Berry causing excessive bleeding during surgery, and the nerve injury may occur in an effort to control the bleeding in this region especially when electrocautery is used. Occasionally, the laryngeal nerve may be nonrecurrent, and identification of the nonrecurrent nerve is critical in order to avoid unanticipated injury. As this anatomic variant is associated with an aberrant innominate artery or retroesophageal subclavian artery, a preoperative CT scan revealing these vascular anomalies can raise the surgeon’s vigilance for identification of a nonrecurrent nerve. Generally, the presence of a retroesophageal innominate artery (arteria lusoria) leads to the innominate abnormality of being a nonrecurrent RLN. In such patients, extreme care must be undertaken to evaluate the area between the carotid artery and ligament of Berry to avoid injury to the nonrecurrent nerve. The use of a nerve monitor may be extremely helpful in such patients. Generally, the nonrecurrent nerve is identified either at the ligament of Berry or in the region lateral to the superior pole of the thyroid. Occasionally, the vagus nerve may be medial to the carotid artery, which is also an indication of patient having nonrecurrent RLN.

Another important nerve to identify during thyroid surgery is the external branch of superior laryngeal nerve (EBSLN), which has also been called the “Amelita Galli-Curci,” nerve after the famous Italian opera singer whose career declined after she underwent a thyroidectomy. Although less discussed, injury to the (EBSLN) has been estimated to occur in 0% to 53%

of thyroidectomies.[5,6] The superior laryngeal nerve originates from the vagus nerve just below the jugular foramen. It then divides into an internal and external branch. The EBSLN descends inferiorly to innervate the cricothyroid muscle. Cernea anatomically classified variants of the EBSLN.[7] Type 1 nerves cross >1 cm above the upper border of the thyroid gland. Type 2a nerves cross within 1 cm of the upper border of the thyroid. Type 2b nerves cross below the upper border of the gland. The external branch of the superior laryngeal nerve is at risk for injury during ligation of the superior thyroid vascular pedicle most often in patients with the type 2b variant. Patients with injury to the EBSLN during thyroidectomy will complain of inability to yell or "hit a high note."

The superior parathyroid glands ("deep" parathyroids) are derived from the fourth branchial pouch.

Anatomically, these glands exist "deep" to the RLN anatomically. This relationship can change when retracting the thyroid medially during surgery. Classically, the superior parathyroid glands are described as located 1 cm above the intersection of the RLN and inferior thyroid artery. Inferior parathyroid glands ("superficial" parathyroids) are derived from the third branchial pouch. These glands exist superficial to the RLN and are more variable in location. The thymus is also derived from the third branchial pouch, which is why inferior parathyroids are sometimes located in the anterior mediastinum within the thymus.

EVALUATION OF THE THYROID NODULE

Thyroid nodularity is quite common and has been reported to be detected as a palpable nodule in 4% to 7% of the adult population. When imaging is used to evaluate the thyroid, the incidence of nodules identified increases to >50%.[8] Most clinically detected nodules are benign, and the incidence of occult cancer within the thyroid gland ranges from 4% to 35% in adults in autopsy studies. Strikingly, this number approaches 100% in elderly patients.

Generally, nodules >1 cm should be further evaluated for the presence of cancer. However, there are nodules that do not meet this size criterion that should also be evaluated based on suspicious features. Table 19.3 highlights

these features including suspicious ultrasound (US) findings, associated lymphadenopathy, a history of head and neck irradiation, or a history of thyroid cancer in one or more first-degree relatives. Additionally, nodules found incidentally on PET scan have a risk of malignancy of about 33% and may be more aggressive and therefore should be evaluated even if <1 cm.[9] Importantly, the new version of the ATA guidelines recommend not biopsying lesions under 1 cm given the increased interest in observation as a treatment option for subcentimeter PTCs.

Table 19.3 Indications for FNA of Thyroid Nodules <1 cm
Suspicious US findings
Associated lymphadenopathy
History of head and neck irradiation
History of thyroid cancer in first-degree relatives
18FDG-positive nodules

Adapted from ATA Guidelines 2009 version.

Evaluation of a thyroid nodule should include a full history and physical examination. Risk factors, summarized in Table 19.4, include radiation to the head and neck during childhood for cancer or dermatologic pathology such as acne or dermatitis, exposure to radiation secondary to fallout from nuclear accidents such as occurred in Chernobyl, a family history of thyroid carcinoma, or thyroid cancer syndromes such as Cowden, familial polyposis, or type 2 multiple endocrine neoplasia (MEN 2). A history of rapid growth or hoarseness should raise suspicion for malignancy. Physical examination should include the thyroid gland, lateral cervical lymph nodes, and laryngeal examination.

Table 19.4 Clinical Features of a Malignant Thyroid Nodule

Age—Very Young or Very Old
Sex—Male
History of thyroid cancer syndromes
Hoarseness-vocal cord paralysis
Hard, Fixed Nodule
Rapid Growth
New onset of rapid growth in a longstanding stable nodule
Cervical Metastases
Pulmonary Metastases

In the clinically apparent or incidentally found thyroid nodule, a TSH level should be ordered to differentiate functioning from nonfunctioning nodules. If the TSH is low, then a hyperfunctioning nodule should be considered and a radionuclide thyroid scan can be obtained. Hyperfunctioning nodules rarely harbor malignancy, if one is found that corresponds to the nodule in question, no cytologic evaluation is necessary. In contrast, if the TSH is normal or low, further cytologic evaluation is indicated. Interestingly, high TSH has been associated with a higher risk of malignancy.[10] With biochemical evaluation, radiographic assessment is essential in the evaluation of thyroid nodules. Ultrasound of the thyroid gland and lateral neck provides valuable information. First, is there a nodule that correlates to a palpable or radiographic abnormality? If so, how big is it, where is it located with regard to the strap muscles, RLN, or airway? Is it cystic or solid? Completely cystic nodules have a low likelihood of malignancy.[11] Are there other nodules within the gland? Does the nodule have any suspicious findings? Ultrasound characteristics associated with a higher rate of malignancy include hypoechogenicity, increased intranodular vascularity, irregular infiltrative margins, microcalcifications, an absent halo, and taller than the wider diameter. Findings of isoechogenicity and spongiform appearance are more common in benign nodules.[12] Table 19.5 summarizes ultrasound findings, which are useful in distinguishing benign from malignant lesions. Is there concerning lymphadenopathy? Ultrasound

can also help guide fine-needle aspiration (FNA) in nodules that are nonpalpable, partially cystic, or posteriorly located. FNA is the workhorse for cytologic and molecular assessment of thyroid nodules. Cytologic evaluation is classified by the Bethesda System for Reporting Thyroid Cytopathology[13] (Table 19.6).

Table 19.5 Ultrasound Finding in Thyroid Nodules

Benign Features	Malignant Features
Pure cystic nodule Spongiform appearance Benign nodules	Micro- or Macrocalcifications Marked hypoechogenicity Taller-than-wide shape Spiculated margin

Table 19.6 Bethesda Criteria

Bethesda Criteria	FNA Result	Chance of Malignancy
I	Nondiagnostic or Unsatisfactory	1%–4%
II	Benign	0%–3%
III	Atypia of Undetermined Significance Follicular Lesion of Undetermined Significance	5%–15%
IV	Follicular Neoplasm or Suspicious for a Follicular Neoplasm	15%–30%
V	Suspicious for Malignancy	60%–75%
VI	Malignant	97%–99%

From Cibas ES, Ali SZ. The Bethesda system for reporting thyroid cytopathology. *Am J*

Clin Pathol. 2009;132(5):658–665.

Molecular testing may provide further information on thyroid nodules including risk of malignancy and prognosis. Afirma is a molecular test used in indeterminate nodules by FNA (Bethesda III and IV) as a “rule out test.” This test takes into account mRNA expression levels in a 164-gene panel. This Gene Expression Classifier (GEC) provides results that are either benign (<6%) or suspicious (40% chance of malignancy) with a negative predictive value of 94%.[14] The majority of the clinicians will use this information to consider surgery especially if the Afirma is reported to be suspicious.

However, it is important to appreciate the risk of malignancy is still ~40% and not 100%. Afirma is also more likely to be positive in patients presenting with Hashimoto thyroiditis, and it is always confusing in Hurthle cell lesions as it invariably turns out to be suspicious. Obviously, some of these decisions are best made by the clinician based on other clinical and radiologic features and parameters. ThyroSeq Thyroid Cancer Next-Generation Sequencing Panel is also used in indeterminate nodules by FNA (Bethesda categories III, IV, V) and malignant nodules when molecular testing is expected to affect the decision to perform surgery or extent of surgery. Mutations in thyroid cancer–related genes and gene fusions are detected by next-generation sequencing. This may also be useful in clinical decision making with regard to administration of radioactive iodine, intensity of follow-up, and targeted therapies.[15] An algorithm for the evaluation of the thyroid nodule is provided in Figure 19.5.

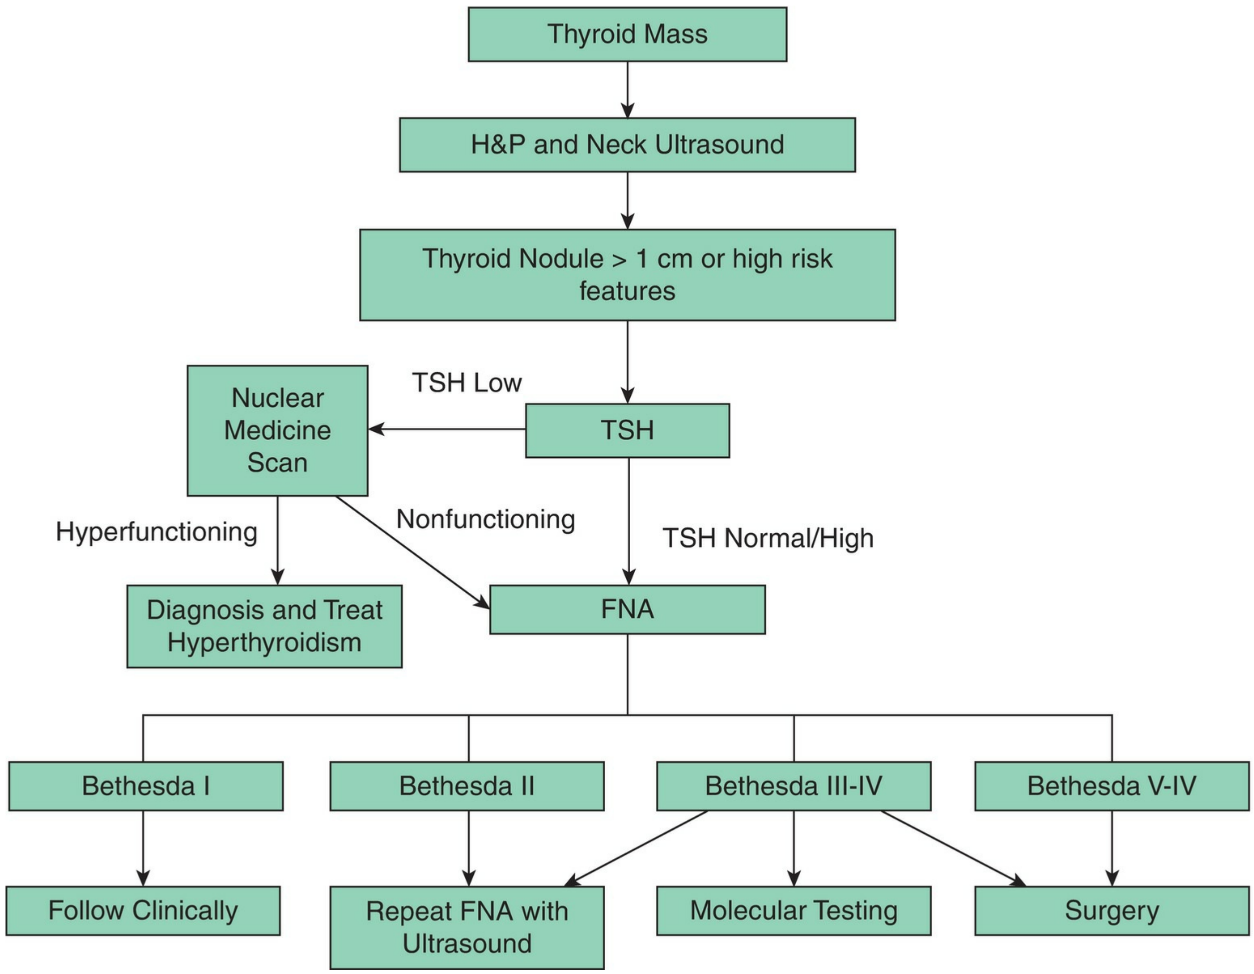

Figure 19.5. Evaluation of thyroid nodule.

MOLECULAR BIOLOGY OF WELL-DIFFERENTIATED THYROID CANCER

Noteworthy advances in the understanding of the molecular biology of thyroid cancer are beginning to be incorporated into clinical practice. The Cancer Genome Atlas Research Network recently reported on genomic landscape of 496 papillary thyroid cancers (PTCs).[16] The genome of PTC is described as relatively "quiet," as compared to other cancers as defined as a low frequency of somatic alterations, and this may offer a biologic basis for the indolent clinical behavior of PTCs. Common known drivers will be discussed in greater detail.

Proto-oncogenes Associated with Thyroid Cancer

Chromosomal Rearrangements (RET/PTC)

Rearrangement of the RET proto-oncogene *RET* results in the aberrant production of chimeric forms of the receptor (RET/PTC) in thyroid cells, which leads to constitutive activation of several downstream pathways, including mitogen-activated protein kinase (MAPK), extracellular signal-related kinase (ERK), and phosphatidylinositol 3-kinase (PI3K). This rearrangement has been observed in post-Chernobyl pediatric thyroid cancers (RET/PTC1) and has been associated with classical PTC, as well as solid variant PTCs (RET/PTC3).[17]

Ras Oncogenes

The 3 classical Ras proto-oncogenes encoding Hras, Kras, and Nras belong to an extended family of small G proteins. *Ras* mutations are found in follicular adenomas and carcinomas[18] and are also observed in 13% of PTCs.[16,19] Ras mutations are thought to be an early event in thyroid cancer genesis and some have shown they follow a more aggressive clinical course.[20]

BRAF and MAP Kinase Signaling Pathway

The BRAF missense mutation in exon 15, which leads to the substitution of the amino acid valine for glutamic acid at residue position 600, is the most frequent genetic change in PTC and has been observed in 60% of tumors.[16] Mutant BRAF is a potent activator of the downstream effectors, the MAP kinases in the Raf–MEK–ERK pathway, which mediate cellular responses to growth signals. Clinically, PTCs with BRAF mutations are more common and are associated with an aggressive clinical course including extrathyroidal invasion, greater rates of recurrence, and treatment failure,[21] which translates into worse clinical outcomes.[22]

BRAF mutation has also been shown to be responsible for the suppression of expression of the sodium/iodide symporter (NIS) leading to RAI resistance.[23] Inhibitors of the BRAF kinase have been developed and show promise in treating several cancer types. However, development of resistance to BRAF kinase inhibitors is common. In addition, inhibitors of the MAP kinase pathway have been developed and are beginning to be used clinically.

Well-Differentiated Thyroid Cancers

Papillary and follicular carcinomas collectively grouped as differentiated thyroid cancer constitute more than 90% of all malignant neoplasms of the thyroid gland. These two entities share similar diagnostic and treatment algorithms and have an overall excellent prognosis of 97.8% at 5 years when diagnosed and treated appropriately.

Staging and Prognostic Schemas

Cancer staging is an essential prognostic tool that is integral part of cancer management. The familiar tumor–nodal–metastasis (TNM) staging system is the most widely applied staging system in thyroid cancer. Unique to thyroid cancer, age at diagnosis is incorporated in the staging system reflecting its marked influence on outcome. The American Joint Committee on Cancer (AJCC) 7th edition (Tables 19.1 and 19.2) has been shown to predict differentiated thyroid cancer–related death.[24] The prognostic factors in thyroid cancer are well defined and reported from several independent datasets, starting from the EORTC study published in 1979.[25] In the United States, Cady of the Lahey Clinic and Hay et al. of the Mayo Clinic reported similar prognostic factors in the 1980s.[26,27] The Mayo Clinic revisited their data and included completeness of resection as an important prognostic factor leading to their acronym of MACIS.[28] Memorial Sloan Kettering Cancer Center subsequently also suggested similar prognostic factors with the acronym GAMES (grade of the tumor, age, distant metastasis, extrathyroid extension, and size of the tumor).[29] These schemas are summarized in Table 19.7. A risk-stratified approach has also been adopted in the ATA guidelines and is summarized in Table 19.8.

Table 19.7 Prognosis Schemas of Well-Differentiated Thyroid Cancer

Lahey Clinic[17]	Mayo Clinic[19]	MSKCC[30]
A—Age M—Metastasis E—Extent S—Size	M—Metastasis A—Age C—Completeness of surgical resection I—Invasion S—Size	G—Grade of the Tumor A—Age M—Metastasis E—Extrathyroidal extension S—Size

Table 19.8 Three Level Risk Stratification of Recurrence

Low Risk	Intermediate Risk	High Risk
No local or distant metastases complete resection, no gross disease No locoregional invasion tumor does not have aggressive histology No vascular invasion no 131I uptake outside the thyroid bed on the first posttreatment whole-body RAI scan	Microscopic invasion into the perithyroidal soft tissues Cervical lymph node metastases 131I uptake outside the thyroid bed Aggressive histology or vascular invasion	Gross tumor invasion, incomplete tumor resection Distant metastases Thyroglobulinemia out of proportion to posttreatment scan

Adapted from ATA Guidelines 2009 version.

Histologic Classification of Thyroid Cancers Arising from Follicular Cells

Thyroid cancer represents a spectrum of tumors with different biologic behavior. At one end of the scale, there are the differentiated carcinomas with excellent prognoses, whereas, at the other end of the spectrum, there is anaplastic thyroid cancer (ATC), which has an almost universally fatal outcome. As tumor histology becomes less differentiated, radioactive iodine avidity decreases whereas FDG PET uptake increases. This is also associated with a worse prognosis.[31] We will discuss the tumors on this spectrum from PTC and their multiple clinically relevant variants to follicular thyroid carcinoma (FTC) followed by poorly differentiated thyroid cancer (PDTC) and finally ATC.

Papillary Carcinoma and Variants

PTC is a primary thyroid cancer of follicular epithelial cell origin defined by distinctive nuclear features. Classic nuclear features that define PTC include nuclear crowding with overlap, nuclear enlargement, chromatin clearing or

ground-glass appearance (“Orphan Annie nuclei”), nuclear elongation, nuclear grooves, irregular nuclear membranes, intranuclear cytoplasmic inclusions, and eccentric inconspicuous nucleoli.[32]

Variants of PTC based on histologic feature are reported and are of clinical and prognostic relevance.

Tall Cell Variant

Tall cell variant is rare but associated with an aggressive clinical course. It is histologically defined as cells having a height that is at least twice the width of the cell, eosinophilic cytoplasm, along with characteristic nuclear features of papillary carcinoma (Fig. 19.6). There is a high prevalence of the BRAF mutations observed as high as 80% to 100% in tall cell variant of PTC.[33] Clinically, there is a higher frequency of extrathyroidal extension, higher stage, larger size, and older age (mean 57 years) at presentation. These tumors are commonly PET avid and often do not concentrate RAI.[34]

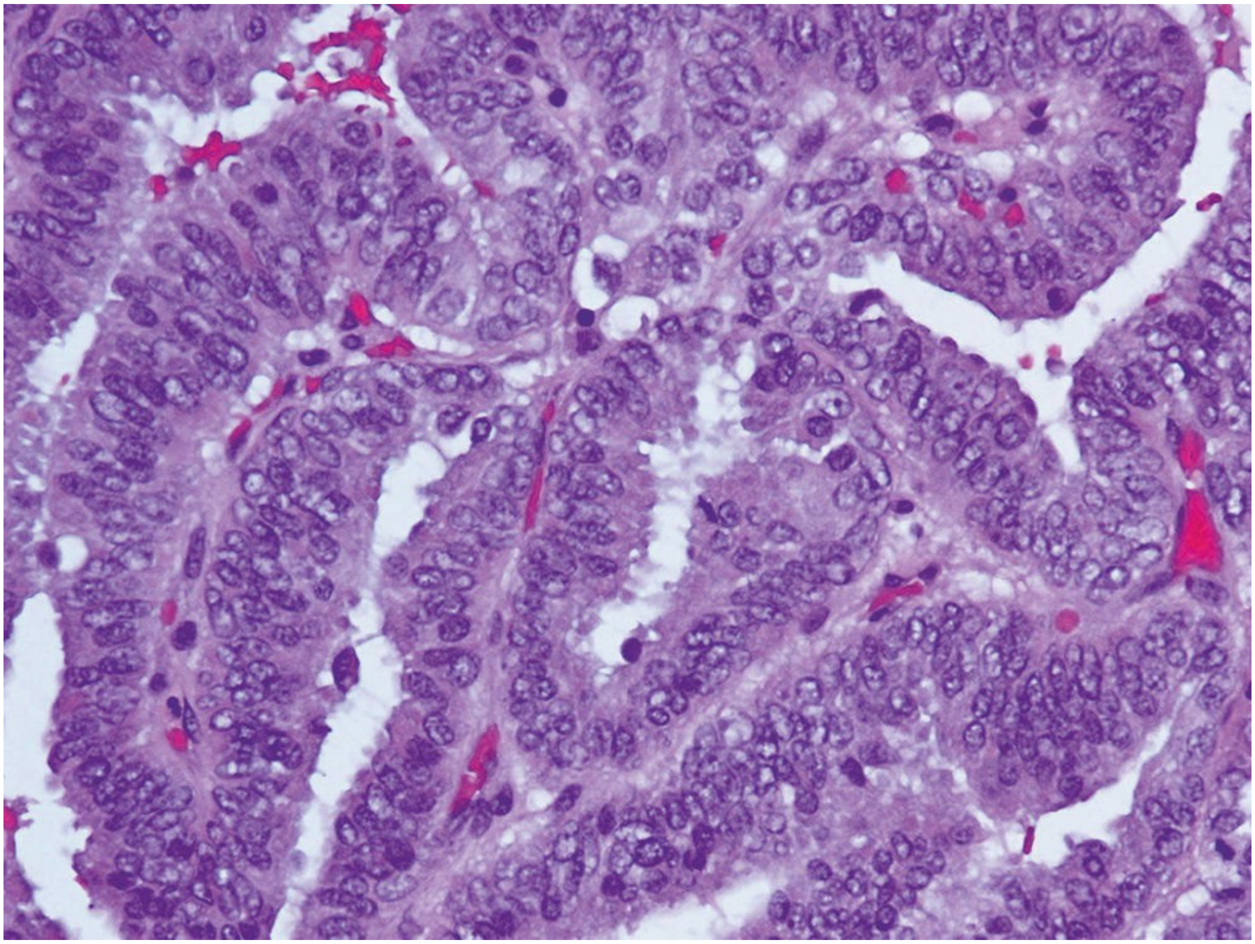

Figure 19.6. Tall cell variant of papillary thyroid cancer. Histologically defined as cells with a height that is at least twice the width with characteristic nuclear features of papillary carcinoma.

Columnar Cell Variant

The columnar variant of PTC has an aggressive clinical course, histologically associated with elongated columnar cells, with prominent nuclear stratification and elongated nuclei. In contrast to classic PTC, intranuclear cytoplasmic inclusions may not be found and nuclear grooves may be rare. These tumors are more often associated with extrathyroidal extension, recurrence, and aggressive local growth when the tumor is well encapsulated and metastases are rare.[35]

Diffuse Sclerosing Variant

Diffuse sclerosing variant is another biologically aggressive histology of

PTC, which is known to present at a younger age (mean age 18 years; range 6 to 49 years) in the setting of thyroiditis. These tumors are more often bilateral and show increased stromal fibrosis and sclerosis, squamous metaplasia, lymphocytic infiltrate, and psammoma bodies.[36]

Cribriform–Morular Variant

Clinically, this lesion is important for its association with the familial adenomatous polyposis (AFP) syndrome. When associated with AFP, tumors of this subtype are more commonly found to be multifocal and bilateral; therefore, total thyroidectomy is recommended. These tumors tend to follow an indolent course.[37]

Solid Variant

If >50% of the tumor shows a focal solid growth pattern, the solid variant of PTC is diagnosed. Clinically, these tumors are associated with prior exposure to radiation and are seen in children. Thirty percent of cases that have been reported are associated with the Chernobyl nuclear accident.[38] Nikiforov et al.[39] showed that cases of solid variant PTC are associated with a slightly higher frequency of distant metastases and less favorable prognosis than classical PTC.

Follicular Variant of Papillary Thyroid Carcinoma

The follicular variant of papillary thyroid carcinoma (FVPTC) is a common subset of (PTC) and is found in up to 24% of patients with PTC.[40] This variant is composed entirely or almost completely of follicles, which are lined by cells that have the nuclear features of papillary carcinoma. FVPTC appears to be a heterogeneous disease composed of 2 distinct groups: an infiltrative/diffuse (nonencapsulated) subvariant, which resembles classic PTC in its metastatic lymph node pattern and invasive growth, and an encapsulated form, which behaves more like follicular adenoma/follicular carcinoma.[41] Consistent with this statement, Baloch et al.[42] showed that encapsulated FVPTCs can metastasize to distant sites in the absence of cervical lymph node metastases, mimicking the behavior of FTC. Nonencapsulated FVPTCs that are invasive are easily diagnosed as cancer.

However, the encapsulated form diagnosed solely on nuclear features

consistent with PTC can be more difficult. In a retrospective analysis of the MSKCC thyroid database, Liu et al. reported that the rate of lymph node metastasis was significantly higher in patients who had nonencapsulated tumors. In addition, patients with encapsulated tumors had no recurrences; the authors concluded that encapsulated FVPTCs could be treated by lobectomy alone.

Follicular Carcinoma

Follicular carcinoma of the thyroid gland accounts for between 4% and 39% of all malignant thyroid tumors and lacks the nuclear features associated with PTC.[43] FTC is differentiated from follicular adenoma by the presence of capsular invasion and vascular invasion. In contrast to PTC, which has a propensity to metastases via lymphatics, FTC more commonly disseminates systemically in the form of distant metastasis. These characteristics should be taken into consideration when planning primary management and surveillance. A large number of previously reported follicular carcinomas were probably FVPTC.

Hurthle Cell Carcinoma (HCC)

Although once thought to be an oncocytic variant of follicular carcinoma, genetic profiling has provided evidence that this entity may be a unique thyroid cancer distinct from papillary and follicular thyroid cancer.[44] HCC accounts for 3% to 4% of all thyroid cancers[45] and is characterized by large cells with hyperchromatic nuclei and an abundant granular cytoplasm containing large numbers of mitochondria.[46] Like FTC, malignancy cannot be diagnosed without the identification of capsular or vascular invasion. Patients with the widely invasive form of HCC have a poor prognosis compared to those with PTC and FTC with a recurrence rate of 31% and disease-specific mortality of 25% and a high incidence of metastasis.[47,48]

POORLY DIFFERENTIATED THYROID CANCER

PDTC represents a middle ground between well-differentiated, papillary carcinomas and the usually lethal, anaplastic carcinomas. These tumors

occupy an intermediate position both clinically and histologically. There has been some debate regarding the histologic definition. The Turin proposal of PDTC included (1) presence of a solid/trabecular/insular pattern of growth, (2) absence of the conventional nuclear features of papillary carcinoma, and (3) presence of at least one of the following features: convoluted nuclei, mitotic activity ≥3 × 10 HPF, and tumor necrosis.[49] At Memorial Sloan Kettering Cancer Center, PDTC is defined by the presence of necrosis and/or a high mitotic rate, irrespective of growth pattern and cell type.[50] These features were shown to define clinical behavior independently of architectural grade, and PDTC defined on the basis of mitoses and/or necrosis are associated with RAI refractoriness, uptake of fluorodeoxyglucose on positron emission tomography, and positive and high rates of recurrence. Additionally, using this definition, overall survival was found to be 60%, which is intermediate between differentiated and AT cancer.

MANAGEMENT OF THYROID CANCER

Management of thyroid cancer requires a multidisciplinary approach involving a surgeon, endocrinologist, pathologist, nuclear medicine physician, and, sometimes, a medical oncologist. Evaluation first starts with a through history and physical examination. Symptoms indicative of vocal cord paralysis such as hoarseness, dysphagia, odynophagia, and aspiration should raise concern for aggressive tumors invading the RLN. A full examination of the head and neck should be performed. Emphasis should be placed on evaluation of the thyroid gland, lateral neck, and larynx. It is important to recognize that vocal fold impairment can be present independent of voice changes.

Ultrasound (US) is often the first modality utilized to evaluate a thyroid cancer because it is readily accessible, inexpensive, and noninvasive and it requires no radiation exposure. US is effective at delineating intrathyroidal architecture as well as in the evaluation for lymph node metastasis.

Physical examination sometimes points to involvement of surrounding structures in invasive thyroid carcinoma. Occasionally, to optimally evaluate the locoregional extent of the disease, cross-sectional imaging with a CT scan is indicated. CT scanning is best performed with contrast even though there is a general concern about use of contrast and iodinated dye, which may inhibit

the early use of radioactive iodine ablation. A CT with contrast is quite helpful to the operating surgeon for surgical planning, especially in patients initially presenting with locally advanced disease, such as those with fixed disease in the central compartment adherent to the trachea and esophagus or a paralyzed vocal cord. A CT scan with contrast is also important to evaluate the extent of the lymph nodal metastasis, extent of the paratracheal disease, and extension to the superior mediastinum. It is also helpful to evaluate if there is any presence of retropharyngeal or parapharyngeal disease, which is important to appreciate prior to surgery as this disease is generally not well imaged on a routine ultrasound.

THYROIDECTOMY

The surgery begins with patient positioning and planning of the incision. An incision is first marked and concealed in a natural skin crease. This is done in the preoperative holding area with the patient seated. In young women, a more cranial incision is preferred. In general, the incision should be made just inferior to the cricoid cartilage. Alternatively, a higher skin crease can be selected (Fig. 19.7). Incision length should be based on the extent of the surgery planed, size of the patient, neck configuration, and extent of disease. For example, if a neck dissection will be required as part of the first procedure or likely in future procedures, the incision should be placed adjacent to the cricoid cartilage as this position gives exposure to the entire neck and the J-shaped or apron incision can be avoided. Although cosmetic concerns should be considered, the operating surgeon needs to plan an incision that will allow for the exposure needed for complete resection of the thyroid cancer as this represents the major factor for best control of disease. The planned incision site is infiltrated with lidocaine and epinephrine to avoid excessive bleeding from the skin and subcutaneous tissues.

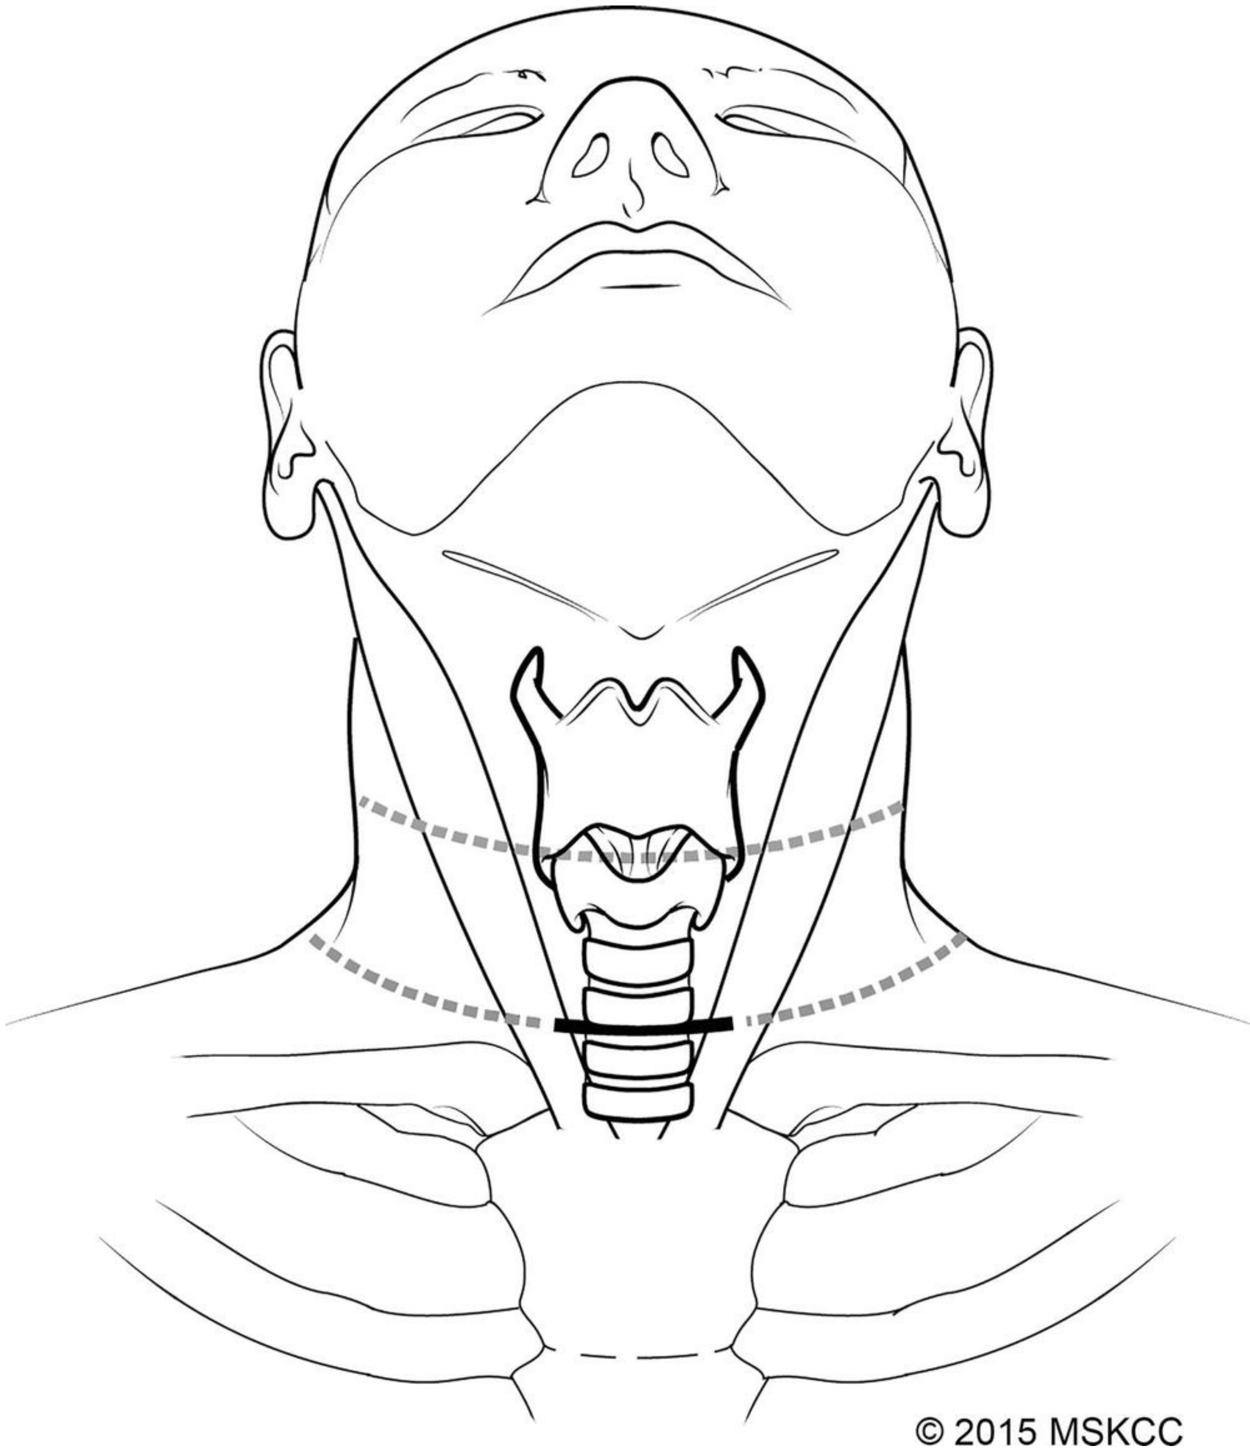

Figure 19.7. The incision should be made just inferior to the cricoid cartilage. Alternatively, a higher skin crease can be selected, which gives better access to the superior pole vessels.

The optimal positioning is with a standard supine position with arms padded and tucked. The head is extended and the operating table is

maintained in a reverse Trendelenburg position. A transparent plastic drape allows continuous monitoring of the endotracheal tube and anesthesia circuit (Fig. 19.8). The skin is incised with a knife and then most of the remaining dissection is undertaken with unipolar or bipolar electrocautery. For the subcutaneous tissue, pointed electrocautery is used and subsequently a flat electrocautery is used. Once the incision is deepened through the subcutaneous tissue, the platysma muscle is incised. The platysma is sparse in the midline and therefore is better identified laterally. A subplatysmal flap is then raised. The superior flap is elevated under traction with the use of skin hooks where the plane is avascular to the thyroid notch. An inferior flap is then undermined as far as the sternal notch (Fig. 19.9). The midline fascia is then exposed and should be incised running parallel to the muscle. Often, there is a bridging vein communicating between the two anterior jugular veins, which should be dissected and ligated. The strap muscles are then separated in the midline. Opening this area is much like opening a “gift” box,[51] with the thyroid contained inside of the strap muscles and investing fascia. The anterior most strap muscle (sternohyoid) is then easily separated and retracted laterally. The sternothyroid is then exposed. There is debate about cutting the inner strap muscle. We generally prefer to cut the sternothyroid muscle superiorly and inferiorly from both an oncologic point and for better exposure of the superior thyroid pole. Attention is then turned from midline dissection to lateral dissection. The middle thyroid vein is identified, clamped, and ligated. Gentle dissection is performed inferiorly to expose the tracheoesophageal groove.

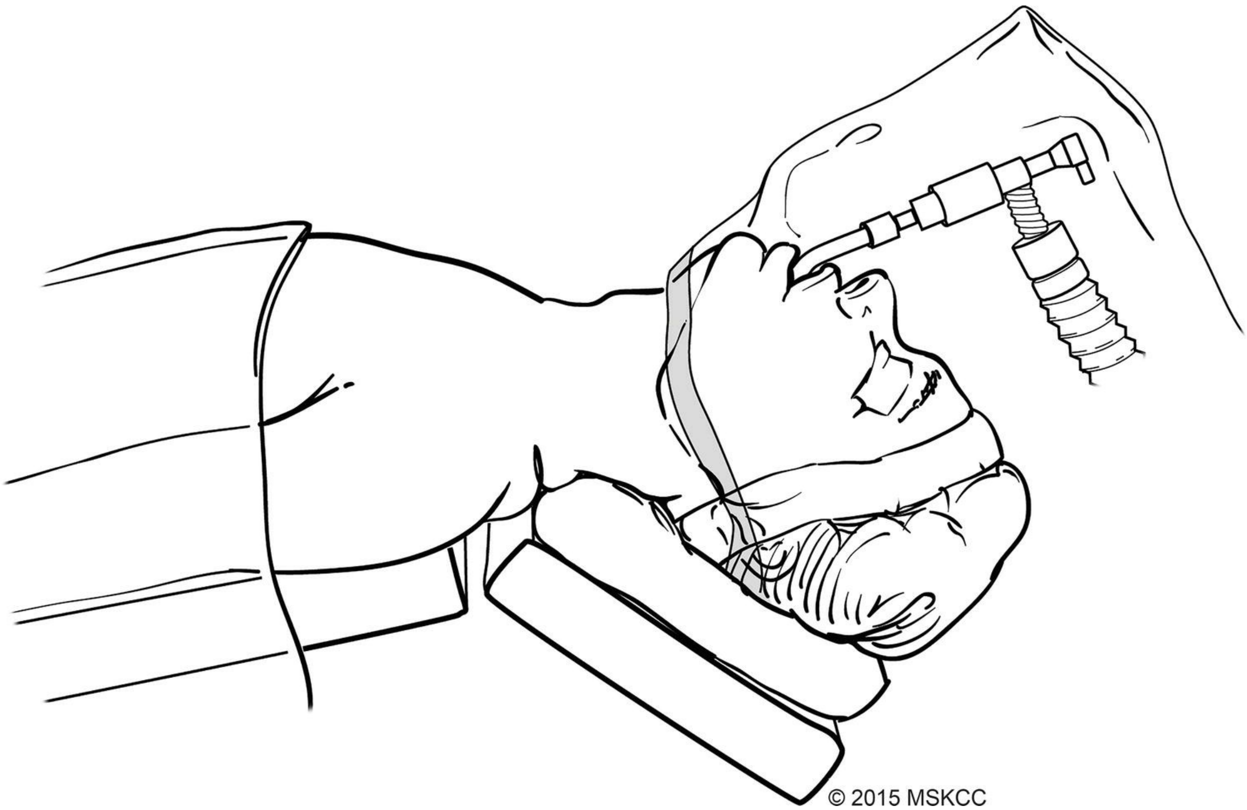

Figure 19.8. The patient is positioned supine on the operating table, which is maintained in a reverse Trendelenburg position with the neck extended.

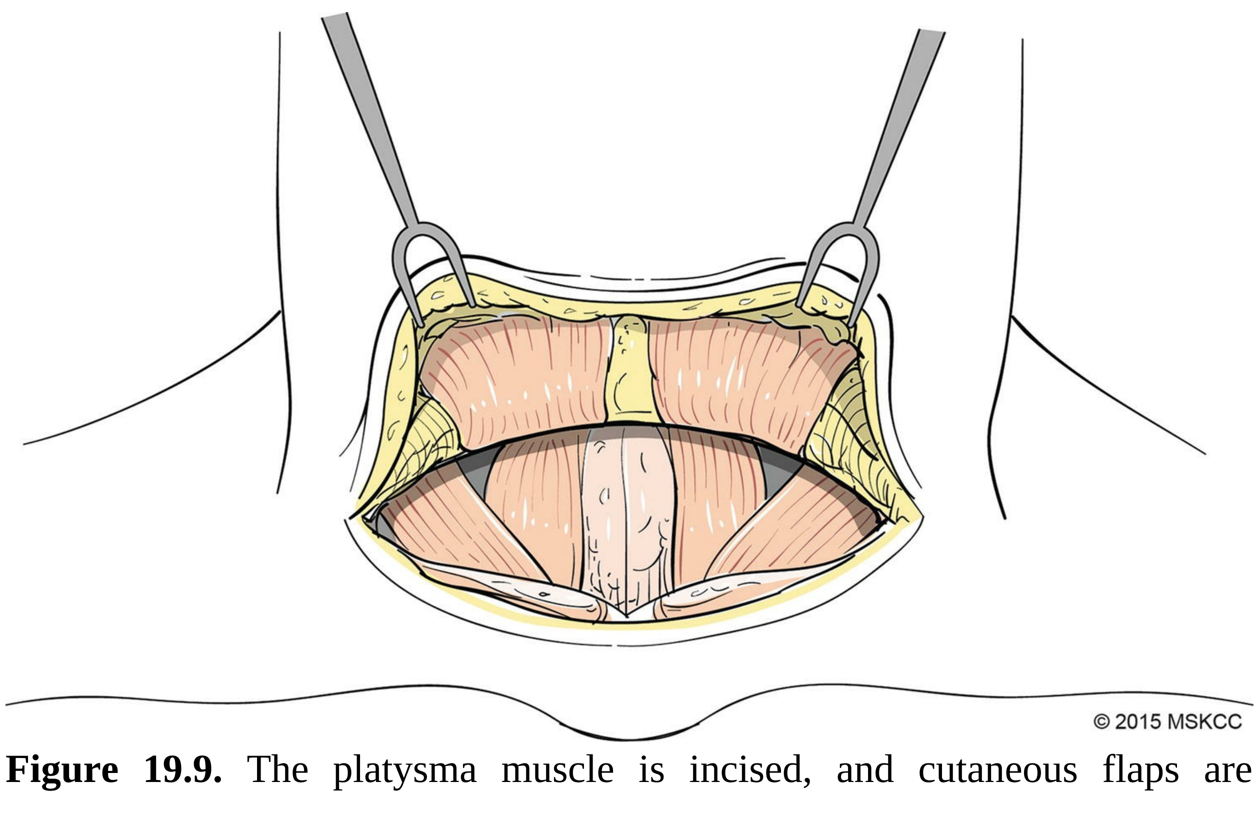

Figure 19.9. The platysma muscle is incised, and cutaneous flaps are

developed in the subplatysmal plane.

Attention is then turned to the superior pole. It is first exposed and a clamp is placed on the upper portion of the thyroid lobe. Retraction with the clamp helps to pull the thyroid in an inferior and lateral direction. This maneuver opens the medial aspect of the superior thyroid vessels known as Joll’s triangle. In this area, attention must be paid to the tiny veins arising from the superior thyroid vein. These should be cauterized. With gentle traction of the superior pole vessels in the inferolateral direction, the external branch of the superior laryngeal nerve should be identified. Approximately 40% to 50% of the time, the superior laryngeal nerve may be difficult to identify, and therefore, individually clamping and ligating the superior pole vessels close to the thyroid gland are important to avoid injury to the superior laryngeal nerve.

Vessels can be tied or controlled with harmonic scalpel or LigaSure. Dissection is then once again directed laterally. When dissecting on the right side, consideration should be given to evaluate if the patient has a nonrecurrent LN. The dissection continues on the lateral aspect of the thyroid gland while retracting the gland medially. Finger retraction of the thyroid lobe is used during dissection of the paratracheal area as use of Allis or Lahey clamp can result in capsular trauma and bleeding from the thyroid gland. As the superior pole and lateral thyroid gland is exposed, the tracheoesophageal groove area should also be exposed. There is always a tiny vein in front of the cricoid cartilage, which should be ligated as this may be a source of bleeding postoperatively.

Parathyroid glands can be identified in the superior and inferior portion of the thyroid gland in front of and behind the RLN. Occasionally, the parathyroid glands may be within the thyroid capsule. In these cases, careful dissection with separation of the thyroid from the parathyroid gland is required to avoid bleeding. Every effort should be taken to avoid disrupting the blood supply to the parathyroid glands. When the inferior thyroid artery is ligated, care should be taken that is close to the thyroid gland in order to preserve blood supply to the parathyroid gland (Fig. 19.10). If at the end of the operation the gland appears devascularized, it should be autotransplanted into the sternocleidomastoid muscle on the side contralateral from the tumor. Frozen section conformation of parathyroid tissue should be performed

before reimplantation, in order to avoid implantation of lymph nodes or metastatic carcinoma. The area of implantation is marked with a silk stitch for future reference.

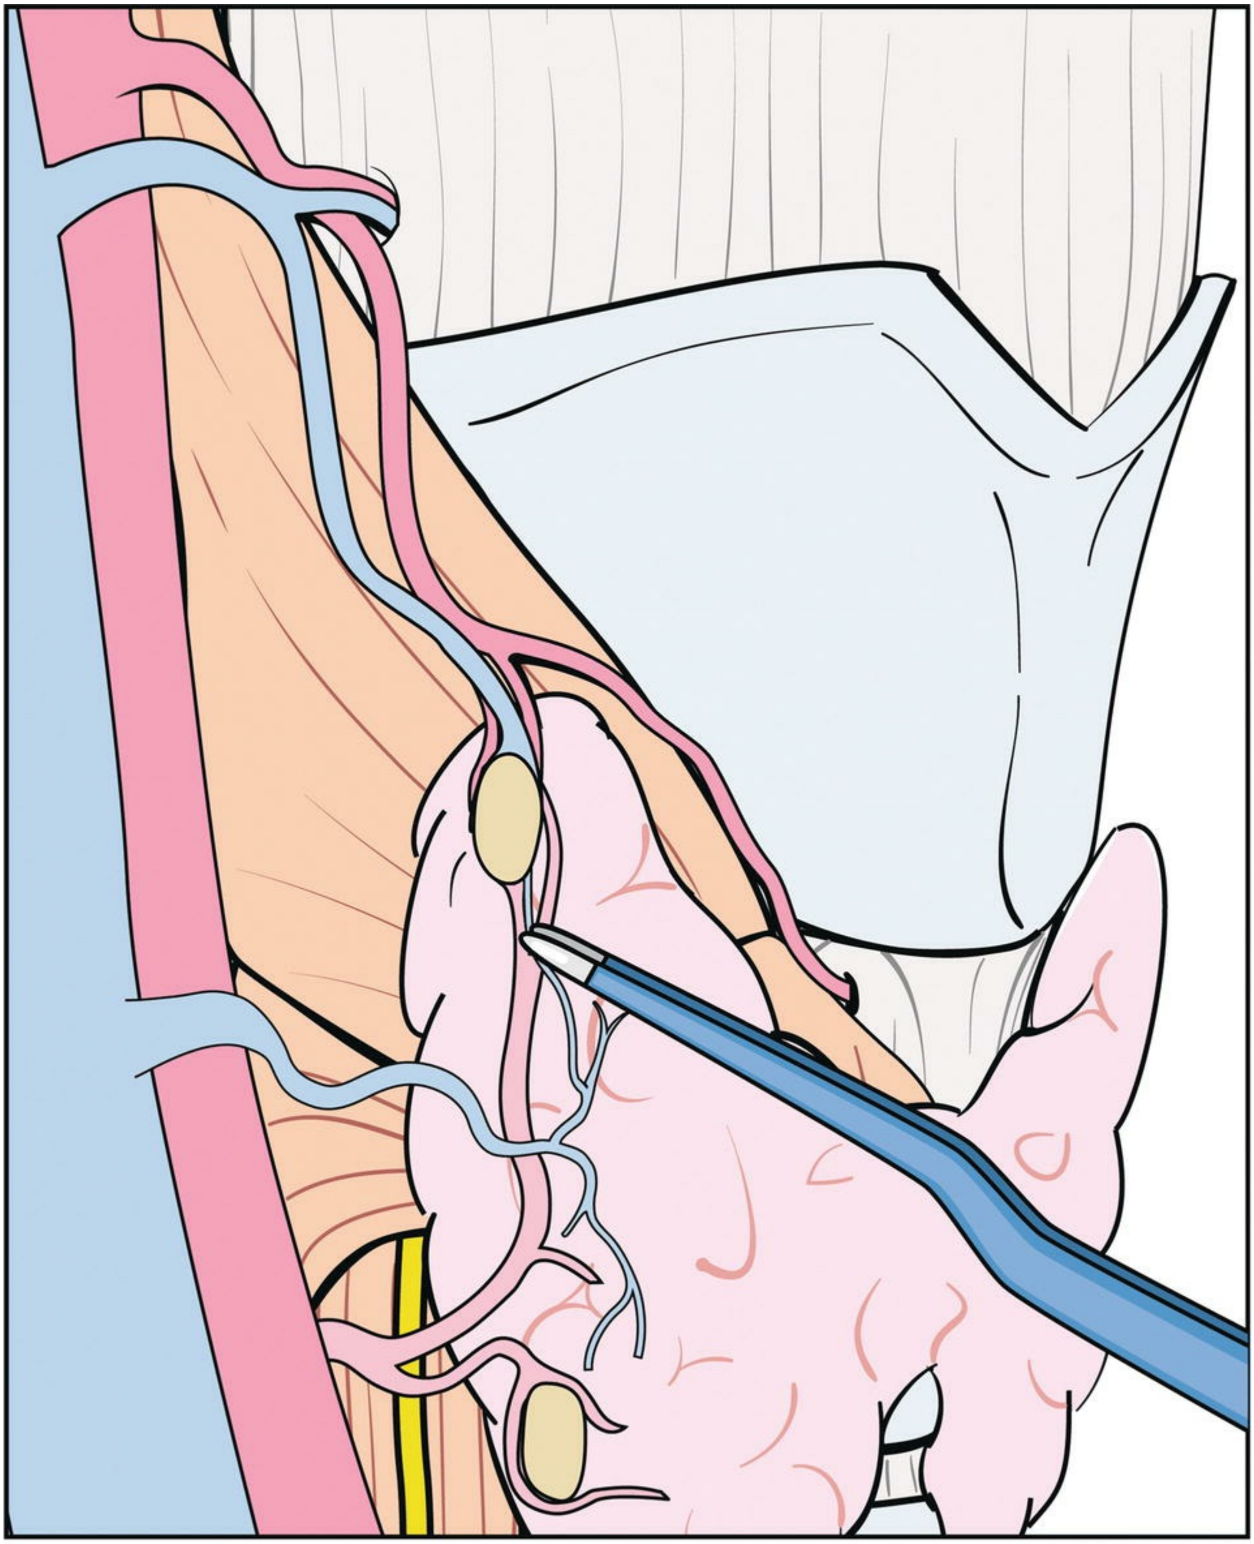

Figure 19.10. In order to preserve blood supply to the parathyroid gland, the inferior thyroid artery is ligated close to the thyroid gland.

Continuing laterally, the tuberculum Zuckerkandl is then identified. The RLN is generally located posterior to this structure. This can be identified by retraction of the tuberculum. Identification of the RLN is then carried out. It can be identified in three distinct areas. First, it can be identified in the tracheoesophageal groove and traced superior until the cricoid cartilage. This is a useful strategy in patients with suspicious lymph nodes. Second is at the intersection of the nerve and inferior thyroid artery. In most patients, the nerve courses under the inferior thyroid artery; however, in 25% of patients, it crosses over and this anatomic variability needs to be considered when using this technique (Fig. 19.11). Our practice is to identify a short segment near Berry's ligament behind tuberculum Zuckerkandl. The operation slows during dissection in the region of the ligament of Berry and the tuberculum Zuckerkandl as this is a critical portion of the operation and meticulous dissection is essential. During this portion of the operation, the thyroid gland is retracted medially; however, it must be realized that traction injury secondary to forceful retraction can result in nerve palsy. The tumor may involve the RLN. In these cases, if the nerve is functioning preoperatively, the tumor can usually be peeled off of the nerve. If instead the nerve is directly involved with tumor and there is a possibility of leaving gross tumor behind, resection of the ipsilateral nerve may be required. Prior to resection of a functioning nerve, the contralateral lobe should be mobilized with preservation of the contralateral RLN. The gland is then released from the laryngeal cartilage by identifying and transecting the ligament of Berry. During the release of the ligament of Berry, control of bleeding from tiny vessels, which run in the ligament, will be required. One must be careful in this area as the nerve is quite close and bipolar cautery with fine-tip forceps should be used to reduce heat to surrounding tissues while maintaining precise control of bleeding. If suture material is required in this area, something that is dissolvable such as polyglactin or chromic gut is advantageous. The inferior thyroid veins, which are often numerous and run parallel to the RLN or trachea, should be ligated carefully. Sometimes, an arteria thyroidea ima vessel from the brachiocephalic trunk along the trachea will be present. This vessel can retract into the mediastinum and can cause bleeding that is difficult to control, and therefore, it is important to be vigilant for this vessel and to identify and ligate it with care.

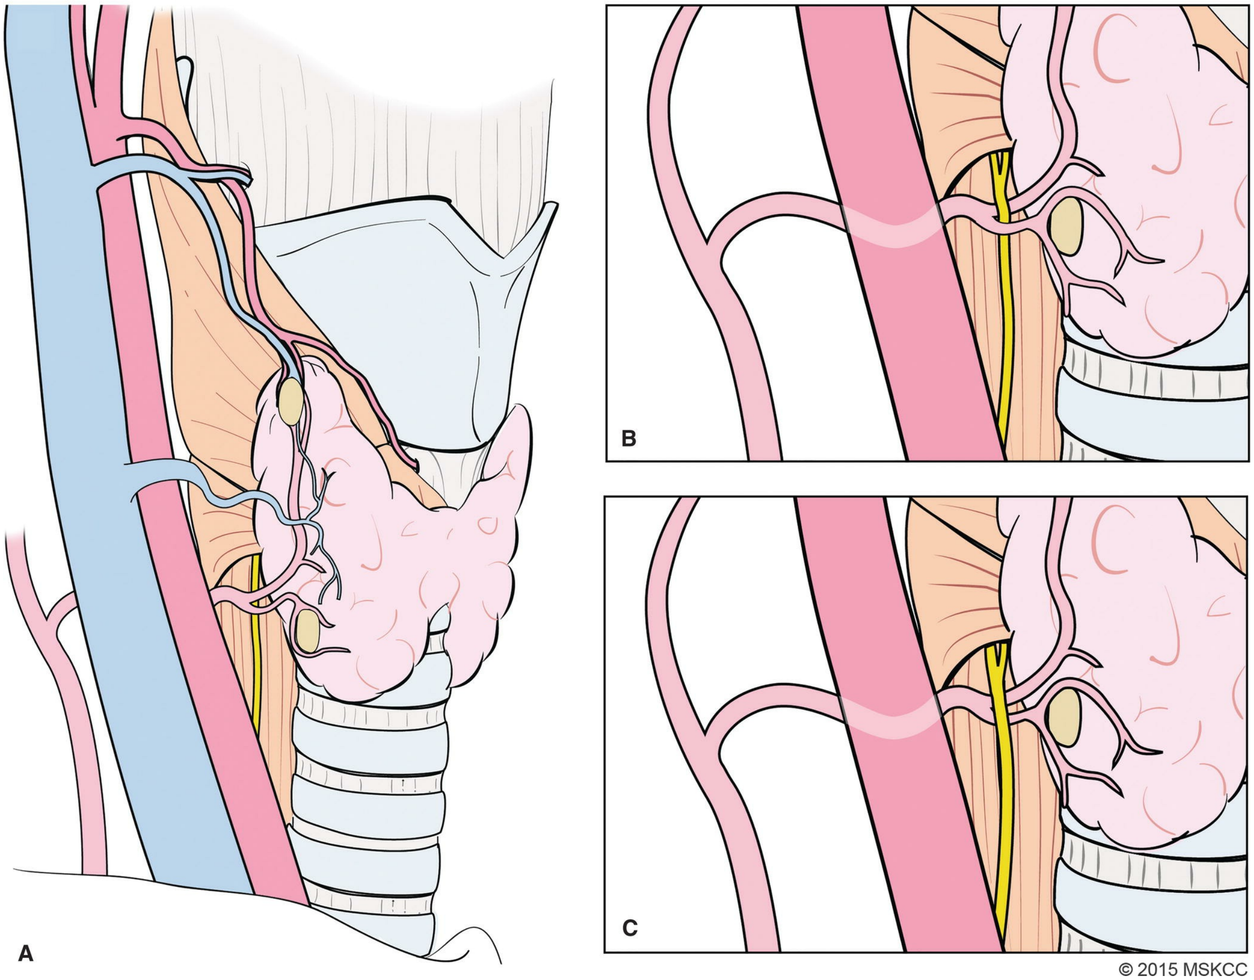

Figure 19.11. Anatomy of inferior thyroid artery **(A)**. In most patients, the nerve courses under the inferior thyroid artery **(B)**; however, in 25% of patients, it crosses over the inferior thyroid artery **(C)**.

After the entire gland is mobilized, the dissection continues on the surface of the trachea in the avascular pretracheal plane. The extent of thyroidectomy will depend on the philosophy of the operating surgeon and the disease process at hand. Generally, a true extracapsular thyroidectomy is done for patients with malignancy. Sometimes, a small portion of thyroid tissue may be left near the ligament of Berry, the superior pole, or in the pyramidal lobe area.

In some cases of locally advanced thyroid carcinoma, the tumor may be adherent to the trachea. At this time, the surgeon must make a critical decision about removing the tumor from the trachea. Obviously, if the tumor is invading the trachea, tracheal resection will be required. However, if there

is no invasion, the tumor can often be shaved off the trachea with careful attention to avoid inadvertently violating the trachea.

Once the thyroid gland has been mobilized out of the surgical bed, the field is inspected. Some surgeons may consider transecting the isthmic area before proceeding to the other side; however, we usually leave the specimen intact and proceed to other side for completion of the thyroidectomy by repeating the discussed steps. Hemostasis should be confirmed and the tracheoesophageal groove should be examined for suspicious lymph nodes. If there are suspicious lymph nodes present, they should be excised and analyzed by frozen section. If positive for malignancy, the central compartment should be dissected. Some surgeons perform an elective central neck compartment dissection in high-risk patients. Appropriate evaluation of the superior mediastinum for metastatic lymphadenopathy is also important.

At the conclusion of the procedure, we prefer to only use minimal irrigation of the wound because excessive irrigation may disrupt parathyroid glands or result in accidental suctioning a gland out of the surgical bed. At the end of the procedure, a Valsalva maneuver is requested from the anesthesiologist to confirm that there are not any bleeding areas. The strap muscles are then approximated in the midline with two sutures. Watertight closures are avoided, which may worsen airway effects in the case of a postoperative hematoma. The platysma is then approximated with polyglactin sutures and the skin is closed with a running subcuticular absorbable suture. Figure 19.12 demonstrates total thyroidectomy specimen with a dominant nodule. Drains are rarely used in standard total thyroidectomy but are commonly used in patients with large substernal goiters or those with bleeding during surgery. Drains are also used in patients who require more extensive dissection such as in those with Grave disease or Hashimoto thyroiditis. If a drain is used, a closed suction drain is recommended and can be removed in most patients 24 hours after surgery prior to discharge.

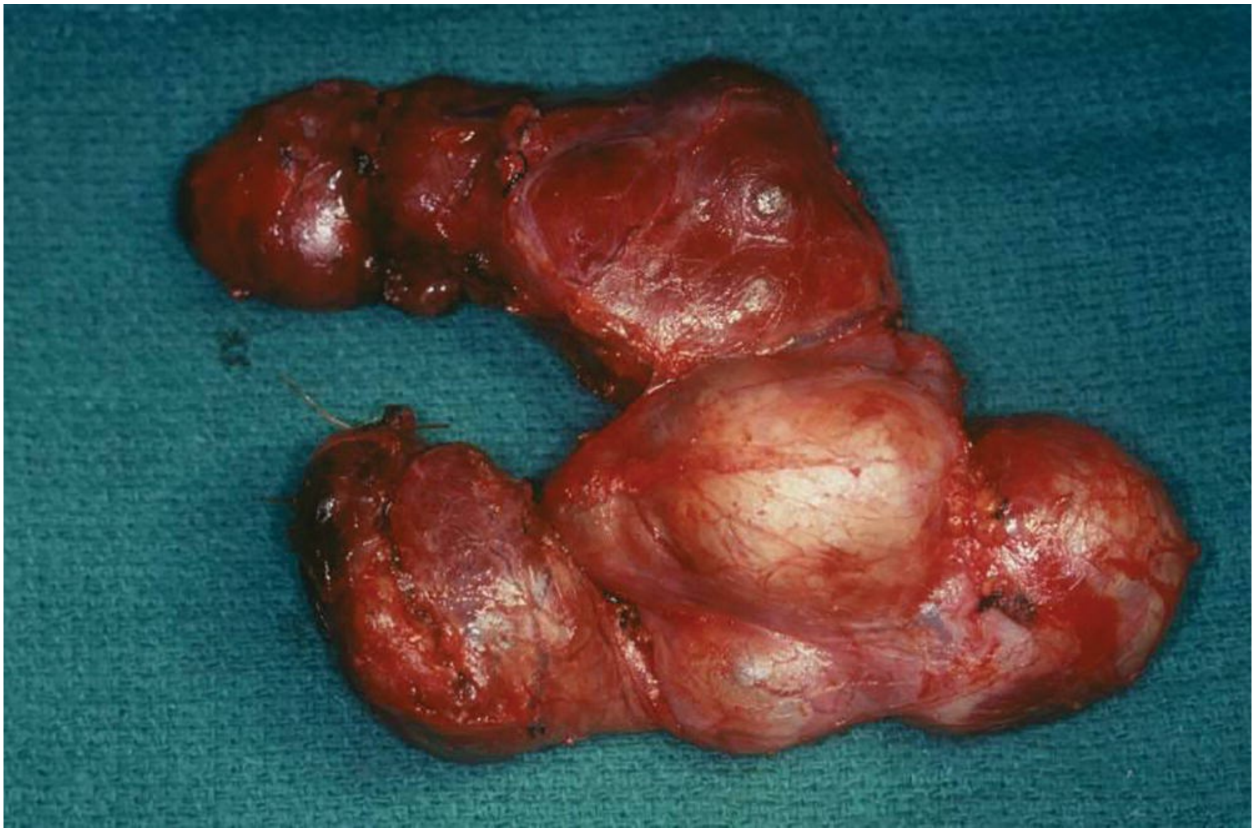

Figure 19.12. Total thyroidectomy specimen with dominant nodule.

POSTOPERATIVE CARE AND COMPLICATIONS

A hematoma may develop in the acute postoperative period. Although small collections can simply be observed, an expanding hematoma requires urgent attention. Because of the close proximity of the surgical field to the airway, in severe cases, the surgical incision should be opened at the bedside, thereby removing pressure on the central compartment and airway. Once the acute airway pressure has been alleviated, the patient should be returned to the operating room for exploration of the wound, control of hemorrhage, and irrigation.

Transient parathyroid dysfunction may be observed commonly after thyroid surgery, and therefore, it is recommended that patients be monitored clinically as well as biochemically after total thyroidectomy. Serum calcium that has been corrected to account for albumin or ion calcium is often used. Postoperative intact PTH has been shown to predict need for

hypoparathyroidism and need for calcium supplementation.[52] Some patients will require calcium with or without vitamin D postoperatively. Most patients can be weaned from this supplementation as most cases are transient and resolve in 4 to 6 weeks.

Permanent RLN injury is uncommon, occurring in 1% to 2% of cases. Transient injuries in the presence of a preserved nerve are most often related to traction and will usually recover spontaneously. In cases where there has been significant prolonged vocal fold dysfunction, or permanent paralysis, a medialization procedure can be considered.

More common and less recognized is injury to the external branch of the superior laryngeal nerve. Patients will often present with the complaint of not being able to "hit high notes" or yell after surgery. Identifying this nerve as well as taking superior pole vessels close to thyroid and individually is helpful in preserving function of this nerve postoperatively.

SUMMARY OF ATA RECOMMENDATIONS FOR MANAGEMENT OF PRIMARY TUMOR AND CERVICAL LYMPH NODES

The ATA has played an important role in developing guidelines for well-differentiated thyroid cancer over the last 10 years. The first edition of these guidelines was published in 2006 and the revised edition was published in 2009. A new edition with considerable revisions will be published in 2015 and it is based upon a deep understanding of the biology of thyroid cancer, risk group stratification, prognostic factors, and judicious use of adjuvant therapies including radioactive iodine ablation. The ATA guidelines include both patient and tumor factors and stratify the patients into low-, intermediate-, and high-risk groups for recurrence of thyroid cancer. This risk classification is very important in the primary management of thyroid cancer. The extent of thyroidectomy, which was defined initially as total thyroidectomy for tumors more than 1 cm, has been revised considerably and a lobectomy may be performed for intrathyroidal tumors up to 4 cm. The NCCN guidelines have always adhered to the role of lobectomy in patients

with intracapsular thyroid tumors up to 4 cm. However, the ATA has changed the guidelines now to adhere to the overall principles of more conservative management of low-risk thyroid cancer. The understanding of the risk group's stratification is critical in the determination of the extent of thyroidectomy and the need for paratracheal and/or lateral nodal dissection and adjuvant treatment. It appears from the most recent guideline that the extent of thyroidectomy can be limited to lobectomy with isthmusectomy in selected patients with low-risk thyroid cancer or intrathyroidal tumors where the quality of life is thought to be enhanced in patients who still have a natural source of thyroid hormones. Naturally, some of these patients may need additional supplementation with thyroid medication even though they have native thyroid tissue in situ. It is important to note that the opposite lobe needs to be followed to see if patients will develop further nodularity or even obvious cancer in the opposite lobe at which time they will definitely require completion thyroidectomy.

A major debate remaining in the management of thyroid cancer concerns the role of prophylactic central compartment dissection and the extent of lateral neck dissection. In the first edition of the ATA thyroid guidelines, there was a statement made about the use of prophylactic nodal dissection in patients presenting with tumors more than 1 cm. However, it was soon apparent to the surgical community that if more prophylactic neck dissections are performed, there is a greater likelihood of nerve injury and temporary and permanent hypoparathyroidism. Therefore, there is not a strong rationale to perform routine prophylactic node dissection especially in the low-risk thyroid cancer patients. Although ~40% to 50% of the patients will have microscopic nodal disease in thyroid cancer, the removal of these microscopic foci of metastatic tumor has very little impact on the long-term survival and outcome, providing a strong rationale for closely observing as opposed to electively dissecting the central compartment. Nevertheless, in individuals who are older and have bulky nodal disease or aggressive histology, the removal of the central compartment nodes should be considered. This is reflected in the second edition of ATA guidelines, which recommends prophylactic nodal dissection in high-risk patients, such as T3 and T4 tumors, or patients presenting with extrathyroidal extension of the disease or aggressive histology.

The extent of the lateral neck dissection in patients with clinically or

radiologically apparent nodal metastasis remains the selective neck dissection of level II to level V. The incidence of metastatic disease at level I is so low that unless there is gross metastatic disease at level II, level I can be spared. Similarly, level Va nodal metastasis is quite rare and this region can be spared in an effort to avoid injury to the spinal accessory nerve. Similarly, nodal metastasis to level IIb is quite rare in thyroid cancer and this region can be easily spared in an effort to avoid traction injury to the accessory nerve.

There is also considerable interest in avoiding the routine use of radioactive iodine ablation especially in low-risk thyroid cancer patients. There does not appear to be any major benefit of routine use of radioactive iodine in low-risk patients, as there is a high incidence of complications such as chronic sialadenitis and dry mouth as well as a slightly higher incidence of second primary tumors. Postoperative surveillance by monitoring serum thyroglobulin level is also quite helpful to make certain decisions regarding adjuvant treatment with RAI. However, there is a general consensus currently to avoid RAI in most of the low-risk thyroid cancer patients.

MINIMALLY INVASIVE THYROIDECTOMY (MIT)

In the recent past, there has been great interest in thyroidectomy through a “minimally invasive” approach. Much of the interest has come from surgeons who have observed the benefits of minimally invasive techniques in general surgery, cardiothoracic surgery, and orthopedic surgery. Where there have been numerous published reports of decreased pain, shorter hospital stay, and improved patient satisfaction, a smaller or completely absent scar on the neck has been a commonly reported outcome of MIT.

MIT can be divided into two broad categories. These include those in which the thyroid is approached through a small incision in the neck and thyroidectomy in which the approach is extracervical. We will discuss the four approaches: nonendoscopic MIT, endoscopic thyroidectomy through a neck incision, robotic assisted via axilla and breast, and robotic assisted via a facelift approach.

Nonendoscopic Minimally Invasive Thyroidectomy

The minimally invasive, nonendoscopic thyroidectomy (MINET) is a response to patients' requests for smaller incisions on the neck. In contrast to the traditional Kocher incision of 6 cm in the lower neck, the MINET incision is a 2.5-cm (1-in) incision that is made just caudal to the cricoid cartilage. This allows for control of structures at the superior pole. This operation is limited by the size of the thyroid neoplasm being excised. However, the incision can be easily extended to accommodate delivery of the thyroid mass.

Minimally Invasive Video-Assisted Thyroidectomy

This technique first described by Miccoli[53] and Bellantone[54] combines a traditional open thyroidectomy technique modified with a combined endoscopic approach. This is done without insufflation and uses blunt dissection. Briefly, a 30-degree, 5-mm diameter endoscope is introduced through a low (one fingerbreadth above the sternal notch) incision in the neck. Using external retractors, the superior pole vasculature is ligated under direct visualization.

Once the external branch of the superior laryngeal nerve, the superior parathyroid gland, and the RLNs are also visualized endoscopically and the superior pole is mobilized, the thyroid is retracted outside of the incision and the remaining portion of the operation is completed under direct vision. In a prospective randomized study, Miccoli reported that although cosmesis and postoperative pain were significantly better in MIVAT, conventional thyroidectomy still offers an advantage in terms of decreased operative time.[55] Patient selection plays an important role in this approach. Patient and tumor limitations include (1) thyroid nodule <3.5 cm; (2) absence of thyroiditis; (3) thyroid volume <15 mL; (4) cytologic and clinical evidence of benign disease, follicular tumor, or low-risk papillary carcinoma; and (5) absence of ultrasonographically enlarged lymph nodes in the neck.

Robotic Thyroidectomy

Robotic thyroidectomy represents a remote access thyroidectomy using the da Vinci robot. The published advantage of these approaches is improved cosmoses, although some suggest better visualization and magnification of the operative field and better surgeon ergonomics and dexterity with a robotic

approach.[56] The two robotic approaches described include a transaxillary approach and robotic facelift thyroidectomy (RFT). The largest experience with transaxillary thyroidectomy comes from Yonsei University, South Korea,[57–59] with some reports from the United States.[60,61] Robotic thyroidectomy using a gasless transaxillary approach eliminates the need for any cervical incisions. Experienced centers report excellent cosmetic results, decreased neck discomfort, and swallowing dysfunction.[59] Complications including stretch injury to the brachial plexus, perforation of the trachea, and injury to the carotid artery and internal jugular vein have been reported.[61] Lee et al.[62] reported on extending this approach to include patients with micropapillary carcinoma. Long-term oncologic follow-up is needed to fully assess the benefits of this approach.

An alternative remote access approach to the thyroid is the RFT, which uses a facelift incision in the postauricular area to provide entry to the thyroid compartment. This technique was developed with expectations that it would be less invasive and safer than the axillary-based approaches. In a small series, Terris compared transaxillary robot-assisted hemithyroidectomy versus RFT and reported a more rapid learning curve reflected by shorter operative times. Additionally, in the RFT arm, 9 of 10 patients were managed without a drain and in an outpatient setting, whereas all 5 of the transaxillary approaches were managed with drains as inpatients.[63] Certainly, long-term outcomes and large cohorts of patients have not been reported and are needed to fully assess the utility of this procedure.

Patient selection is critical with robotic thyroidectomy. Ideal patients are those with indeterminate, likely benign lesions <3 cm, where a unilateral lobectomy is indicated and body mass index <35 kg/m^2. Patients with inflammatory or previous neck surgeries should be considered poor candidates for remote access surgery as surgical planes may be difficult to dissect. Additionally, lesions located more deeply and posteriorly in the tracheoesophageal groove are more difficult to access with increased risk of injury to the trachea, esophagus, and RLN.

In summary, MIT offers patients an improved cosmetic outcome in the context of safely performed thyroid surgery by experienced surgeons. There is a significant learning curve associated with performance of these techniques and appropriate patient selection. Long-term outcome studies are

still needed especially with respect to oncologic outcomes.

MANAGEMENT OF LOCALLY ADVANCED THYROID CANCER

Surgical Management

Locally advanced thyroid cancer (LATC) is the result of direct extrathyroidal tumor extension (ETE) or extracapsular extension of involved lymph nodes into surrounding structures. As discussed above, gross ETE into surrounding structures is a poor prognostic indicator. The intricate relationship between the biology of the tumor, the risk of complete surgical resection at the expense of sacrificing vital structures, and the goals of the patient is essential in the management of LATC. The principles of surgical management of LATC are (1) removal of all gross tumor, (2) preservation of functioning structures, (3) preservation of vital structures, and (4) appropriate and selective use of adjuvant therapies. Structural imaging utilizing CT with contrast (Fig. 19.13) or MRI is essential in the preoperative evaluation of patients with ETE. Given the high association of ETE and distant metastases,[64] assessment for systemic disease should be undertaken before aggressive surgeries undertaken.

Figure 19.13. CT scan demonstrating LATC recurrence with airway invasion.

Invaded structures in LATC can be divided into central and laterally located structures. The most common structures invaded in the central neck include the strap muscles, RLN, trachea, laryngeal framework, esophagus, and pharyngeal constrictors.[65] Laterally, the carotid artery, internal jugular vein, vagus nerve, spinal accessory nerve, and phrenic nerve can be involved. Invasion of structures can occur in isolation or in combination with invasion of other involved structures. Discussion of structures invaded will be taken independently.

Recurrent Laryngeal Nerve Involvement

The findings of the preoperative evaluation of the vocal cords provide valuable information needed to make intraoperative decisions. Assessment of both the involved side of RLN and the contralateral nerve is important. Vocal cord paralysis is specific for RLN invasion; however, pressure can also result in impairment in vocal cord function.[66] In the clearest situation, a nerve that

is preoperatively paralyzed and found to be invaded at the time of surgery should be resected. Inability to remove all gross disease from the RLN is also an indication for resection. However, if vocal cord function is intact preoperatively, well-differentiated thyroid cancer can be peeled off the nerve cleanly during surgery if a gross total (R1) resection can be achieved. In nerves that function preoperatively, the Mayo Clinic and Japanese group have demonstrated that leaving microscopic disease on the RLN does not alter survival or local recurrence.[67,68]

For RLNs that are sacrificed, reanastomosis at time of surgery with the great auricular nerve, ansa cervicalis, or sural nerve has been shown to be effective in voice rehabilitation.[69,70] Early vocal fold medialization, especially in older patients with less ability to compensate, should be considered.

Laryngotracheal Invasion

A patient with LATC presenting with a fixed mass or less commonly hemoptysis should be evaluated for laryngotracheal invasion. Although tracheal invasion is the third most common site of invasion (after the strap muscles and RLN), direct laryngeal involvement is far rarer.[71]

Given the rarity of laryngeal involvement in LATC, cases should be considered on an individual basis. If the tumor can be shaved off of the laryngeal framework, this should be considered. For tumors invading laryngeal framework, resection of laryngeal cartilage or partial laryngectomy can be used. However, if the tumor is extending transluminal and invading the cricoid cartilage, total laryngectomy may be indicated.

Tracheal invasion is far more common than laryngeal invasion and therefore is more extensively studied and characterized. Shin et al.[72] described a staging system based on the depth of invasion (Fig. 19.14): Stage I cancer invades through the capsule of the thyroid gland and abuts but does not invade the external perichondrium of the trachea. Stage II cancer invades into the cartilage or causes cartilage destruction. Stage III cancer extends into the lamina propria of the tracheal mucosa with no elevation or penetration of the mucosa. Stage IV cancer is full-thickness invasion with expansion of the tracheal mucosa that is visible bronchoscopically as a bulge or an ulceration.

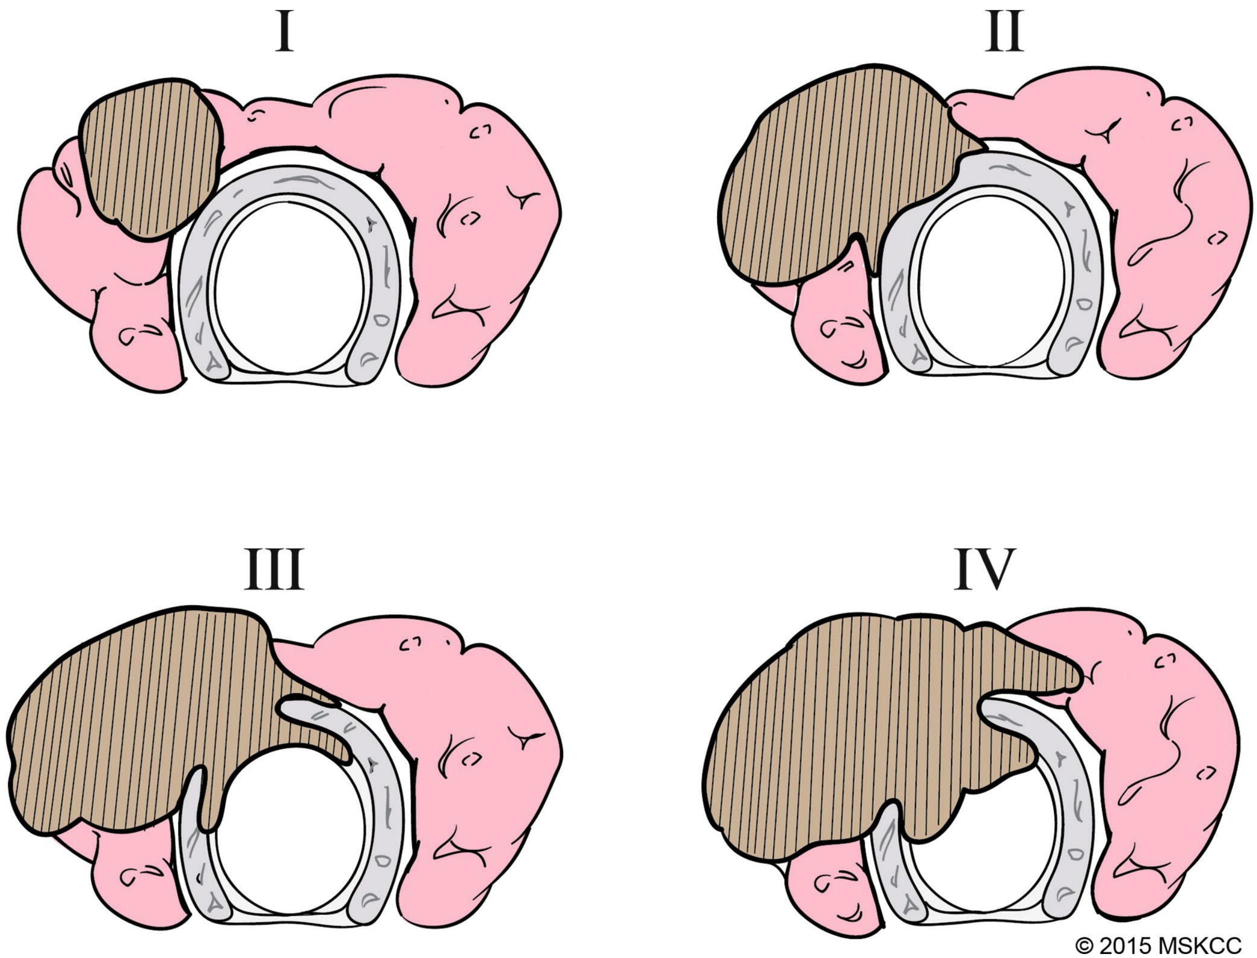

Figure 19.14. Tracheal invasion as described by Shin. Stage I invades through the capsule of the thyroid gland and abuts but does not invade the external perichondrium of the trachea. Stage II invades into the cartilage or causes cartilage destruction. Stage III extends into the lamina propria of the tracheal mucosa with no elevation or penetration of the mucosa. Stage IV is full-thickness invasion with expansion of the tracheal mucosa that is visible bronchoscopically as a bulge or an ulceration.

In the management of stage I tumors, although some have shown similar survival and local control rates when comparing shave procedures with more radical resection,[71] others have shown higher recurrence rates and worse survival.[73]

When conservative surgical management will most likely leave macroscopic disease behind on the trachea, more aggressive surgery is required. Options include window resection or wedge resection with primary closure or sternocleidomastoid muscle patch closure. When the tumor

involves more than one tracheal ring, sleeve resection and anastomosis should be undertaken. Resection of as many as seven to eight tracheal rings can be performed with primary anastomosis. In order to preserve blood supply, dissection should not extend 360 degrees of the trachea.

Esophageal Invasion

Direct extension via extracapsular spread from paratracheal or paraesophageal lymph nodes can result in invasion of the esophagus in one-fifth of patients with LATC and is a poor prognostic indicator.[71] Most commonly, the mucosa and submucosa layers are spared allowing an isolated resection of the muscularis layer resulting in a clear margin. However, in cases that require through and through resection, primary closure can often be achieved. An esophageal bougie or feeding tube placement can be helpful in identification of the esophageal lumen intraoperatively. Large defects may require reconstruction with local flaps or free tissue transfer.

Adjuvant Therapy

Patients with LATC have a higher rate of local recurrence, and completeness of surgical resection occasionally may not be achievable due to the extent of disease on presentation. In these cases, adjuvant therapy plays a significant role in the control of LATC. For patients with differentiated thyroid cancer that readily takes up iodine, RAI can be used for microscopic residual disease. In patients with gross residual disease, retrospective studies have shown external beam radiation therapy (EBRT) to be effective for local regional control.[74,75] Chow et al.[76] recommended adjuvant EBRT in patients with gross residual disease, positive resection margins, pT4, pN1b, or a lymph node size of >2 cm. The benefits of EBRT after adequately resected WDTC and in tumors with microscopic residual disease that readily take up iodine remain unclear. RAI scan results and PET scan results are useful in selecting patients most likely to benefit from RAI versus EBRT. Cytotoxic chemotherapy has shown little benefit in LATC. Overall, locoregional and progression-free survival (PFS) have been found to be equal for patients receiving EBRT versus EBRT plus chemotherapy. A benefit was observed in poorly differentiated histology; however, this was associated with a significantly worse distant metastasis-free survival.[77]

Targeted Therapy in Locally Advanced and Metastatic Thyroid Cancer

Over the past decade, we have observed significant advancement in the medical treatment of advanced thyroid cancer. Two multikinase inhibitors, levatinib[78] and sorafenib,[79] have been approved by the FDA for the treatment of patients with progressive, recurrent, or metastatic thyroid cancer that does not respond to treatment with radioactive iodine. Sorafenib was approved based on the phase 3 DECISION trial, which studied patients with recurrent and/or metastatic differentiated thyroid cancer and found that the median PFS was significantly longer in the sorafenib-treated group 10.8 months than in the placebo group 5.8 months.[79] The SELECT trial lead had similar inclusion criteria as the DECISION trial and led to the approval of lenvatinib. This trial demonstrated a median PFS in the treatment group of 18.3 months compared with 3.6 months in the placebo group with an overall objective response rate of 64.8%.[78] These drugs are hypothesized to exert their actions by targeting tumor angiogenesis by inhibiting vascular endothelial growth factor receptors VEGFR-1, VEGFR-2, and VEGFR-3. In addition, these agents also inhibit other kinases including RET, BRAF, and the platelet-derived growth factor receptor (PDGFR)-β in the case of sorafenib. In contrast, lenvatinib inhibits PDGFR-α, RET, the mast/stem cell growth factor receptor Kit, and the fibroblast growth factor receptors FGFR-1, FGFR-2, FGFR-3, and FGFR-4. These different kinase profiles may contribute to the differences in clinical efficacy observed in these two compounds. These drugs are associated with significant toxicity with 82% of patients requiring a dose interruption in the SELECT trial.[79] Quality of life and the long-term cumulative toxicities of therapy remain areas in need of further research. A comprehensive picture of how these systemic therapies benefit patients long term is still open to question.

MEDULLARY THYROID CANCER

Medullary thyroid cancer (MTC) was first described as the thyroid tumor that contained amyloid by Jacquet,[80] much later Hazard noted this as a histologically distinct thyroid carcinoma,[81] and it was then shown that this tumor originates from the neural crest–derived parafollicular C cells that

function and secrete polypeptide calcitonin.[82] It soon became clear that both sporadic and familial forms of MTC existed. The genetic forms exist as a component of the type 2 MEN syndromes MEN2A, MEN2B, and the related syndrome familial MTC (FMTC). Ten years after Takahashi et al.[83] discovered the rearranged during transfection (RET) oncogene in 1985, it was found that virtually all patients with MEN2A, MEN2B, and FMTC have RET germ-line mutations and ~50% of sporadic MTCs have somatic RET mutation.[84–86] The RET proto-oncogene is located on chromosome 10q11.2 and encodes a single-pass transmembrane receptor of the tyrosine kinase family that assists in cell trafficking, differentiation, and signal transduction.[87]Study of the RET proto-oncogene has added to the clinical understanding of the MTC, provided evidence for genetic counseling and prophylactic interventions, as well as opened the door for the utilization of targeted therapy. Common mutations are summarized in Table 19.9.

Table 19.9 Common Mutations in Medullary Thyroid Cancer

	Mutation	Exon	Phenotype	MTC Aggressiveness
Extracellular Cystein Rich Domain	533	8	FMTC	Moderate
	609	10	FMTC	Moderate
	611	10	FMTC/MEN2A	Moderate
	620	10	FMTC/MEN2A	Moderate
	630	11	FMTC	Moderate
	634	11	MEN2A	High
Intracellular Tyrosine Kinase Domain	768	13	FMTC	Moderate
	790	13	FMTC	Moderate
	804	14	FMTC	Moderate
	883	15	MEN2B	High
	891	15	FMTC	Moderate
	912	16	MEN2B	Moderate
	918	16	Men2B	Very High

Secretory Products of MTC and Their Clinical Utility

Parafollicular cells (C cells) comprise only 0.1% of thyroid cells that are scattered throughout the thyroid gland but are most numerous at the junction of the upper third and lower two-thirds of the gland. This accounts for the higher portion of MTCs located in the superior lobes. Parafollicular cells primarily secrete calcitonin, which acts to decrease blood calcium levels opposing the effects of parathyroid hormone (PTH). Other secretory products

include CEA, somatostatin, ACTH, vasoactive intestinal peptide (VIP), gastrin-releasing peptide, neurotensin, prostaglandins, and chromogranin. Patients with tumors secreting calcitonin and VIP can present with diarrhea and flushing. Cushingoid signs and symptoms can be observed in patients with tumors secreting ACTH.

Of these secretory products, calcitonin and CEA are valuable tumor markers in patients with MTC and can be useful for diagnosis, staging, and surveillance. Often, cytologic samples from MTC samples are difficult to distinguish based on the appearance of the cells alone. Higher accuracy has been reported with immunohistochemical staining for calcitonin or CEA in cases with suspected MTC.[88] Once the diagnosis of MTC is made, preoperative serum calcitonin levels have been correlated to tumor size and likelihood of surgical "biochemical cure." This correlation is more straightforward in familial and less correlative in sporadic cases.[89] In cases of nodal metastases, basal calcitonin levels can be in the range of 10 to 40 pg/mL (normal range <10 pg/mL), whereas distant metastases are typically associated with a calcitonin level >150 pg/mL and often >1,000 pg/mL. The ATA has incorporated preoperative calcitonin in deciding on the extent of surgical resection. In patients with MTC without distant metastases and no evidence of neck metastases on US, dissection of lymph nodes in the lateral compartments may be considered based on serum calcitonin levels.[90] However, although calcitonin levels are sensitive, a diagnosis of MTC cannot always be excluded by a normal preoperative calcitonin level.

Calcitonin levels play a significant role in prognosis and surveillance of patients postoperatively. Barbet et al. concluded that postoperative calcitonin doubling time (DT) is among the most powerful prognostic indicators in MTC. When calcitonin DT was <6 months, the 5- and 10-year survivals were 25% and 8%, respectively, whereas a calcitonin DT between 6 months and 2 years is associated with 5- and 10-year survivals of 92% and 37% and whereas all 41 patients with calcitonin DT >2 years were alive at the end of their study.[91] This clearly demonstrates the rapidity of rise in calcitonin levels can be used to aid in counseling and management of patients with MTC.

CEA is another useful tumor marker found in 50% of patients with MTC. Importantly, an increasing CEA level in the presence of a stable calcitonin level can be a sign of dedifferentiation of the tumor and is associated with a worse prognosis.

Incidence and Genetic Alterations in Sporadic and Hereditary MTC

MTC comprises 3% to 4% of all thyroid cancers. Most are sporadic accounting for about 75% of cases,[92] whereas the remaining coexists with hereditary syndromes including MEN2A and MEN2B syndromes or FMTC.

Sporadic MTC

The sporadic form of MTC comprises the majority of cases and most commonly presents a unifocal lesion later in life, most often in the fourth decade. Six to ten percent of patients with sporadic MTC harbor a de novo germ-line RET mutation.[93] Specific mutations have been shown to result in a more aggressive course. Specifically, somatic RET codon M918T mutation in sporadic MTC has been shown to have an aggressive clinical course and a poor prognosis.[94] However, overall sporadic MTC confers the best prognosis of all types of MTC.

Hereditary MTC

During the 1960s, Sipple noted an association between MTC, pheochromocytoma, and mucosal neuromas. Sipple syndrome (MEN2A) is inherited in an autosomal dominant fashion with the development of MTC reaching nearly 100% penetrance, usually before the age of 6 in a multifocal, bilateral pattern.[30] Fifty percent of patients with MEN2A will have an associated pheochromocytoma. Prior to surgery, pheochromocytoma should be excluded by measuring plasma or urine metanephrines.

MEN2B confers the worst prognosis of all types of MTC. Malignancies are multifocal, bilateral, and present extremely early in life, usually during infancy. MTCs develop with nearly 100% penetrance, and this syndrome also cares a 50% risk of pheochromocytoma. MTCs develop in infancy and are often multifocal and bilateral. In addition, MEN2B patients also have gastrointestinal mucosal ganglioneuromas and marfanoid body habitus.

FMTC denotes the best prognosis of the inherited MTC syndromes, and in contrast to MEN2 syndromes, it does not carry the risks of other clinical entities.[95] Like MEN2 syndromes, the MTCs associated with FMTC does present bilaterally in a multifocal pattern however is observed much later in

life, often in the third decade. A history of multiple family members presenting with MTC in isolation, later in life, helps distinguish MEN2A syndrome from FMTC.

Presentation of Patients with MTC

Age at presentation is often dependent on etiology. The typical age of presentation of sporadic MTC is in the fifth or sixth decade. In contrast, MEN2A and FMTC typically present in the third decade of life, and MEN2B usually presents in those younger than age 20. MTC patients will most often present with a palpable solitary thyroid nodule or thyroid mass. At the time of diagnosis, 70% of the patients will have cervical metastasis and 10% have distant metastases.[96] Presenting symptoms vary from asymptomatic to dysphagia or hoarseness secondary to RLN invasion. Systemic symptoms secondary to the functioning nature of these tumors are also common as discussed above. Diarrhea and flushing may be present, especially if calcitonin and/or VIP levels are elevated, and Cushingoid symptoms may be present if ACTH levels are elevated.

Management of MTC

Total thyroidectomy and dissection of cervical lymph node compartments, depending on serum calcitonin levels and US findings, are the standard treatments for patients with sporadic or hereditary MTC. Extent of lymph node dissection is controversial. Lymph node metastases are common. In patients with unilateral tumors, lymph node metastases have been observed in 81% of central node dissections, 81% of ipsilateral functional (level II to V) dissections, and 44% of contralateral neck dissection specimens. In bilateral tumors, the findings were similar. Importantly, these findings did not correlate to size.[97] Lymph node basins involved correlate with biochemical measures. Basal serum calcitonin levels exceeding 20 pg/mL, 50 pg/mL, 200 pg/mL, and 500 pg/mL were associated respectively with metastases to lymph nodes in the ipsilateral central and ipsilateral lateral neck, the contralateral lateral neck, and the upper mediastinum.[98]It is worth noting that the sensitivity of the surgeon’s intraoperative assessment for nodal metastases is 64%, with a specificity of 71%,[97] suggesting intraoperative assessment is not an optimal management plan in deciding extend of neck dissection.

The ATA has made recommendations on the extent of neck dissection that should be included in management of MTC in patients without distant disease.[90] Patients with no evidence of neck lymph node metastases by US examination should have a total thyroidectomy and dissection of the lymph nodes in the central compartment (level VI). Lateral compartments (level II to V) may be considered based on serum calcitonin levels. For patients with ipsilateral disease based on imaging, but negative in the contralateral neck compartment, contralateral neck dissection should be considered if the basal calcitonin level is >200 pg/mL.

It is essential to recognize the importance of parathyroid management in MTC. Patients with MEN2a can have parathyroid hyperplasia although it is often mild and often asymptomatic in comparison to MEN1.[99] The recommended treatment for primary hyperparathyroidism secondary to four-gland hyperplasia includes a subtotal parathyroidectomy leaving one gland, or a piece of one gland, in situ, or resection of only enlarged glands, with intraoperative PTH monitoring to document complete removal of hyperfunctioning parathyroid tissue. Ideally, this diagnosis should be made preoperatively.

Prophylactic Thyroidectomy

Prophylactic thyroidectomy is recommended in at-risk patients before the onset of clinically significant disease. A classic progression from C-cell hyperplasia to MTC to regional lymph node involvement and ultimately spread to distant sites is seen in patients with hereditary MTC. Timely thyroidectomy for MTC favorably alters the associated morbidity and mortality and the goal of prophylactic thyroidectomy is to intervene early in this progression. This should be balanced with the higher complication rates associated with thyroidectomy, the most significant being hypoparathyroidism in children compared to adults. This is less so in experienced hands. Therefore, the ATA has recommended that experienced physicians and surgeons in tertiary care centers should be responsible for the management of children with MEN2A or MEN2B. The age at which surgical management should be performed is dependent on mutational status.

Adjuvant Therapy in the Treatment of MTC

RAI therapy is ineffective in MTC. External beam radiation has not been studied in a prospective fashion and retrospective findings are often difficult to evaluate. Locoregional control is a valid endpoint in patients with MTC, as progression in the cervical region can have a significant impact on quality of life and survival. EBRT may improve locoregional control. 34 patients at high risk for MTC recurrence following thyroidectomy treated with a median total radiation dose of 60 Gy had a 5-year locoregional relapse-free survival rate of 87%. This would suggest some benefit of EBRT in locoregional control. It is important to note that R0 resection represents the best chance of locoregional control, however, but in patients with a high risk of recurrence due to positive margin, extrathyroidal extension, extensive lymph node metastases, or airway involvement, EBRT may be considered.

Systemic Therapy

Traditional single-agent chemotherapy has a low response rate in MTC. The most effective regimens are combination therapy with doxorubicin and another agent or 5FU and dacarbazine. Recent advances with targeted molecular therapies indicate that these agents may have benefit for patients with refractory disease.

Based on the results of two completed phase III clinical trials, the FDA approved two orally administered drugs vandetanib[100] and cabozantinib,[101] for the treatment of patients with advanced progressive MTC. Vandetanib targets the RET, EGFR, and VEGFR kinases. Partial responses were observed in 45% of patients treated with vandetanib, with a predicted median duration of response of 22 months. The improvement in quality of life, pain reduction, and diarrhea allowed a number of patients in the vandetanib arm to resume a normal social life. Responses were independent of RET mutation.[100]

Cabozantinib targets the kinases of RET, c-MET, and VEGFR. In the phase III trial, median PFS was significantly improved from 4.0 months (placebo) compared to 11.2 months (cabozantinib), and the overall response rate was 28%.[101]

Toxicity is not insignificant with the use of these two agents. Twelve percent of patients receiving vandetanib discontinued treatment due to toxicity and 35% required dose reductions because of an adverse event.[100]

For cabozantinib, 16% of patients receiving this agent discontinued treatment due to toxicity and 79% required dose reductions because of an adverse event.[101] Side effects included diarrhea, abdominal discomfort, fatigue, hypertension, and rash. Vandetanib was also associated with cardiac side effects specifically prolongation of the QTc interval.

Unanswered questions remain regarding the use of these agents. Resistance is observed over time, and toxicity remains and the issue of when to start and terminate these therapies are areas of ongoing debate and research.

ANAPLASTIC THYROID CANCER

ATC is a rare but highly lethal form of thyroid cancer. ATC patients have a median survival of 5 months and a 20% 1-year survival rate.[102] Patients with ATC will usually present with a rapidly enlarging neck mass often associated with symptoms consistent with invasion of surrounding structures including hoarseness and dysphagia. Risk factors for ATC are not well understood, but patients may have a history of goiter or prior coexisting differentiated thyroid cancer. It has been hypothesized that as the tumors dedifferentiate, more mutations develop, with ATCs commonly having multiple genetic abnormalities. Mutations in p53, BRAF, and Ras are common.[103]

Accurate histologic diagnosis of ATC is important in order to exclude other treatable entities with a better prognosis including PDTC and lymphoma. Although variable, a common morphologic presentation, and one that is most easily recognized as an anaplastic carcinoma of thyroid, is that of the biphasic spindle and giant cell tumor (Fig. 19.15). Other tumors are dominated by bizarre malignant giant cells, and still others may show a more pure population of spindle and squamoid cells. Tumors are highly proliferative with numerous mitotic figures and areas of necrosis.

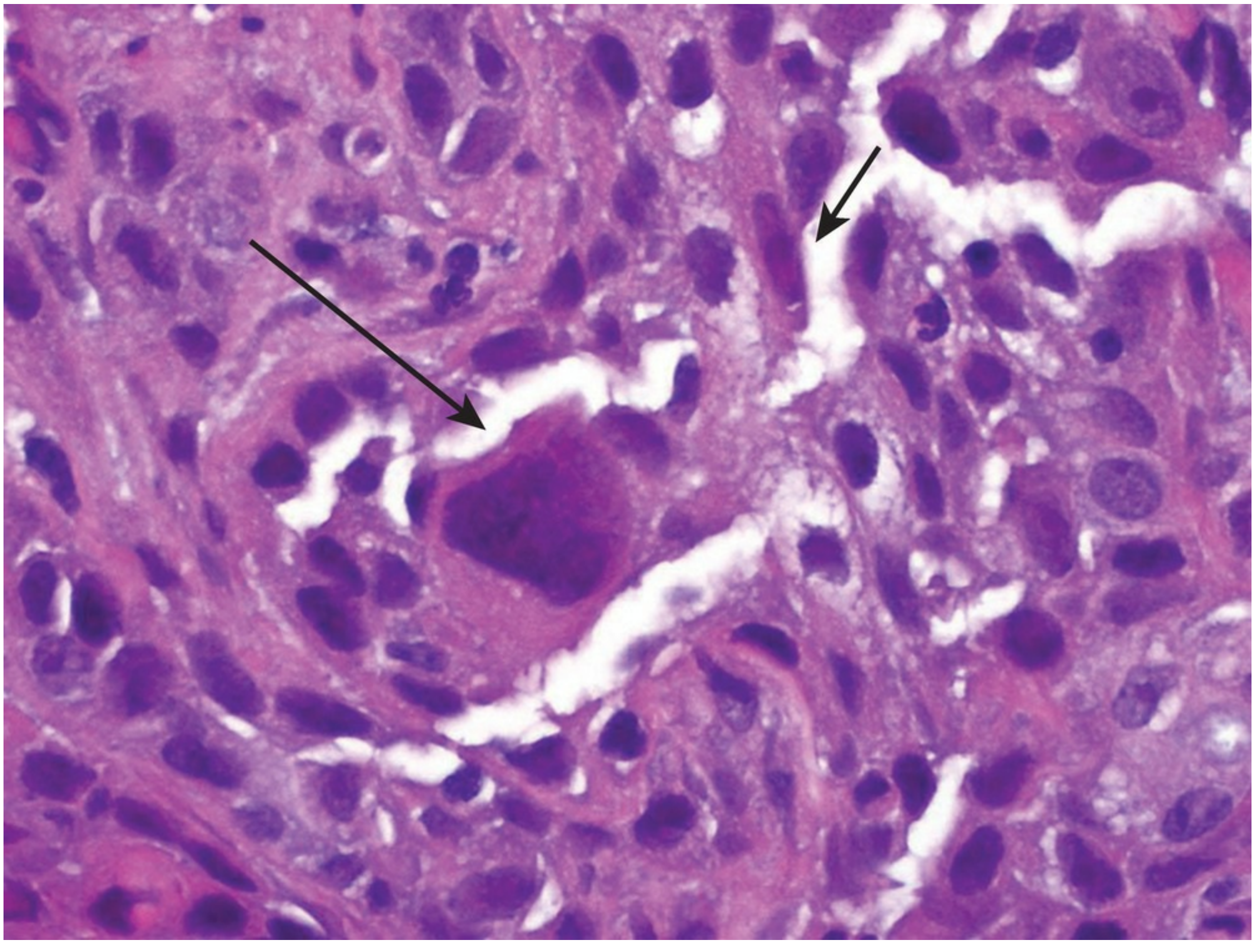

Figure 19.15. ATC with histologically characteristic giant cells (*long arrow*) and spindle cells (*short arrow*).

Management of ATC is challenging. Given the rapid progression of this disease, timely diagnosis and evaluation are essential. Once a diagnosis of ATC is made, a multidisciplinary team including a palliative care specialist should discuss the goals of care.

Patients with anaplastic thyroid carcinoma, resectable disease, and no distant metastases should be considered for surgical resection for better control of locoregional disease.

Goals of surgery must be clearly defined. If complete resection (R0/R1) can technically be achieved with minimal morbidity, it should be performed and may be associated with improved survival.[104] Importantly, gross tumor resection rather than debulking should be the goal of surgery. In patients with locoregional disease, the determination of whether the tumor is resectable should be based on what structures are involved, whether a satisfactory

resection can be achieved (R0/R1), and whether resection of the involved structure will result in significant morbidity or mortality. Surgery also plays a role in the management of ATC if the patients present in respiratory distress. Elective tracheostomy is best avoided unless there are acute airway issues. This has been an area of significant controversy. Although tracheostomy does prolong life, evading acute airway distress, and impending mortality, the chances of long-term survival are quite small in this patient population and there is question if the tracheostomy may prolong suffering. Certainly, this controversial area represents another challenge in treating patients with ATC.

Radiation is discussed in two patient populations with ATC. First is the surgically resected patient (R0/R1) receiving adjuvant radiation and the second is in the patient with unresectable ATC.

Selection bias certainly plays a role when analyzing treatment paradigms in ATC as patients presenting with less advanced/aggressive disease will often be the group offered therapy but a population in SEER-based study of 516 patients in a multivariate analysis revealed that, along with age, the combined uses of surgical resection and external beam radiotherapy were identified as the only independent predictors of survival.[105] In contrast, another group observed a survival benefit of 2 months with postoperative radiation that was not significant.[106] In patients with good performance status who wish to proceed with aggressive treatment, EBRT is offered with or without concurrent chemotherapy as soon as possible after surgery at our institution. Radiation with or without concurrent chemotherapy is also offered in patients who have undergone R2 resection or have unresectable disease with good performance status and who wish an aggressive approach. Radiation can also be used to palliate local symptoms.

Cytotoxic chemotherapy involving some combination of a taxane (paclitaxel or docetaxel) and/or anthracyclines (doxorubicin) and/or platin (cisplatin or carboplatin) can be given concurrently with radiation in patients who wish to proceed with aggressive management.

SUMMARY AND CONCLUSIONS

Thyroid cancer is the cancer with the most rapid increase in incidence worldwide. The incidence of thyroid cancer has almost quadrupled in the last quarter of the century, but fortunately, the vast majority of these tumors are

well-differentiated microcarcinomas with overall survival approaching 98%. There have been several new advances in the diagnostic evaluation of thyroid cancer including genetic expression classifiers and molecular analyses of needle biopsies. These are ancillary tests that help make a decision that thyroid nodules have a high index of suspicion for cancer and need to be operated on. The debate continues regarding the extent of thyroidectomy and lobectomy versus total thyroidectomy in early-stage disease. Another debate now revolves around the role of prophylactic central compartment dissection and extent of lateral neck dissection recommended in the treatment of early- to intermediate-risk tumors. The role of radioactive iodine continues to evolve with less and less use of radioactive iodine in patients with low-risk thyroid cancer. If RAI is to be used, it is best used now with recombinant TSH rather than making patients hypothyroid for 6 to 8 weeks. This is a major advance in maintaining the quality of life of these patients with thyroid cancer. Posttreatment tumor surveillance is based on serum thyroglobulin assay and ultrasound of the thyroid. PET scan plays an important role in aggressive thyroid cancers such as tall cell or poorly differentiated thyroid cancer. The role of external radiation therapy continues to evolve as we understand more about the prognostic factors of thyroid cancer and aggressive histologies. Ultrasound has become an important diagnostic tool both preoperatively and postoperatively for long-term follow-up. Genetic evaluation of patients presented with MTC is extremely critical especially with respect to RET mutation as this test plays an important role when considering prophylactic thyroidectomy in children with MTC and RET mutation. Calcitonin DT and thyroglobulin DT are also important prognostic markers in the management of MTC patients. There is considerable interest in nerve monitor and energy devices such as harmonic and LigaSure during the procedure of thyroidectomy. Remote access thyroid surgery appears to be quite popular in Southeast Asia with debatable interest in the United States. Anaplastic thyroid carcinoma continues to be a major treatment challenge to the treating physicians and it appears that we have made very little progress in the management of this nearly universally lethal disease. However, combination chemotherapy, external radiation therapy, and targeted therapies have enabled us to offer the best treatment available today.

20 Tumors of the Parathyroid Gland

Katrina Chaung William S. Duke David J. Terris

The parathyroid glands maintain a delicate calcium homeostasis within the body, and dysfunction of these glands may result in significant sequelae. The recognition and treatment of parathyroid disorders can be challenging. Modern advances in imaging techniques and intraoperative parathyroid hormone (PTH) assays are invaluable in the contemporary management of parathyroid disorders.

HISTORY

The history of the parathyroid glands, from their discovery to the understanding of their physiologic and pathologic importance, unfolded somewhat recently. In November of 1849, the two-ton great Indian Rhinoceros owned by the Zoological Society of London passed away. Sir Richard Owen, a renowned British anatomist and Conservator of the Museum in the Royal College of Surgeons, dissected the cadaver in his own resident quarters.[1,2] He provided the first recorded description of the parathyroid gland: “a small compact yellow glandular body attached to the thyroid at the point where the vein emerged.”[1]

In 1880, a Swedish medical student Ivar Viktor Sandström identified a vascularized organ distinct from the thyroid gland and lymph nodes that he named *glandulae parathyroidae*.[1–3] In his writings, Sandström even noted the variable location of these entities.[3]

It was not until the work of French physiologist Eugene Gley some years later that the function of these structures became evident.[1] Tetany was first described following thyroidectomy cases performed by Bilroth in the late 1870s. Initially, this complication was attributed to hyperemia of the brain as

a result of the thyroidectomy.[3] Gley observed that tetany and death ensued if these *glandulae parathyroidae* were excised during thyroidectomy in dogs. Further studies revealed that the abnormal neuromuscular sequelae seen in animals postthyroidectomy could be prevented by autotransplantation of these glands.[1]

In 1891, Friedrich Daniel von Recklinghausen described lesions that he termed osteitis fibrosa cystica of von Recklinghausen.[1,2] A Viennese pathologist, Jakob Erdheim, also found enlarged parathyroid glands on autopsy of patients with osteomalacia and osteitis fibrosa cystica.[3] At that time, the bone disease was not attributed to a parathyroid abnormality; in fact, parathyroid enlargement was believed to be a compensatory consequence of the bone disease.[1–3] In 1915, another Viennese pathologist, Friedrich Schlagenhaufer, described two patients with osteomalacia who were each found to have a single parathyroid tumor at autopsy, suggesting that the enlarged parathyroid glands might actually be the cause of the bone disease.[1]

It was not until 10 years later that Felix Mandl, a Viennese surgeon, attempted the first excision of a parathyroid tumor in a patient with severe von Recklinghausen disease. The patient, a tram conductor, was severely disabled and unable to ambulate due to his disease.[1,2] He underwent a neck exploration with excision of a 25-mm “yellowish-brown almond-shaped tumor” in the area of the left inferior thyroid gland. A few days postoperatively, the patient was able to walk without assistance and demonstrated significantly lower blood and urine calcium levels. He did well for 6 years before experiencing recurrent hypercalcemia and nephrolithiasis. Upon reoperation, Mandl was unable to find abnormal parathyroid tissue, and the patient passed away shortly thereafter. The recurrence was attributed to ectopic parathyroid tissue, but, interestingly, none was found at autopsy.[1,2]

The first parathyroid operation in the United States followed shortly thereafter. The patient, sea captain Charles Martel, was diagnosed with hyperparathyroidism (HPT) and had lost 6 inches in height due to associated bone demineralization.[2,3] He underwent six operations, beginning in 1927, at the Massachusetts General Hospital that either removed normal parathyroid tissue or found no abnormal tissue. By 1932, his renal function had begun to deteriorate and Dr. Churchill, under the insistence of Martel himself, planned a mediastinal exploration to search for ectopic parathyroid tissue. A 3-cm

tumor was identified in the mediastinum and removed. Unfortunately, the patient developed an impacted ureteral stone several weeks later and passed away from laryngospasm during a procedure to relieve the obstruction.[2] The first documented parathyroid carcinoma was excised at Cook County Hospital in Chicago in 1926. The patient, a 29-year-old female, had multiple masses in the neck and required multiple subsequent excisions for recurrences.[3]

In 1963, Berson and Yalow developed a radioimmunoassay for PTH that allowed for the accurate acquisition of serum PTH levels.[2–4] The development of multichannel autoanalyzing systems made it possible to rapidly determine serum calcium levels. With the advent and subsequent improvement of these innovations, asymptomatic patients could be diagnosed with parathyroid abnormalities before presenting with advanced bone and renal disease, allowing for more expeditious and efficacious management.

EMBRYOLOGY AND ANATOMY

During the 5th week of gestation, the inferior and superior parathyroid glands develop from the dorsal endoderm of the third and fourth branchial pouches, respectively.[2,4,5] As the cervical spine lengthens and the heart and great vessels descend, the inferior glands migrate caudally within the tail of the thymus. As the thymus migrates further into the upper thorax, its tail involutes, leaving the inferior glands near the inferior poles of the thyroid gland.[2,4,5] Concurrently, the superior glands migrate intimately associated with the ultimobranchial bodies, halting at the lateral aspect of the posterior superior to the middle third of the thyroid gland. This disparity in migrational distance during development explains the increased variability of anatomic locations of the inferior parathyroid glands as compared to those of the superior glands.[5] Ectopic parathyroid glands have a reported incidence ranging from 6% to 19%.[6,7]

Most individuals have four parathyroid glands. Fewer than four glands have been found in ~2% to 3% of individuals.[8–11] The incidence of supernumerary glands ranges from 5% to 13%.[5,8,9] Dissection of 428 cadavers by Gilmour[12] in 1928 revealed 5 parathyroid glands in 6.7% of the specimen, 6 in 0.05% of the specimen, and 12 parathyroid glands in one

specimen. Supernumerary glands are commonly found in the mediastinum within the thymus or associated with the thyrothymic tract.[2] Surgeons must be cognizant of the potential variability in the number of parathyroid glands, particularly in patients with multigland disease. In one study of over 2,000 patients who underwent surgery for primary HPT, the offending parathyroid adenoma was found to be a supernumerary gland in 0.7% of the cases.[13]

The superior parathyroid glands lie dorsal to the coronal plane created by the course of the recurrent laryngeal nerve (RLN) through the neck; the inferior glands lie ventral to this plane.[5] This relationship to the plane of the RLN is nearly always constant and therefore an important concept during surgical exploration of the glands.

In approximately 80% of patients, the superior parathyroid glands can be identified within 1 cm above the intersection of the RLN and inferior thyroid artery. They are usually intimately associated with the thyroid capsule at the posterosuperior thyroid pole.[2,5] The glands can be distinguished from neighboring thyroid nodules by their mobility within the extension of the pretracheal fascia that also envelopes the thyroid gland.[2] Common locations of ectopic superior parathyroid glands include paraesophageal, retroesophageal, and retrolaryngeal sites; the tracheoesophageal groove; within the thyroid gland; the posterior mediastinum; and within the carotid sheath.[5,7,14] In rare instances, they are found in lateropharyngeal or intercricothyroid and retropharyngeal locations.[2] In some instances, the superior glands may be overly descended, lying inferior to the inferior parathyroid glands; alternately, they may also be found in an undescended location near the hyoid bone or pharyngeal musculature.[4]

The inferior parathyroid glands are generally found on the posterolateral aspect of the lower thyroid pole, inferior to the intersection of the RLN and inferior thyroid artery. They may also be found within the thyrothymic ligament.[7,15] As mentioned previously, due to its longer course of migration during development, the inferior glands have more variability in anatomic position than the superior glands.[5] Additionally, if there is a delay or failure to separate from the thymus, the inferior glands may be drawn into the anterior mediastinum.[5] Common ectopic locations include the thyrothymic ligament and anterior mediastinal, intrathymic, and intrathyroidal positions.[5] Less common ectopic sites include the aortopulmonary window, the carotid

sheath, and pericardial and pyriform sinus locations.[2,7]

Acquired ectopia of enlarged neoplastic and normal parathyroid glands results from migration under the influence of gravity, changes in intrathoracic pressure, deglutition, and mechanical mass effect as in the case of large goiters. In such instances, superior parathyroid glands can migrate along the posterior vertebral fascia into the posterosuperior mediastinum.[2,7,16] Similarly, the inferior glands can migrate into the anterior mediastinum along the thyrothymic ligament.[5] It is estimated that up to one-third of missed parathyroid adenomas are ultimately located in the anterior mediastinum.[2]

With some variability, the superior glands derive their blood supply from a single branch off of the inferior thyroid artery. Occasionally, the arterial supply is from a branch of the superior thyroid artery or from an arterial anastomoses.[2,5] Venous drainage is usually via the superior or lateral thyroid veins. The inferior thyroid artery also supplies the inferior parathyroid glands; this relationship is often retained even in cases of ectopic mediastinal migration, but rare cases of arterial supply from a branch of the internal mammary artery or a direct branch off the aortic arch have been reported.[5,15] Venous drainage is often via the lateral or inferior thyroid veins.[5] Lymphatic drainage of the parathyroid glands parallels that of the thyroid gland, draining into the paratracheal and deep cervical lymphatic nodes.[2] Preservation of the vascular supply during surgery is crucial in maintaining the viability and function of the gland.

Normal parathyroid glands are smooth with an oval or bean shape. They typically weigh between 40 and 50 mg, though some studies have cited the upper limit of normal to be 65 mg.[2,5] Variations in weight have been observed between ethnicities, genders, comorbidities, and even within individuals. Contingent upon vascularity, adipose tissue, and oxyphil content, their color ranges from tan to reddish brown.[2,4] Parathyroid glands can easily be confused with adipose tissue, thyroid nodules, lymph nodes, or thymic remnant. They may be distinguished from adipose tissue by a characteristic “gliding” motion against the surrounding tissues. Careful visual observation and subtle differences in palpation can distinguish between a normal and abnormal gland.

Histologically, a thin connective tissue capsule is present with septae extending into the parenchyma, dividing the gland into clusters of functional

cells. The parenchyma is predominantly composed of chief cells residing in an adipose tissue–rich stroma. The functional chief cells are slightly eosinophilic and contain copious PTH secretory granules. The percentage of adipose tissue content in normal glands, previously thought to be a marker of functional status, has been seen to vary among individuals depending on age, gender, and possibly other factors.[2] Oxyphil cells contain an abundance of mitochondria. Although their function is unknown, some theorize that their high mitochondrial content may explain the high avidity of abnormal parathyroid glands for the technetium (Tc)-99m used in localization scans.[2]

PHYSIOLOGY

PTH is an essential factor in the intricate balance of serum calcium homeostasis. PTH secretion is primarily in response to low serum ionized calcium levels, the active component of serum calcium. This is a sensitive relationship; even minute alterations in calcium concentration by as little as 0.04 mmol/L have been shown to elevate serum PTH by 100% or more.[2] Its influence is exerted via cyclic adenosine monophosphate (cAMP) pathways on bone to increase osteoclastic reabsorption and on the kidneys to increase tubular calcium absorption, decrease calcium excretion, and increase tubular phosphate excretion. Additionally, PTH promotes renal 1α-hydroxylase–mediated conversion of 25-hydroxyvitamin D3 (calcifediol) to 1,25-dihydroxyvitamin D3 (calcitriol). This biologically active form of vitamin D, in turn, stimulates the small intestine to increase absorption of calcium and phosphorus. Calcitriol also promotes the release of calcium and phosphate from bone. The net effect is an increase in serum calcium and a drop in serum phosphate. The increase in serum calcium produces negative feedback to decrease the secretion of PTH (Fig. 20.1). As a further feedback mechanism, if calcium levels are too high, calcitonin, produced by parafollicular C cells of the thyroid gland, inhibits calcium reabsorption from bone and increases renal clearance of calcium and phosphate.[2,5,17]

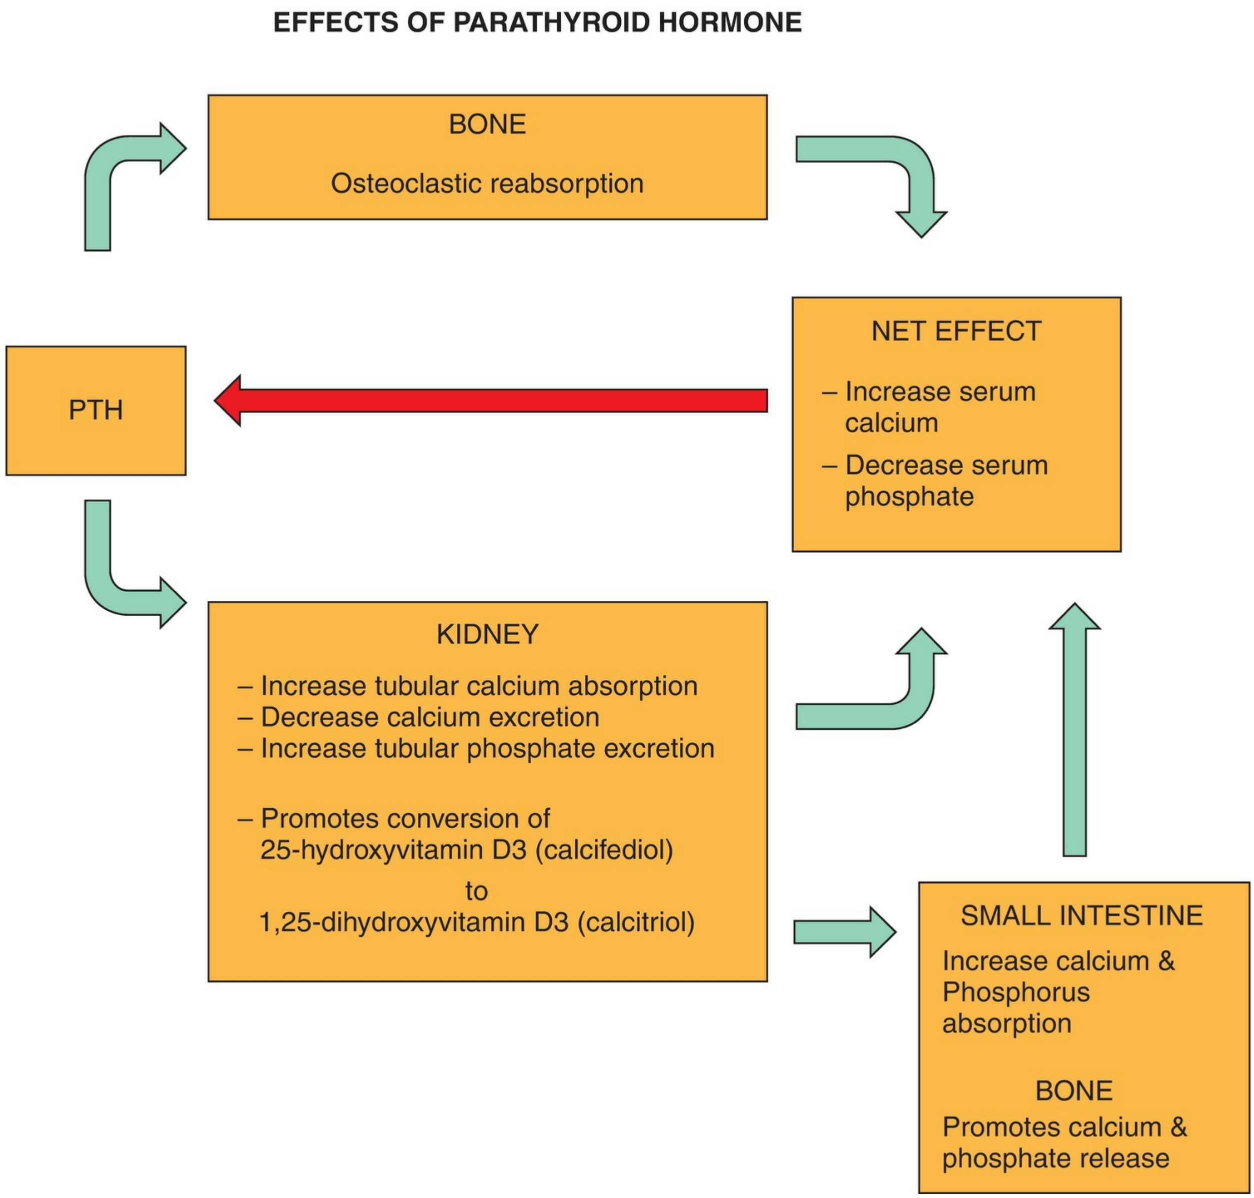

Figure 20.1. Effects of parathyroid hormone (PTH).

Once secreted from the parathyroid gland, the biologically active (1 to 84) PTH molecule is rapidly degraded, with a half-life of 3 to 5 minutes in individuals with normal renal function. The intact form is cleaved into a biologically active amino-terminal fragment that is rapidly cleared from the circulation and an inactive carboxyl-terminal fragment that undergoes slow renal clearance.[2,17] The initial PTH radioimmunoassays took up to 24 hours to obtain results. With the development of immunoradiometric assays and subsequent immunochemiluminometric assays (which utilize distinct antibodies for the amino and carboxyl terminals of the intact PTH molecule),

the process can be reduced to <15 minutes. Newer assays that measure the intact hormone are a more accurate measure as compared to older assays that principally measured the inactive fraction.[2,17] Such assays can be used for rapid intraoperative assessments of PTH levels. Recent studies have found that some assays may utilize antibodies that cross-react with fragments they were not intended to target. This may hold especially true for patients with renal failure and may account for some of the variability between different assays types.[17]

Of note, nonparathyroid sources of PTH have been reported in rare cases of malignancy including ovarian, small cell carcinomas, and neuroendocrine tumors.[2,18]

BENIGN LESIONS

Parathyroid Adenoma

Parathyroid adenomas are benign tumors of the parathyroid gland and account for 80% to 90% of primary cases of HPT.[2,5] Parathyroid adenomas have a female predominance with an increased incidence in individuals over the age of 50. An association between head and neck ionizing radiation exposure at an early age and development of parathyroid adenomas has also been shown.[19,20] The majority of adenomas occur sporadically and usually involve a solitary gland. Some sources indicate inferior gland involvement more frequently than the superior glands.[2,5,21] The incidence of multiple adenomas has been reported to range from 1.7% to 11.5%.[22,23]

Parathyroid adenomas are monoclonal neoplasms composed of a clonal expansion of cells with altered calcium sensitivity.[22,24] Various genomic events have been proposed as the trigger for this cellular propagation. Among the events recognized are a rearrangement of protooncogene *parathyroid adenomatosis 1* (PRAD1) into the vicinity of the regulatory region responsible for PTH synthesis.[25,26] Somatic mutations of the *multiple endocrine neoplasia 1* (MEN1) tumor suppressor gene have been demonstrated in 20% of primary HPT cases.[27] The loss of tumor suppressor function, specifically of loci, located on chromosome 1p, is believed to be an even more common cause of sporadic adenomas.[28]

Upon gross examination, parathyroid adenomas tend to have a more reddish-brown coloration and an increased, rubbery consistency as compared to normal glands. Adenomatous glands may be bi- or multilobed with a smooth, nodular, or cystic-appearing capsule.[2] Histologic examination reveals hypercellular nodules of chief cells arranged in sheets or cords surrounded by a rim of normal-appearing parathyroid tissue. Compared with those contained in normal glands, chief cells within adenomas are larger with more nuclear pleomorphism and giant cell formation. Nuclear atypia and mitotic figures may also be observed, but these characteristics are not of diagnostic value in distinguishing between benign or malignant parathyroid abnormalities.[2,5,29]

Various subtypes of parathyroid adenomas have been reported, including oncocytic adenomas, lipoadenomas, water-clear cell adenomas, large clear cell adenomas, and atypical adenomas. Most have previously been thought to be nonfunctioning entities; however, recent evidence may suggest associations with HPT.[2]

Hyperplasia

Primary chief cell hyperplasia causes enlargement of all parathyroid glands either uniformly or variably and accounts for 5% to 15% of primary HPT cases. As with parathyroid adenomas, hyperplasia also shows a female predilection.[2,5] It is characterized by a proliferation of chief cells, and sometimes oncocytes, in multiple glands, causing an increase in parenchymal bulk without a known stimulus for elevated PTH secretion. The parenchymal cells can form solid sheets, cords, or follicles.[5] Nuclear atypia and mitotic figures are very rarely seen.[2] Hyperplastic glands lack the “rim” of normal parathyroid tissue found in adenomas, but a “pseudorim” around nodules may be seen within the hyperplastic glands.[5] Approximately 30% of cases are associated with some type of familial HPT or MEN syndrome.[2]

A rare form of hyperplasia, water-clear cell hyperplasia, can cause significant hypercalcemia. Interestingly, this is the only condition where the superior parathyroid glands are consistently larger than the inferior glands. Glands affected by this hyperplasia are often asymmetrically enlarged with lobular extensions and have a dark chocolate brown color. Microscopically, there is a diffuse proliferation of clear cells with small dense nuclei and

cytoplasm filled with small vacuoles.[2,5] Histologically, the appearance is similar to that of renal cell carcinoma.[2]

In cases of hyperplasia secondary to renal failure, the glands appear to be more uniform in size early in the disease. Asymmetry becomes more pronounced as the disease progresses, and the degree of enlargement seems to mirror the severity of renal disease.[2]

Multigland Disease

The incidence of synchronous double parathyroid adenomas ranges from 2% to 10% and increases with age. It is estimated that ~50% of double adenomas localize to two distinct locations on preoperative studies.[2] Intraoperative PTH assessment can be extremely helpful in reflecting the sequential decrease in hormone levels after excision of each hyperfunctional gland. Identification of at least one normal gland is crucial in ruling out four-gland hyperplasia.

In approximately 10% to 15% of patients with sporadic primary HPT, diffuse hyperplasia of the parathyroid glands may be present.[2] A thorough medical and family history must be performed to rule out MEN syndrome. Preoperative localization studies may not localize in these cases. Bilateral exploration should be performed if this condition is suspected. Intraoperative PTH levels are useful to confirm that all hyperfunctional tissues have been removed.

MALIGNANT LESIONS

Parathyroid Carcinoma

Parathyroid carcinoma is a rare malignancy and accounts for <1% of cases of primary HPT. In contrast to the previously mentioned etiologies of primary HPT, there is equal gender distribution, and this condition often presents during the fourth through fifth decades, ~10 years younger than patients with benign primary HPT. There is no apparent ethnic or geographic predominance.[5,30,31] Purported association with history of head and neck irradiation, chronic renal failure, and familial HPT, in particular familial isolated HPT and hereditary hyperparathyroidism–jaw tumor syndrome (HPT-JT) and MEN syndromes, has been reported.[30,32–34] Overexpression of

cyclin D1 has been found in a high percentage of parathyroid carcinomas, but the significance of that finding is unknown. An inactivating mutation of a recently described tumor suppressor gene *HRPT2* that encodes for the protein parafibromin, a protein with unknown function, has been identified as a possible factor in the pathogenesis of parathyroid carcinomas.[30,35]

Parathyroid carcinomas have been identified in eutopic, ectopic, and supernumerary glands.[36] In contrast to patients with benign causes of primary HPT who generally present with mild hypercalcemia, patients with parathyroid carcinomas can present with significantly elevated calcium levels that are 3 to 4 mg/dL above the upper limit of normal.[5,30] Approximately 70% of patients present with serum calcium levels above 14 mg/dL and intact PTH levels at least five times the upper limit of normal. Additionally, a palpable firm cervical mass is noted in 30% to 50% of patients upon presentation.[2,37] Eighty percent of patients complain of hypercalcemic symptoms including fatigue, weakness, and polydipsia, and many manifest evidence of target organ effects, specifically within the kidney and skeletal system. One series reported nephrolithiasis in 56% and renal insufficiency in 84% of patients with parathyroid carcinoma; another cited concomitant bone and renal disease in 50%.[30,31,37] This is in contrast to patients with benign causes of HPT where only about half complain of symptoms and neck masses are very rarely seen.[30] The finding of RLN palsy should also heighten suspicion for carcinoma.[2,5,38]

Definitive preoperative diagnosis is impossible. Biopsy is not recommended due to the possibility of tumor seeding.[5] Treatment consists of an en bloc wide resection with a tumor-free margin of tissue, central neck dissection, and ipsilateral thyroidectomy.[2,39] If local infiltration into surrounding structures including the strap muscles, RLN, trachea, or esophagus is found, excision is required to reduce risk of recurrence. Regional metastases to the lateral cervical nodal basins and distant spread to the lungs, liver, kidney, and bone can also be seen. If local or metastatic spread is evident, a wide resection of the metastases is indicated with the aim of reducing tumor burden and thereby serum calcium levels. Metastatic cancer to lateral cervical neck basins is rarely encountered during the initial presentation; thus, lateral neck dissections should be performed only for clinically or radiographically identifiable lymphadenopathy.[2,40]

Some investigators have also advocated for the use of postoperative adjuvant radiotherapy in select cases to reduce the rate of locoregional recurrence.[41–45] One recent series followed 27 patients treated at MD Anderson and reported that the rate of local recurrence appeared to be lower in patients who received adjuvant radiotherapy.[44] To date, studies have followed small patient cohorts without comparison groups, so quantitative significance remains unclear.[43,46] The context of disease, such as extent of disease, positive margins, and angioinvasion, in which adjuvant radiotherapy may be indicated still remains to be defined.[47] The efficacy of other treatment modalities including chemotherapy, bisphosphonates, and biotherapy has also not yet been proven.[2,48]

Parathyroid carcinomas are considered a slow-growing disease in most cases. Morbidity and mortality are secondary not to tumor spread but rather to the effects of severe hypercalcemia. The overall 5- and 10-year survival rates are estimated to be 77% and 63%, respectively.[5] Appropriately aggressive surgical resection during the initial operation is considered one of the most crucial prognostic factors for parathyroid carcinoma.[2,31] Although cure is rare in cases of recurrent cancer, which may present up to 20 years or more after initial treatment, every effort to perform reoperations should be undertaken to reduce the tumor burden and the associated hypercalcemia.[2,5]

Grossly, parathyroid carcinomas are firm, grayish-white masses with increased vascularity and are often found to be densely adherent to surrounding soft tissues. As frozen section is unreliable, diagnosis is made histologically based on presence of capsular and vascular invasion. Mitoses can be an indicator of malignancy, but as mentioned previously, mitoses may also be identified in cases of parathyroid adenoma or hyperplasia; furthermore, the absence of mitotic figures does not exclude the diagnosis of carcinoma.[49] Desmoplastic reaction, nuclear atypia, and necrosis may also be more common in carcinoma than in benign lesions but also do not constitute a diagnosis. It is also unclear if parathyroid carcinoma arises from malignant transformation of an existing benign lesion.[2]

HYPERPARATHYROIDISM

Primary Hyperparathyroidism

Primary HPT is a disorder of excess PTH production by one or more parathyroid glands with subsequent serum calcium level elevation. Primary HPT should also be considered in cases where the PTH level is within the normal range but is inadequately suppressed relative to the serum calcium level. The disease is three times more common in women and typically presents during the sixth decade. The prevalence of primary HPT in the general population is 0.1% to 0.3% but is 1% or higher in women over 60 years of age.[2] Wermers et al.[50] determined from a population-based study from 1993 to 2001 that a significant spike in the diagnosis of primary HPT in the 1970s, attributable to the widespread use of automated serum calcium measurements, gave way to a progressive decrease in incidence. Theories for this decline include an increase in supplemental calcium and vitamin D use, the use of head and neck irradiation for various benign childhood disorders becoming obsolete, and the removal of serum calcium levels from routine chemistry panels at that institution. Parathyroid adenomas are responsible for 80% to 90% of primary HPT cases, and the majority of those are from single-gland disease. Approximately 5% to 15% are due to parathyroid hyperplasia and <1% are due to parathyroid carcinoma.[2,5,22,51]

Secondary Hyperparathyroidism

Secondary HPT is caused by an external stimulus, usually chronic renal failure, which induces a disruption in calcium homeostasis. This results in elevated serum PTH levels in the setting of hypocalcemia. Other etiologies include osteogenesis imperfecta, Paget disease, multiple myeloma, pituitary adenoma, and conditions that cause vitamin D deficiency.[2,52]

In chronic renal failure, the kidneys are unable to excrete phosphorus, reabsorb calcium, or produce adequate levels of calcitriol. Consequently, serum calcium levels decrease, providing stimulus to the parathyroid glands. Hyperphosphatemia can also directly stimulate PTH synthesis while indirectly decreasing the free calcium level.[2,5] Chronic HPT in patients with renal failure can lead to bone disease including osteitis fibrosa cystica and mixed uremic osteodystrophy. Other consequences like neurobehavioral changes and soft tissue calcification, including that of the cardiovascular system, can also be seen.[52,53] In fact, coronary artery calcifications have been shown to be more common in younger patients on dialysis.[54]

The first-line treatment is correction of the underlying cause and medical therapy. Surgery is usually considered in cases refractory to medical therapy and in cases of severe hypercalcemia, severe bone disease, calciphylaxis, severe pruritus, or severe myopathy. PTH levels are usually >1,000 pg/mL.[52] There are no firm National Institutes of Health (NIH) guidelines for surgery as there are for primary HPT, but recent studies have supported surgical treatment in improving the symptoms and quality of life in patients with secondary HPT.[55] Percutaneous ethanol injection therapy (PEIT), first introduced in the 1980s but used sporadically due to its technical difficulty, has been recommended by groups in Japan as an alternative to surgical therapy in select cases.[56]

Tertiary Hyperparathyroidism

Tertiary HPT is characterized by autonomous overproduction of PTH from the parathyroid glands following long-standing secondary HPT that persists after the inciting stimulus has been rectified. This state is no longer influenced by serum calcium levels. Persistently elevated serum PTH levels in the setting of hypercalcemia and low phosphorus levels are seen after renal transplantation. In this condition, correction of the underlying etiology, for instance, successful renal transplantation in chronic renal failure patients, does not halt the excess production of PTH. Etiologies besides chronic renal failure causing tertiary HPT are rare.[5,52]

Most cases demonstrate hyperfunction of all the parathyroid glands; thus, a total or subtotal parathyroidectomy is recommended. As in secondary HPT, there are no NIH guidelines for surgery. The exact mechanism of tertiary HPT is yet unknown but is theorized to be due to the monoclonal expansion of parathyroid cells forming nodules within already hyperplastic glands and a shift in the set point of the calcium-sensing mechanism.[2,52]

Familial Causes of Hyperparathyroidism

HPT is typically sporadic with familial cases accounting for <5% of all cases (Table 20.1).[2] Familial cases of HPT tend to present at a younger age with multigland involvement. There is a higher proclivity for persistent or recurrent disease as compared to sporadic cases, mandating long-term surveillance.

Table 20.1 Familial Causes of Hyperparathyroidism

Disease	Associated Abnormalities	Characteristics
Multiple endocrine neoplasia type 1 (MEN1)	Anterior pituitary tumors Pancreatic neoplasms Parathyroid hyperplasia	Increased rate of persistent and recurrent disease as compared to sporadic disease
Multiple endocrine neoplasia type 2 (MEN2A)	Medullary thyroid carcinoma Pheochromocytoma Parathyroid hyperplasia	Less aggressive than MEN1 disease Screening for RET protooncogene should be performed Screen for pheochromocytoma prior to surgery
Familial isolated hyperparathyroidism	—	Presents at a young age More aggressive than sporadic or MEN-associated disease
Hyperparathyroidism–jaw tumor syndrome (HPT-JT)	Fibroosseous tumors of the mandible Wilms tumor Recurrent parathyroid adenomas	Possible association with parathyroid carcinoma
Familial neonatal hyperparathyroidism	—	Presents with hypotonia and failure to thrive Urgent treatment indicated
Benign familial hypocalciuric hypercalcemia (BFHH)	—	Nonsurgical disease

MULTIPLE ENDOCRINE NEOPLASIA

Multiple Endocrine Neoplasia Type 1

Multiple endocrine neoplasia type 1 (MEN1 or Wermer syndrome) is an autosomal dominant entity characterized by anterior pituitary tumors, parathyroid hyperplasia, and pancreatic neoplasms. Carcinoid tumors of the gastrointestinal tract, bronchus, and thymus as well as ovarian, thyroid, and adrenal tumors have also been reported. Subcutaneous lipomas and angiofibromas are seen in up to one-third of patients. MEN1 is rare but has a penetrance as high as 95% by the age of 40; disease manifestations are thought not to present before the age of 5.[57,58] Patients with MEN1 are found to have a mutation of the *MEN1* tumor suppressor gene at the 11q13 loci that encodes the protein menin.[59]

The most common manifestation of MEN1 is primary HPT, which is present in over 95% of patients under 30 years of age. Diffuse four-gland parathyroid hyperplasia is usually found.[2] MEN1 should be considered in patients who manifest symptoms of pituitary or pancreatic tumors or who reveal a family history of MEN or other endocrinopathies.

Treatment of HPT secondary to MEN1 is a total parathyroidectomy with autotransplantation or subtotal parathyroidectomy. The extent of resection is a subject of debate given a higher rate of persistent or recurrent disease as

compared to patients with sporadic disease after the same operation. Continued exposure of a parathyroid remnant to a yet unknown trophic factor has been postulated to account for the higher rate of persistent or recurrent disease as compared to sporadic hyperplasia cases.[2,60] Persistent disease has often been found to be due to a missed supernumerary gland; thus, bilateral transcervical thymectomy is also advocated.[2,60]

Multiple Endocrine Neoplasia Type 2A

Multiple endocrine neoplasia type 2 (MEN2A or Sipple syndrome) is an autosomal dominant syndrome with high penetrance, characterized by medullary thyroid carcinoma, pheochromocytoma, and HPT. Other disease manifestations include lichen planus, amyloidosis, and Hirschsprung disease. Although the expression may vary, medullary thyroid carcinoma is seen in almost all cases. HPT usually presents after the age of 30 and appears to show a lesser degree of hypercalcemia and symptomatology than that seen in MEN1 or sporadic HPT.[2]

Mutations of the *RET* protooncogene on chromosome 10 that encodes a tyrosine kinase receptor protein have been found to be responsible for this syndrome.[61] Patients with medullary thyroid carcinoma should be screened for the *RET* protooncogene as should their family members if a *RET* mutation is identified.

Prior to surgical treatment, screening for pheochromocytoma with serum and urine catecholamine and metanephrine levels is indicated to avoid intraoperative hypertensive crises and potential disastrous consequences.

Patients with MEN2A have less frequent multiple parathyroid gland involvement and a lower rate of persistent or recurrent HPT after surgery as compared to patients with MEN1, though the rate of recalcitrant disease is still higher than in sporadic cases. During surgery, all four glands are identified with excision of only morphologically abnormal or enlarged glands; thymectomy is usually not indicated as supernumerary glands are rare but should be considered if all four glands are found to be hyperplastic.[2]

FAMILIAL ISOLATED HYPERPARATHYROIDISM

Familial HPT is suspected in hyperparathyroid patients who have a first-degree relative with surgically proven HPT in the absence of a family history of MEN syndromes. Familial HPT patients tend to present younger, between the ages of 10 and 30, with a more aggressive course than sporadic or MEN-associated HPT. Hypercalcemic crisis may even be the presenting picture. Nephrolithiasis is also seen in one-third to one-half of patients. The rate of recalcitrant disease after surgery has been reported to be as high as 33% due to a high incidence of multigland and supernumerary gland disease. Before treatment, all other familial causes of HPT should be excluded.[2]

Hyperparathyroidism–Jaw Tumor Syndrome

Hyperparathyroidism–jaw tumor syndrome (HPT-JT) presents as recurrent parathyroid adenomas, fibroosseous tumors of the mandible and Wilms tumors. Renal cysts and hamartomas can also occur. Primary HPT is the most common manifestation, and a possible association with parathyroid carcinoma has also been reported.[30]

Familial Neonatal Hyperparathyroidism

This is a rare entity with clinical signs manifested as early as the first week of life but occasionally not evident until 3 months or later. Severe hypercalcemia is seen in association with severe hypotonia, failure to thrive, and respiratory distress.[62] Many individuals with familial neonatal HPT have a family history of benign familial hypocalciuric hypercalcemia (BFHH). Familial neonatal HPT is caused by two mutated alleles at the 3q locus; in fact, patients with BFHH have been found to be heterozygous for the mutation. This condition usually requires urgent treatment with a total parathyroidectomy with autotransplantation and bilateral transcervical thymectomy and is associated with a high recurrence rate.[2]

Benign Familial Hypocalciuric Hypercalcemia

BFHH presents the biochemical profile of primary HPT but is a nonsurgical entity. BFHH is inherited in an autosomal dominant fashion and is linked to inactivating mutations of calcium-sensing receptors of the parathyroid cell. A low 24-hour urinary calcium excretion level relative to the degree of hypercalcemia is seen as well as a urinary calcium to creatinine clearance

ratio of <0.01.[2] BFHH usually does not yield any long-term adverse effects and surgery is not indicated.

Clinical Presentation

Symptoms of HPT may be varied and vague. Fatigue, depression, memory problems, malaise, appetite change, abdominal discomfort, constipation, weight loss, musculoskeletal pain, and muscular weakness may serve as the only indicators of disease. Though some patients may appear "asymptomatic," upon specific questioning, most do endorse symptoms. As previously mentioned, routine serum calcium screenings during routine health screenings have aided in the diagnosis of primary HPT in patients in whom the symptoms may be nonspecific and subtle. Consequently, presentation with the "classic" symptoms of hypercalcemia such as osteitis fibrosis cystica, nephrolithiasis, pathologic fractures, and hypercalcemic crisis is presently less common.

In the past, over 50% of patients with HPT suffered nephrolithiasis, mostly composed of calcium oxalate stones, and nephrocalcinosis, compared with ~10% to 20% of patients in recent years.[2,63] Osteitis fibrosis cystica is a condition in which areas of osteoclastic resorption are replaced by peritrabecular fibrosis causing a cyst-like brown tumor. These are most often seen in the phalanges, facial bones, and ribs and generally regress after treatment of the HPT. Previously a common manifestation, currently, it is encountered only in ~2% of patients with HPT.[64] Other effects of PTH on the skeletal system include osteomalacia, osteoporosis, and pathologic fractures. Weakness and fatigue of proximal muscle groups are also seen in ~40% of patients with mild primary HPT, and evidence of EMG changes and atrophy of skeletal muscle seen on biopsy have been reported. Severe disease may even preclude ambulation and function. Most symptoms are noted to improve after parathyroidectomy. Neuropsychiatric symptoms of anxiety, depression, cognitive dysfunction, memory loss, and even frank psychosis are more common in the elderly who have baseline mild cognitive abnormalities. Increased gastrin and gastric acid production secondary to hypercalcemia may also lead to peptic ulcer disease, pancreatitis, and cholelithiasis.[2] Hypercalcemic crisis may occur in cases of significantly elevated calcium levels, causing mental status changes, dysrhythmias, coma, or death.[2]

Long-term investigations of untreated mild HPT have noted that many patients have a benign disease course without significant signs of progression. A significant percentage, however, did show disease progression as evidenced by loss of bone mineral density loss or renal function impairment. There are no known predictive factors to identify which patients will experience a progressive disease course, though younger patients do seem to be at increased risk.[2]

EVALUATION OF HYPERPARATHYROIDISM

History and Physical

A comprehensive history should be performed and should include specific inquiry regarding hypercalcemic symptoms and associated morbidities such as nephrolithiasis or fracture history. A history of current medications is also important to obtain as certain agents such as lithium and thiazide diuretics can induce hypercalcemia. Any history of irradiation is also important to note. A family history of endocrine disorders or related entities is imperative for correct diagnosis, consideration of genetic testing, and evaluation for related entities such as pheochromocytomas, which could have significant ramifications on the treatment plan.

As previously mentioned, physical examination is usually unremarkable without neck masses or neuromuscular abnormalities. A palpable mass in the neck or RLN palsy on laryngeal examination should heighten the suspicion for malignancy.

Laboratory Testing

Serum calcium, intact PTH, albumin, vitamin D, phosphate, magnesium, and chloride levels should be obtained. Forty-three percent of circulating serum calcium is in the free ionized form, which is the major influence on PTH production. Total calcium levels can be affected by disturbances in albumin levels; ionized calcium levels can be affected by acidosis, which decreases calcium binding to albumin and alkalosis, which increases calcium binding to albumin. Parathyroid carcinoma should be suspected if calcium levels are

>14 mg/dL.[2]

In primary HPT, serum total and ionized calcium and PTH levels are elevated. These levels may also be within the normal range but with the PTH level inappropriately high for the associated level of calcium. Low vitamin D levels, however, could signify a secondary HPT. In primary HPT, chloride levels are elevated, whereas phosphate levels are low normal to low with a chloride-to-phosphate ratio >33. If elevated phosphate levels are found in conjunction with elevated calcium levels, causes for intestinal hyperabsorption or hypervitaminosis D should be explored. Renal function should be assessed for a secondary cause of HPT. Alkaline phosphatase levels are also useful to evaluate for active bone disease. A 24-hour urine calcium and creatinine level should be obtained to exclude BFHH. A low urine calcium to creatinine clearance ratio of <0.01 confirms the diagnosis of BFHH.[2]

Malignancy is the second most common etiology of hypercalcemia due to tumor secretion of PTH-related protein. Current PTH assays prevent the cross-reactivity between intact PTH and PHT-related protein. In cases of hypercalcemia from PTH-related protein, intact PTH levels are often suppressed.

Bone densitometry can reveal the catabolic effects of PTH on bone. The distal third of the radius, lumbar spine, hip, and femoral bones are informative sites for measurement. T-scores of ≤−2.5 are an indication for surgical treatment.[65]

There is no role for fine needle aspiration in the diagnosis of parathyroid disorders given the limitations of cytopathologic interpretation and technical difficulty.[5]

LOCALIZATION STUDIES

Localization studies can be extremely helpful in both the primary and reoperative settings. Development of new techniques and advancements of existing methods have improved the accuracy of these tests. This has allowed more directed and limited dissections while attaining similar outcomes as conventional comprehensive four-gland parathyroid explorations.

Ultrasonography

Ultrasound is considered a first-line modality for parathyroid evaluation and localization. Ultrasonography is rapid, relatively inexpensive, easily accessible, and well tolerated and does not expose the patient to any radiation risk. Additionally, it is a noninvasive method, requiring no injection of dye or radiotracer, and thus may be repeated multiple times if needed.[2,5] A 7.5-MHz transducer may provide the best balance between resolution and penetration for evaluation of the parathyroid glands.[66] It is, however, an operator and equipment-dependent modality; consequently, its sensitivity can be influenced by the operator's experience, resolution of the images, and frequency of the transducer.[67]

On ultrasound imaging, normal parathyroid glands are rarely visible. Parathyroid adenomas, hyperplastic glands, and enlarged glands appear as hypoechoic lesions (Fig. 20.2).[66] Parathyroid adenomas appear as homogenous, well-demarcated masses that are of a lower echogenicity than the surrounding thyroid tissue. They are usually oval or bean shaped but may be multilobulated. Occasionally, they may also contain cystic elements.[2,5] Parathyroid carcinomas may have a less sharply defined border but no other specific ultrasound characteristics.[66]

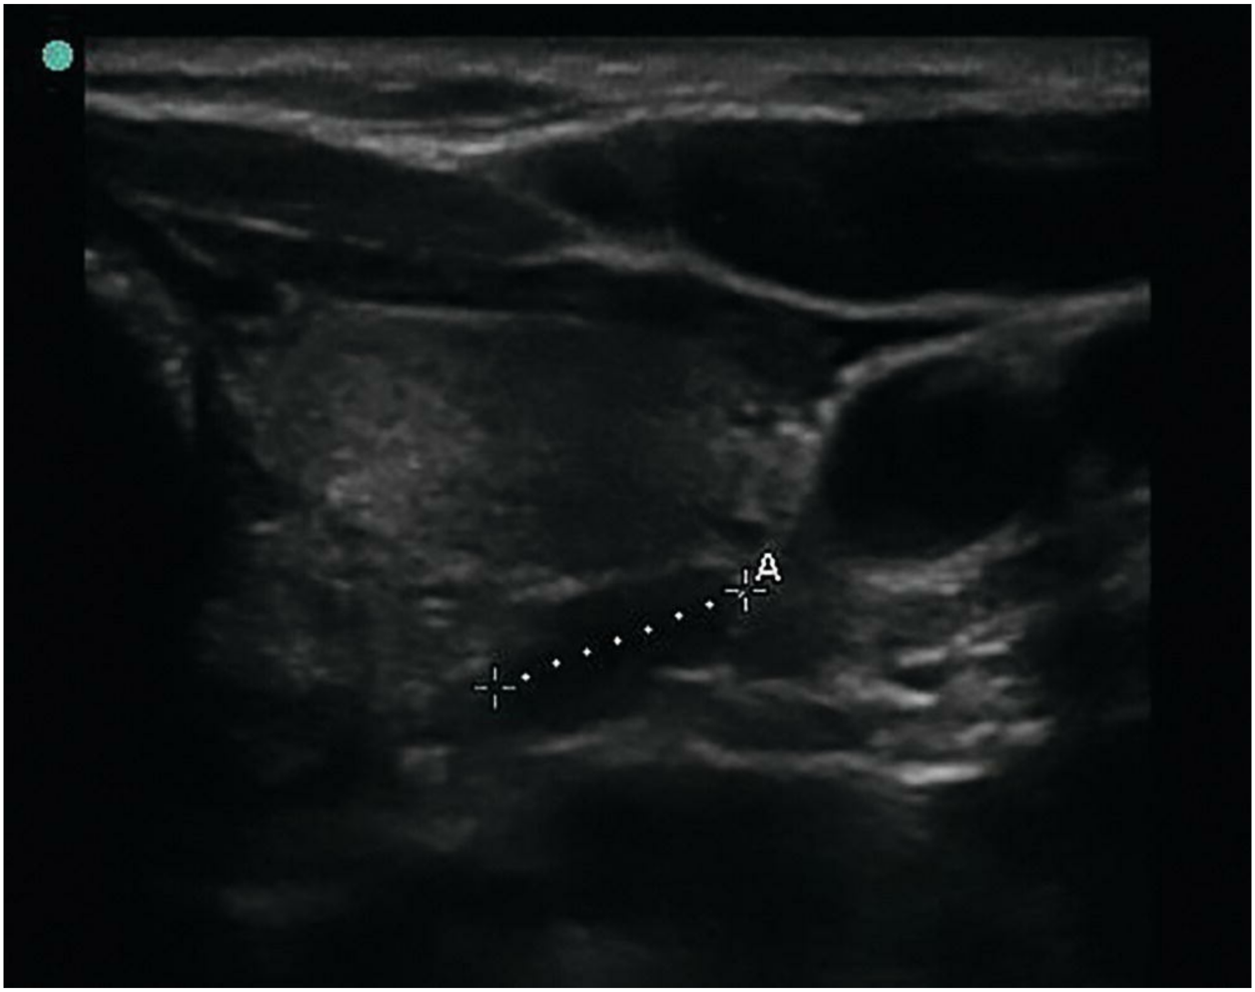

Figure 20.2. Ultrasound image of a hypoechoic lesion corresponding to a parathyroid adenoma (*A*).

Parathyroid glands may be difficult to discern from lymph nodes in a patient with thyroiditis or associated central neck lymphadenopathy. On Doppler imaging, adenomas generally have a distinct vascular pedicle entering at the pole and a characteristic arc or rim of vascularity that represents branching of the feeding artery prior to penetrating into the gland. Conversely, lymph nodes are seen to have an echogenic fatty hilum with a central hilar vessel. Both the transverse and longitudinal planes are useful in identifying parathyroid adenomas. The longitudinal view is particularly helpful in defining position relative to the thyroid gland and vascular structures.[2]

Concurrent nodular thyroid disease, particularly posterior nodules, can significantly limit the evaluation of parathyroid adenomas due to anatomical

distortion of and difficulty discerning nodules from parathyroid glands. Ultrasonography may still be able to discern a thyroid nodule from parathyroid gland that may not be as obvious when viewed by another modality. It may also aid in assessing for intrathyroidal parathyroid adenomas in the setting of cystic thyroid lesions.[68] Additionally, Doppler flow of a discrete blood supply to an intrathyroidal mass may signify an intrathyroidal parathyroid adenoma.[2]

The reported sensitivity and specificity of ultrasonography for the detection of eutopic parathyroid adenomas are ~88% and 98%, respectively, but vary by report. A high positive predictive value has also been described.[69] Surgeon-performed ultrasounds have been promoted by some to be superior to other imaging methods in localizing the correct quadrant of an adenoma and have been advocated as the only preoperative localizing modality necessary.[70–72]

The detection of ectopic parathyroid glands is one limitation of ultrasonography. Mediastinal glands may be difficult to identify due to interference from the sternum, and those in the tracheoesophageal region may be obscured by shadowing and artifact from the laryngeal cartilages.[5] Similarly, retroesophageal and retrotracheal glands are difficult to detect via ultrasound. Deglutition maneuvers during ultrasound may help reveal parathyroid adenomas posterior to the thyroid gland or deep to the clavicles.[66] False-positive results, estimated to be as high as 15% to 20%, may be secondary to the presence of lymphadenopathy, esophageal lesions, or surgical clips.[2,67] Furthermore, in cases of recurrent HPT, ultrasound sensitivity may be lowered due to scar tissue and the probability of an ectopic gland.[66]

Technetium–Thallium Subtraction Scan

Technetium–thallium subtraction scans were one of the earlier applications of nuclear medicine techniques for parathyroid localization. It uses the properties of thallium-201 uptake by both the thyroid and parathyroid glands and Tc-99m uptake by the thyroid gland. Image subtraction of the Tc scan from the thallium scan allows visualization of the parathyroid glands.

The sensitivity of the test has been reported ranging from 78% to 92% and can be significantly lower in previously operated patients.[73,74] The test

may be useful in detecting ectopic glands; however, thallium tends to concentrate in hypercellular areas such as thyroid nodules and can obscure nearby parathyroid glands. Although the thallium–technetium subtraction scan is relatively low risk, it requires prolonged patient immobilization and harbors a high false-positive rate, influenced by motion artifact and concomitant thyroid disease. Given these drawbacks, other methods are generally preferred.[2]

Technetium-99m Sestamibi Scan

Tc-99m sestamibi scintigraphy, initially used for cardiac studies, has been applied to parathyroid imaging. This method relies on the high mitochondrial content of neoplastic parathyroid tissue to sequester and retain more sestamibi than thyroid tissue. A dual-phase scan was developed to produce a planar image to identify areas of increased uptake corresponding to parathyroid adenomas or hyperplasia. The patient is injected with between 20 and 25 mCi of Tc-99m sestamibi, and images are obtained “immediately” at ~10 to 15 minutes and again after an interval of 2 to 4 hours. By the time of the late phase scan, the thyroid tissue will have cleared more sestamibi than the neoplastic parathyroid tissue (Fig. 20.3). These areas of increased uptake likely correspond to parathyroid tissue. Studies have shown the optimum late phase image is obtained at 2 hours.[2]

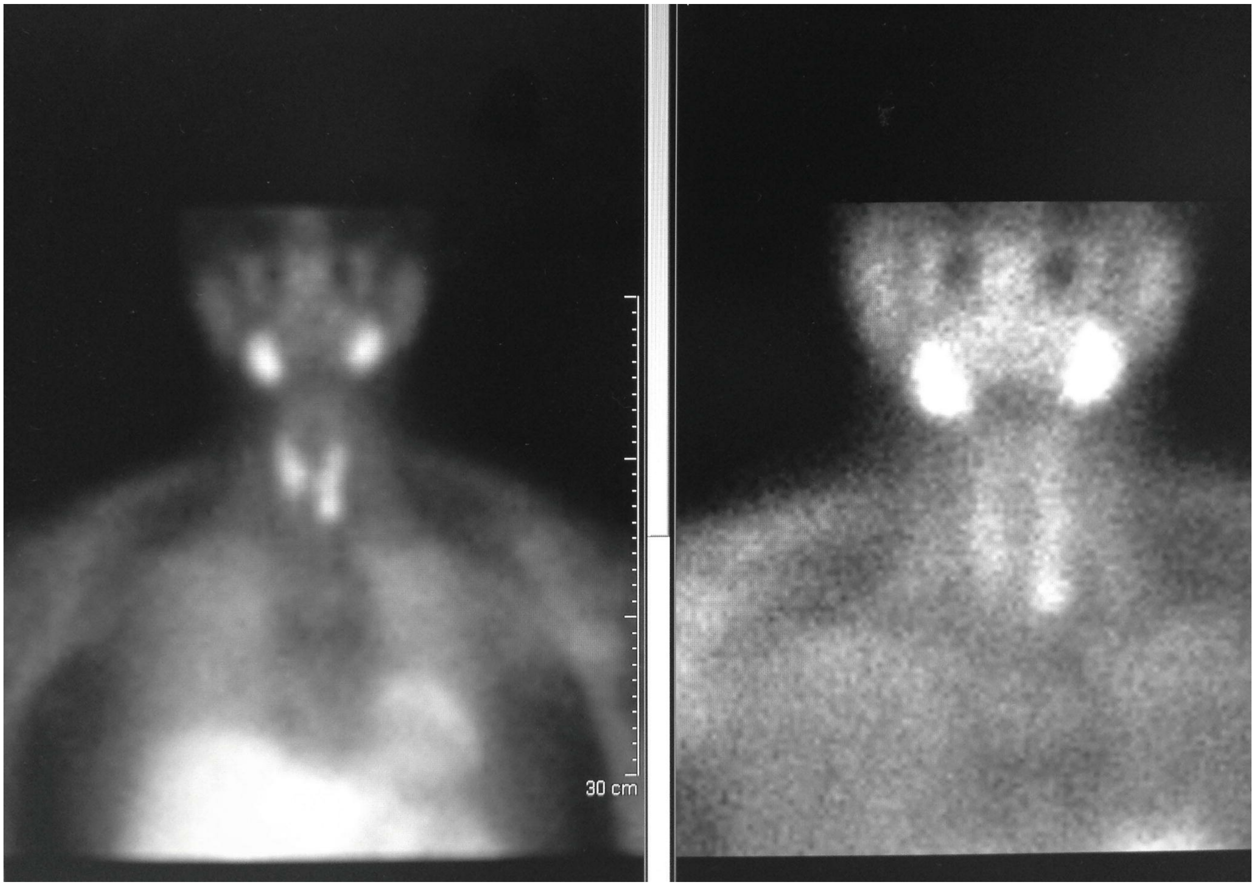

Figure 20.3. Sestamibi scan of a left inferior parathyroid adenoma. The image on the **left** shows the immediate scan. The image on the **right** shows the 2-hour delayed scan.

Sestamibi scanning is superior to ultrasonography in the detection of ectopic glands, particularly mediastinal lesions and double adenomas. False-positives may be seen in the setting of thyroid nodules or Hürthle cell carcinoma lesions. False-negatives may be seen with smaller parathyroid adenomas, inadequate administration of sestamibi, and multigland disease. Parathyroid hyperplasia and presence of Hashimoto thyroiditis may also decrease the accuracy.[2]

Sestamibi scanning has not been widely utilized for cases of secondary and tertiary HPT as some believe it is unnecessary given that a four-gland exploration is generally performed in those instances. However, a high sensitivity and positive predictive value for the detection of ectopic glands has been shown in this population, which may provide better surgical planning and efficiency.[75]

Sestamibi scans have a comparable sensitivity to ultrasonography, and when the two modalities are combined, sensitivity can increase to above 90%. Ultrasound has the advantage of defining the relationship of the gland to the thyroid, and sestamibi scanning has the advantage of detecting ectopic glands. Both are comparably insensitive in situations involving multigland disease.[70,71]

Technetium-99m Sestamibi with Single-Photon Emission Computed Tomography/Computed Tomography

Using a camera collimator that rotates 360 degrees axially around the patient, single-photon emission computed tomography (SPECT) is able to produce a three-dimensional image. This added spatial dimension with the sestamibi–SPECT can better localize ectopic adenomas such as those positioned within the carotid sheath or mediastinum. In particular, the ability to identify anterior and posterior compartment mediastinal lesions helps facilitate surgical planning.

Using specialized software, sestamibi–SPECT may be combined with computed tomography (CT) imaging to enhance the anatomical localization of parathyroid lesions. This single image combines the physiologic information of sestamibi–SPECT with the anatomical information obtained from a CT image. This anatomical refinement can further provide information regarding ectopic glands in thymic, retroesophageal, mediastinal, and intrathyroidal locations. It may also help plan reoperative cases to guide a more focused approach. The localization of parathyroid glands closely associated with the thyroid gland is a significant limitation of this modality.[2] Sestamibi–SPECT/CT has also been shown to be superior to any of these methods alone in detecting multigland disease.[76] According to some reports, combining ultrasound and SPECT/CT for preoperative localization of solitary parathyroid adenomas elevates the sensitivity to as much as 95%.[77]

Computed Tomography

CT imaging is rarely used as a first-line method for parathyroid gland localization. When ultrasound or sestamibi scanning are nonlocalizing or equivocal, CT scanning may provide additional information especially in cases of recurrent or persistent HPT.[78] The information provided is only

anatomic and not physiologic.

CT scanning may be useful in identifying ectopic parathyroid glands in the retrotracheal, retroesophageal, and mediastinal locations, but visualization can be significantly hindered by motion artifact, lymphadenopathy, and nearby vasculature, lending this modality a false-positive rate as high as 50%.[2,5] CT scanning also requires radiation and contrast administration.

Magnetic Resonance Imaging

Magnetic resonance (MR) imaging has a sensitivity ranging from 50% to 80%, for identifying parathyroid adenomas in mediastinal locations in recurrent or persistent cases of HPT.[66,79,80] Parathyroid adenomas have a low signal intensity on T1-weighted imaging and a high intensity on T2-weighted imaging. MR has a high false-positive rate due to difficulty distinguishing lymphadenopathy and thyroid nodules from adenomas.[2] MR imaging does not require the contrast administration or radiation exposure that is needed for CT scanning.

CT and MR imaging have a very limited role in the preoperative localization of parathyroid lesions in the setting of primary surgery due to their relatively high cost and low sensitivity compared to other modalities, but they may have an application in reoperative cases.

4-D Computed Tomography

4-D CT scanning exploits the imaging characteristics of contrast perfusion over time to add functional information. Hyperfunctioning parathyroid glands tend to have a more rapid uptake and washout as compared to normal glands. The sensitivity of 4-D CT has been estimated to be 88% in lateralizing an adenoma and 70% in identifying a specific quadrant.[81] One series found that 4-D CT scanning correctly identified unilateral versus bilateral disease in 95.8% of reoperative cases.[82]

Disadvantages of 4-D CT include significant artifact from involuntary movements, respirations, and deglutition and reduced image quality in larger patients. Additionally, a significant amount of radiation, 10.7 mSv, is delivered to the patient during the examination. This is compared to 7.8 mSv and 6 mSv delivered during an SPECT and standard cervical CT scan,

respectively.[83]

INVASIVE PREOPERATIVE LOCALIZATION

Invasive preoperative localization techniques are rarely used but may provide useful information in the setting of refractory HPT when noninvasive tests are nonlocalizing or equivocal.

Digital subtraction angiography or conventional angiography can be used to visualize parathyroid adenomas because they tend to be hypervascular. Selective arteriography of bilateral thyrocervical trunks, internal mammary arteries, and common carotid arteries can be performed. Catheterization of the thyrocervical trunks can detect glands closely associated with and within the thyroid gland and those in the superior mediastinum along the tracheoesophageal groove. Examination of the internal mammary arteries can identify ectopic glands in the anterior mediastinum or within the thymus. Catheterization of the common carotid arteries can identify parathymic, juxtathyroid, and undescended glands. Some have even described catheterization of the superior thyroid arteries. Complications of parathyroid arteriography can be disastrous including embolic stroke, arterial dissection, and inadvertent injection of contrast into the spinal cord if the costocervical trunk is injected instead of the thyrocervical trunk. The sensitivity of parathyroid angiography has been reported to be ~60%.[2,84]

Selective venous sampling with testing for PTH levels is another tool that can aid in the localization of a parathyroid adenoma. As the venous drainage of parathyroid glands are variable, an arteriogram can act as a guide with the aim of sampling the thymic and inferior thyroid veins; if these have been previously ligated, the vertebral veins may be targeted. The samples obtained from these sites are compared to one from a peripheral vein; if the PTH level is at least double that of the peripheral vein, it is a good indication of a nearby parathyroid adenoma. Internal jugular vein sampling may also indicate the side of the offending gland. This technique may also be used intraoperatively. The sensitivity of selective venous sampling is between 70% and 80%.[84]

Finally, preoperative ultrasound-guided fine needle aspiration of a suspected parathyroid lesion can help identify a hyperfunctional parathyroid

gland. The PTH level of a needle aspirate is a more useful test than cytologic evaluation.[2]

Surgical Management

The success rate of parathyroid surgery has been reported to be above 95% when performed by an experienced surgeon.[85] Preoperatively, patients should be counseled regarding potential complications including temporary or permanent injury to the RLN, temporary or permanent hypocalcemia, and persistent or recurrent HPT.[2]

Surgical Indications

Surgery is always indicated in patients with symptomatic HPT. According to the 2008 NIH guidelines, surgery is indicated for asymptomatic HPT if one of the following criteria is met: serum calcium level at least 1.0 mg/dL above the upper limit of normal, glomerular filtration rate (GFR) of <60 mL/min, a T-score of <−2.5 on bone densitometry scan or history of a previous fragility fracture, or age <50 years old (Table 20.2). The previous indication of a 24-hour urine calcium level of >400 mg/d is no longer included on this most recent guideline.[65]

Table 20.2 National Institutes of Health (NIH) Indications for Surgery for Hyperparathyroidism (2008)

NIH Indications for Surgery for Hyperparathyroidism[57]
Serum calcium level
1.0 mg/dL above the upper limit of normal
Renal function
Glomerular filtration rate (GFR) <60 mL/min
Bone density
T-score <–2.5
History of fragility fracture
Age
<50 years

As previously discussed, there is no indicator to predict which patients with HPT will progress and which will remain asymptomatic. Consideration for surgery is made with the intent to correct any present sequelae and to prevent future consequences.

Intraoperative Parathyroid Hormone Assessment

With the use of preoperative localization studies, the success of minimally invasive surgeries for primary HPT is as high as 95%. The use of an intraoperative PTH assay can further improve that success rate. PTH has a half-life of ~3 to 5 minutes; thus, levels obtained during surgery can quickly provide confirmation that all hyperfunctioning parathyroid tissue has been removed (Fig. 20.4).[85,86]

Image on the right shows the 2-hour scan. **C and D:** Gross appearance of an excised left inferior parathyroid adenoma. **E:** Changes in the intraoperative PTH levels after excision of the parathyroid adenoma.

Intraoperative parathyroid hormone (IOPTH) assays were first reported by Nussbaum in 1988, and their use has become widespread in the United States. They are useful in determining adequate removal of hyperfunctioning parathyroid tissue and in predicting surgical cure, acting like a biochemical frozen section. This real-time assessment of the completeness of surgery can reduce operating time and permit minimally invasive surgery with directed gland dissection. It may also decrease the need for re-exploration in cases of unanticipated multigland disease.[86]

An immunochemiluminescent assay of a peripheral blood sample is used for point-of-care determination of PTH levels with a processing time as rapid as 8 minutes. This speed is conducive to intraoperative assessment and has been shown to be significantly quicker than the turnaround time for central laboratory results.[87] Paired analysis of POC IOPTH compared with central laboratory PTH results revealed that the termination of surgery time based on

POC IOPTH resulted in a mean saving of 16.6 ± 4.5 minutes per case. An overall cost savings has also been shown in using POC IOPTH versus central laboratory methods.[87]

Various recommended algorithms for the timing of PTH level acquisition and criteria for termination of the procedure have been proposed.[85,88,89] Based on analysis of data of a single-surgeon experience from our institution, we prefer to obtain a preincision PTH level followed by a 5-minute postexcision level and, if needed, 10- and 15-minute postexcision levels. In this series of 112 patients with primary HPT, 63.5% of cases were able to be concluded after an adequate decrease (a 50% drop from the preincision baseline into the normal laboratory reference range) in the PTH level obtained at five minutes postexcision. Furthermore, there were no false positives of cure based on this 5-minute level.[85]

In cases of multigland disease such as hyperplasia or double adenoma, intraoperative PTH levels can be instrumental in determining the completeness of surgery and minimizing the extent of surgery. An initial drop may give way to a plateau of the PTH level, signifying that more hyperfunctional parathyroid tissue is present. The PTH levels will further drop with the subsequent excision of this retained hyperfunctional parathyroid tissue.[5] Evidence also suggests that patients with HPT who have low preincision PTH levels may not have as predictable a decrease in PTH levels as patients with higher levels. Such patients may also be at risk for unrecognized multigland disease.[90]

Intraoperative Fine Needle Aspiration

Although not used routinely, point-of-care intraoperative PTH assay of needle aspirates is an accurate method to differentiate parathyroid from nonparathyroid tissue when the distinction is not clear. The mean PTH levels of parathyroid tissue needle aspirates have been shown to be 3,338.9 ± 714 pg/dL as compared to 8.7 ± 1.5 pg/mL for nonparathyroid tissue aspirates. When compared to frozen section analysis, it is less expensive per test and yields more rapid results, affording the potential to shorten operative time.[51]

SURGICAL PRINCIPLES

Parathyroid surgery has traditionally consisted of a bilateral, four-gland exploration. With the development of preoperative localization studies and intraoperative PTH level assessment, a more focused dissection can be performed in appropriate cases. Each case should still be approached with the potential that a four-gland exploration and possibly a superior mediastinal dissection may be required, and patients should be counseled as such.[91]

A thorough knowledge of the embryology and anatomy of the parathyroid glands is paramount in parathyroid surgery. A systematic and meticulous dissection should be undertaken with attention to strict hemostasis as staining of the tissues can obscure identification of parathyroid glands. There should be a low threshold for identification of the RLN not only to ensure nerve integrity but also to aid in distinguishing inferior from superior parathyroid glands. Gentle palpation may also help to identify a parathyroid adenoma, particularly those lying along the prevertebral fascia.[5]

Normal-appearing parathyroid glands and their respective blood supplies should be preserved. In ambiguous cases, such as multigland disease, a biopsy may be performed with care to remove only tissue from the distal tip of the gland in order to not disrupt the blood supply. If the viability of a normal parathyroid gland is questioned, reimplantation should be considered.

Dissection should commence on the side intimated by the preoperative localization studies. The thyroid gland is mobilized to expose the eutopic sites of the parathyroid glands. The middle thyroid vein may be ligated if needed to improve exposure; division of the superior and inferior pedicles is usually not necessary.[5] A systemic approach to identifying parathyroid glands is necessary to prevent overlooking abnormal glands.

In cases of primary HPT where both sestamibi and ultrasound are nonlocalizing, which occurs in 10% of cases, a four-gland exploration may be planned. In such cases, a sestamibi–SPECT/CT may provide important information as it is more sensitive and specific for localizing ectopic glands.[91]

In a four-gland exploration, a unilateral dissection is first performed, followed by exploration of the contralateral neck if a suspicious gland is not identified. If an inferior gland is not found, anterior mediastinal dissection is performed. It may be easier to examine intrathymic contents ex vivo after an anterior superior mediastinal dissection rather than in vivo unless an adenoma

is obvious. If an inferior gland is still elusive, systemic investigation of the retroesophageal area and carotid sheath follow. Unless a suspicious lesion is noted on ultrasound, a thyroid lobectomy is not performed. Four-gland explorations with superior mediastinal dissection yield higher rates of injury to the RLN due to its identification and longer length of dissection compared to more limited dissections. Additionally, in tracing along the RLN, normal parathyroid glands are at risk for becoming devascularized. As a result, higher rates of permanent hypocalcemia occur as compared to limited dissections. Thus, if the blood supply to a normal gland appears to be compromised, it should be autotransplanted.

If all four glands are located and appear normal, a supernumerary gland or four-gland hyperplasia is considered. A cervical thymectomy is performed if a supernumerary gland is suspected. If hyperplasia is suspected, biopsies of the identified glands are sent for frozen section analysis to assess for hypercellularity.

Ectopic parathyroid glands can be found anywhere from the nasopharynx to the inferior pericardium but are most commonly identified in the anterosuperior mediastinum, the majority of which are intrathymic or intimately associated with the thyrothymic ligament.[91]

Transcervical mediastinal dissection usually entails an anterosuperior dissection in conjunction with a thymectomy. This is usually performed when preoperative studies localize to the mediastinum and primary HPT recurs or persists after a four-gland exploration and in cases of MEN1 and secondary HPT, which have higher rates of supernumerary glands. A posterosuperior mediastinal dissection is uncommonly required when search for an ectopic superior gland or supernumerary gland is otherwise unsuccessful.[91]

Most adenomas, including those located in superior mediastinum, are accessible via a transcervical approach with only 2% requiring a thoracic approach.[91] Transcervical access is attempted initially with conversion to a transsternal approach if the lesion is too deep to access through the neck. Sternotomy may occasionally be planned as a solo approach for ectopic glands if indicated on a preoperative localization study.[5,83]

Lesions in certain locations are more likely to require a thoracic approach, including those inferior to the manubrium, brachiocephalic vein, or aortic arch. Techniques such as reverse Trendelenburg positioning, cervical

extension, anterior suspension, sternal or clavicular traction, or posterior displacement of the brachiocephalic vessels may aid dissection as far inferior as the level of the aortic arch through a transcervical approach. Lesions located within the aorticopulmonary window or deep in the mediastinum will undoubtedly require an isolated transthoracic approach. Historically, adenomas in the deep mediastinum were removed through a median sternotomy, but video-assisted thoracoscopic surgery (VATS) has yielded high success rates, particularly for posterior inferior mediastinal lesions, with decreased morbidity and faster recovery.[91]

SURGERY FOR MULTIGLAND DISEASE AND SECONDARY HYPERPARATHYROIDISM

In patients with multigland disease, for instance, those with renal HPT or MEN, all four parathyroid glands identified before any glands are removed. Once all glands are visualized, their size and gross appearances are noted and compared. In cases of renal HPT, patients eligible for renal transplantation should undergo a 3.5 gland parathyroidectomy; patients not eligible for transplantation should undergo a total parathyroidectomy with autotransplantation.[91]

When a subtotal parathyroidectomy is indicated, the smallest and most normal-appearing gland is selected for the remnant. Meticulous dissection of this gland is performed to preserve the blood supply. A medium vascular clip is used to mark the remnant, and the portion of the gland distal to the vascular supply is excised. If the viability of the remnant is dubious, it should be removed and the next most normal-appearing gland selected for the remnant. When the viability of the remnant gland is confirmed, dissection and excision of the remaining glands are then performed (Fig. 20.5). Prior to excision of the last gland, confirmation of the remnant viability is recommended. Care should be taken to prevent any spillage of parathyroid tissue that could lead to recurrent disease.

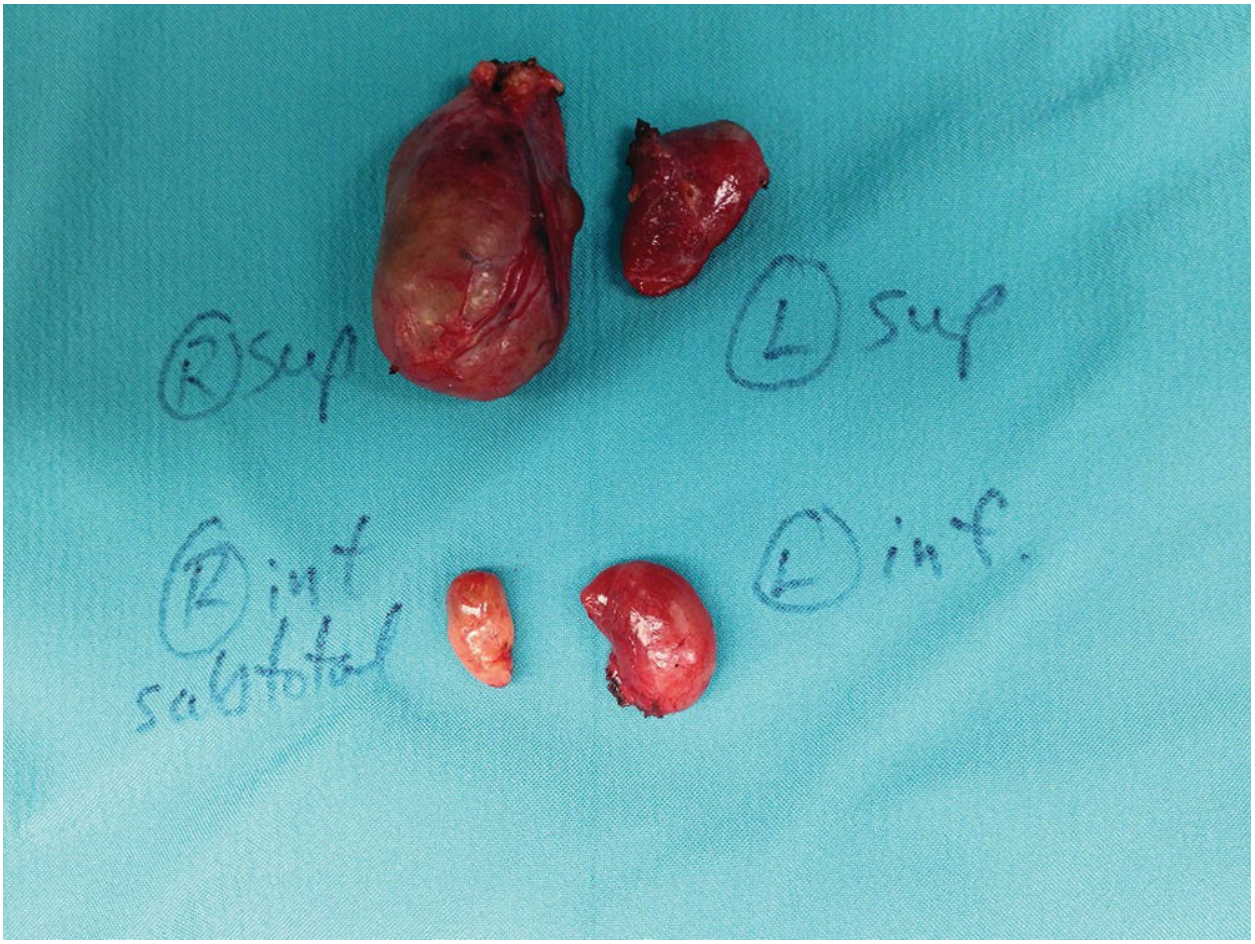

Figure 20.5. Gross specimen of a subtotal parathyroidectomy performed in a patient with secondary HPT from renal disease. Note the asymmetry of the parathyroid glands. The most normal-appearing gland was selected to leave a remnant in vivo.

More aggressive resection with a total parathyroidectomy with or without autotransplantation and bilateral cervical thymectomy is reserved for virulent disease with higher rates of recurrence. This is recommended for cases of familial hyperplasia, neonatal HPT, MEN1, and select cases of secondary HPT.

CAUSES OF SURGICAL FAILURE

The most common finding on re-exploration for persistent HPT is a missed single parathyroid adenoma. One series of 288 reoperations found a solitary adenoma in 77% of the cases, most of which were in eutopic locations.[2]

Twenty-seven percent of adenomas were found in the tracheoesophageal groove. Many were found apposed to the RLN suggesting insufficient dissection around the nerve during the initial operation. Review of previous operative and pathology reports may be informative in regard to remaining glands, missed areas of dissection, and thoroughness of exploration. Greater incidences of temporary or permanent RLN injury and hypocalcemia are seen after reoperations.[2]

MINIMALLY INVASIVE PARATHYROID SURGERY

Recent advances in preoperative localization studies and IOPTH assays have allowed minimally invasive parathyroid surgery with success rates comparable to that of conventional bilateral exploration. This approach may be accomplished with or without endoscopic visualization. In cases of a solitary adenoma with concordant preoperative ultrasound and sestamibi findings, a unilateral quadrant-directed dissection through a small incision with biochemical confirmation of complete removal of hyperfunctioning tissues is certainly feasible. The patient must be counseled and the surgeon prepared for a more comprehensive dissection if IOPTH levels remain elevated.

Minimally invasive parathyroidectomy has the advantages of a shorter operating time, lesser degree of dissection, decreased time of recovery, and less risk of complications (i.e., hypocalcemia) due to minimal dissection. The ability to perform the procedure through an incision as small as 15 to 20 mm also allows improved cosmesis. It has also been shown to be cost-effective when compared to conventional open procedures.

Multiple studies have shown that the long-term biochemical cure rates of minimally invasive parathyroid surgery are comparable to those of conventional parathyroidectomy.[92,93]

Radioguided Parathyroidectomy

Radioguided parathyroidectomy was developed by Norman and Chheda in 1997 to help identify hyperfunctional parathyroid tissue intraoperatively.[94,95] Patients are injected preoperatively with Tc-99 and a handheld gamma

detection probe is used intraoperatively to assess the radioactivity of excised tissue. Adenomatous parathyroid tissue has an increased affinity for the radiotracer due to its abundant amount of mitochondria. Parathyroid tissue that demonstrates at least 20% of the radioactivity of the background surgical field is likely hyperfunctional. Some authors report increased success rates with this technique,[96] whereas other groups have found that that radioactivity levels are not a substitute for changes in intraoperative PTH levels.[97]

POSTOPERATIVE CONSIDERATIONS

Postoperative hypocalcemia may be seen in patients as a result of “bone hunger” from severe skeletal demineralization caused by the hyperparathyroid state. Some may even develop symptoms of hypocalcemia, including tetany, due to the rapid decline in calcium levels even if the serum calcium levels remain in the normal range. Serum calcium levels should reach a nadir at ~48 hours postoperatively. Concomitant hypomagnesemia should be treated as this condition prevents appropriate repletion of calcium levels. In our practice, we prescribe a standard 3-week taper of a combined calcium and vitamin D supplement to prevent postoperative hypocalcemia.

HYPOPARATHYROIDISM

Hypoparathyroidism is most commonly encountered after thyroid or parathyroid surgery. It may also be seen in congenital syndromes such as DiGeorge syndrome in which abnormal development of the third and fourth branchial pouches leads to agenesis of the parathyroid glands.

Symptomatic hypoparathyroidism requires timely treatment with calcium and active vitamin D metabolites. Administration of intravenous calcium may be required in cases of severe hypocalcemia where serum calcium levels are below 7 mg/dL, signs of mental status changes are present, and neuromuscular irritability such as tetany, laryngospasm, or bronchospasm manifests. In cases where calcium correction is too rapid or in patients taking digoxin, arrhythmias can occur.[91]

Magnesium and vitamin D levels should be optimized prior to surgery as suboptimal levels can exacerbate hypocalcemia. Diligent identification of parathyroid glands and preservation of parathyroid blood supply are

instrumental in preventing postoperative hypocalcemia.

CONCLUSION

The understanding and treatment of parathyroid disease have progressed significantly since their initial discovery. Advancements in biochemical screening, preoperative localization, and intraoperative assessment techniques have allowed a high rate of successful surgery and have even permitted minimally invasive procedures to be performed accurately and safely.

21 Cancer of the Salivary Glands

Yekaterina A. Koshkareva Robert L. Ferris

Cancers of the salivary glands are a distinctive group of neoplasms arising in the major and minor salivary glands. The distinguishing features of these cancers include their low incidence, histopathologic heterogeneity, presentation at multiple anatomic sites, and wide spectrum of clinical behaviors. The goal of this chapter is to provide a contemporary, comprehensive review of the demographics, etiology, pathology, and presentation of cancers of the salivary glands, as well as a summary of current recommendations for staging and treating these cancers.

Surgical Anatomy

There are two types of salivary glands; the major salivary glands, which are readily identifiable, with anatomically distinct excretory ducts, and the minor salivary glands, which are less easily identifiable, smaller, and lack distinct ducts. The parotid, submandibular, and sublingual glands are the major salivary glands, whereas the minor salivary glands are not individually named and are found throughout the length of the upper aerodigestive tract.

Parotid Gland

The paired parotid glands are the largest of the major salivary glands and form the lateral portions of the facial contour. The parotid gland is bounded by the cartilage of the external auditory canal posteriorly, the mandibular ramus and the masseter muscle medially, and the buccinator muscle anteriorly. The superior border is the zygoma, whereas the inferior aspect, also known as the “tail,” lies over the posterior belly of the digastric muscle

medially and sternocleidomastoid (SCM) muscle laterally. The medial portion of the parotid gland abuts and sometimes extends into the parapharyngeal space (Fig. 21.1). Accessory parotid tissue may be found anterior to the body of the gland, along the course of Stensen duct, in 21% of the population.[1] The gland is encased by a capsule derived from the deep cervical fascia and is further enveloped by the superficial musculoaponeurotic system (SMAS) in the face and the platysma in the neck. The parotid (Stensen) duct travels along the surface of the masseter and turns medial at its anterior border, transversing the buccal adipose tissue pad and the buccinator, and opens into the oral cavity opposite the second maxillary molar.

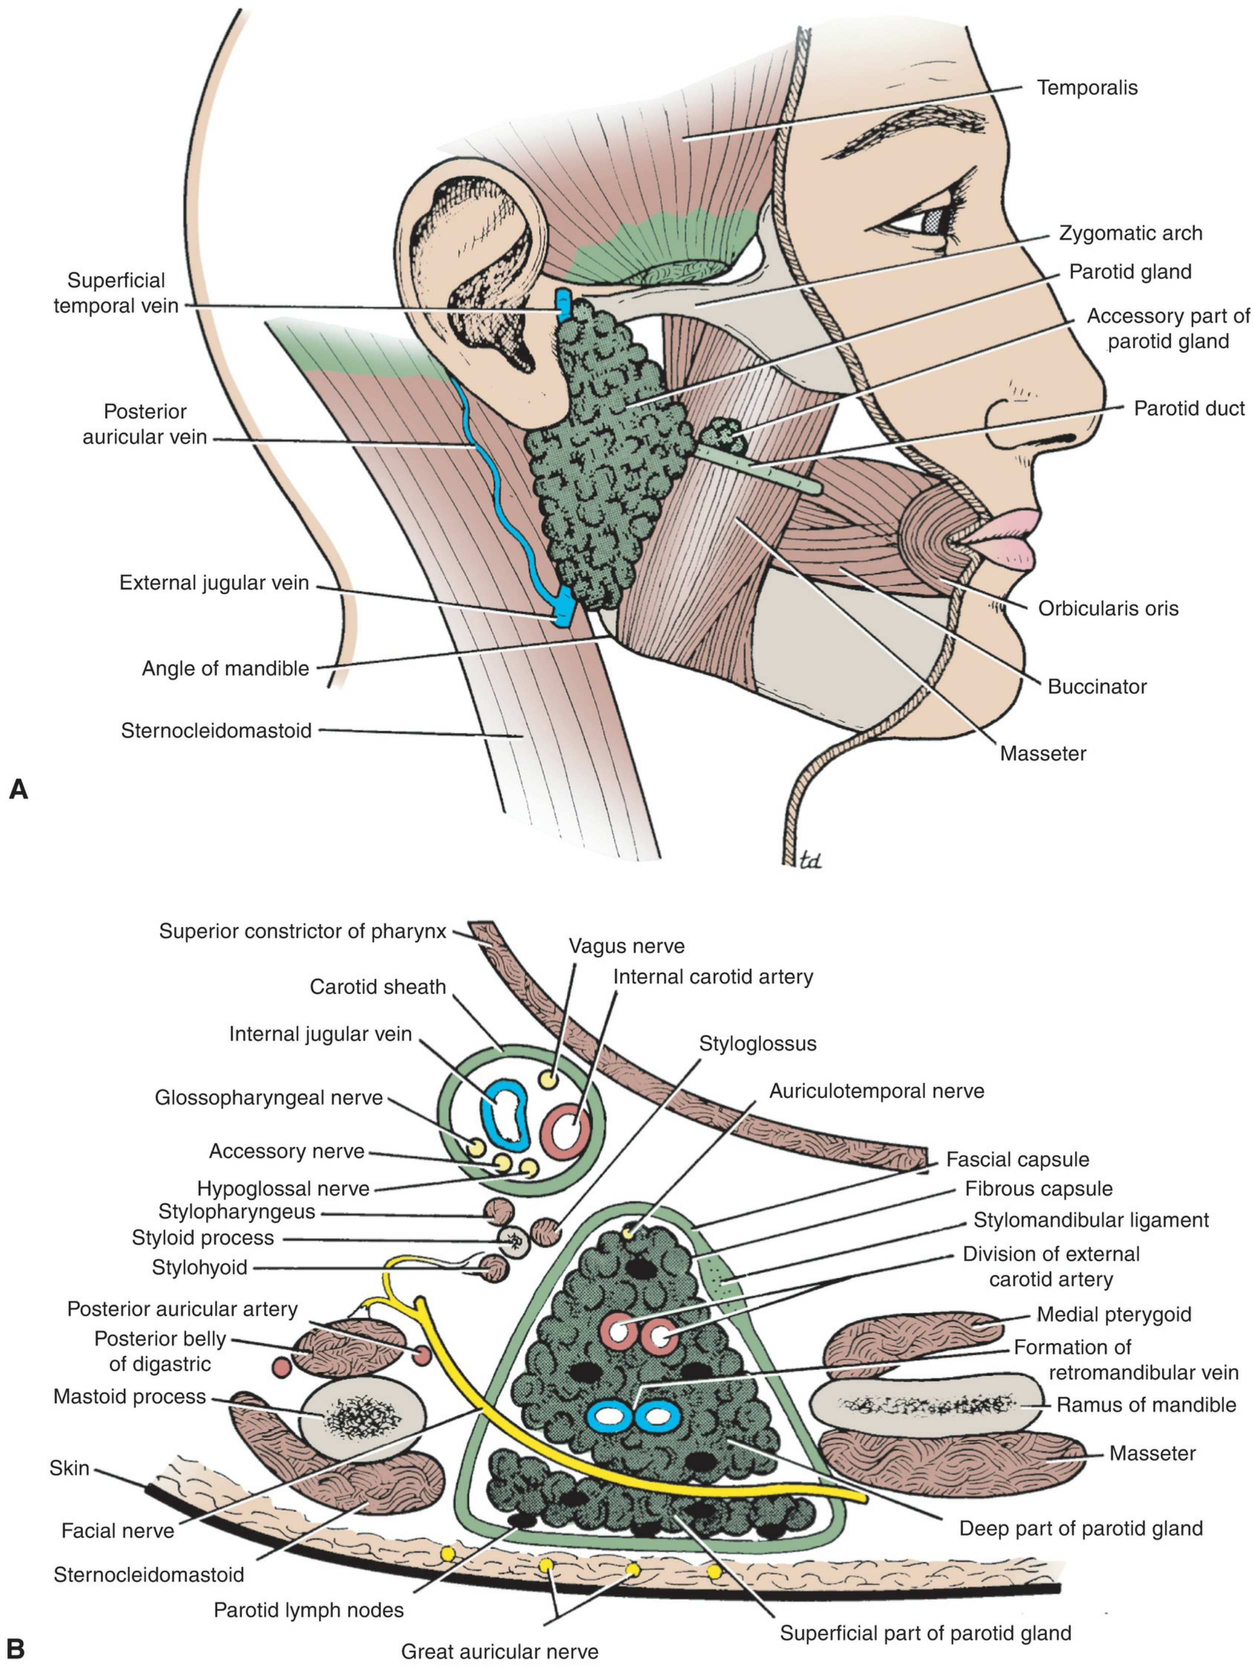

Figure 21.1. A and B: Parotid gland anatomy. (From Snell RS, ed. *Clinical*

Anatomy by Regions. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2011.)

The arterial supply of the parotid gland comes from the two terminal branches of the external carotid artery: the superficial temporal and internal maxillary arteries. The venous outflow is collected by the respective superficial temporal and internal maxillary veins, which then join to form the retromandibular vein. The anterior division of the retromandibular vein along with the anterior facial vein forms the common facial vein. The posterior division joins the posterior auricular vein to drain into the external jugular vein.

There are as many as 20 lymph nodes within and adjacent to the capsule of the parotid gland, and these nodes are the first echelon of nodes to receive lymphatic drainage from the soft tissues of the temporal scalp, cheek, ear, and external auditory canal. Hence, the parotid lymph nodes may harbor metastatic foci from cancers that arise from these sites. Efferent parotid lymphatics drain into the lymph nodes of the superior and middle deep jugular chain.

Another important anatomic structure that must be considered in the management of parotid tumors is the facial nerve, which runs through the gland and serves as a landmark that separates the parotid into superficial and deep lobes. The main trunk of the facial nerve exits the stylomastoid foramen and enters the parenchyma of the parotid gland, where it typically divides into an upper and lower division. It then further subdivides into its five principal branches, but the arborization of the nerve can be quite varied.[2] The point at which the main trunk of the facial nerve divides for the first time is referred to as the pes anserinus. The lower division contains the branches to the platysma (cervical branch) and the lower lip depressors (marginal mandibular branch). The marginal mandibular nerve is located deep to the platysma muscle and lateral to the facial vein and the capsule of the submandibular gland. The midface division (zygomaticobuccal branches) supplies innervation to the buccal, zygomatic, and lower eyelid muscle groups. The buccal branch is identified in the vicinity of the parotid (Stensen) salivary duct. The upper face division (frontal branch) travels lateral to the superficial layer of the deep temporal fascia to supply the frontalis and superior orbicularis oculi muscles.

Other nerves of importance encountered during parotid gland surgery are the greater auricular and auriculotemporal nerves. The greater auricular nerve is found on the lateral surface of SCM muscle, along the lateral border of the parotid gland. Its anterior and posterior branches provide sensation to the inferior aspect of the auricle and periauricular skin. The auriculotemporal nerve is a branch of the fifth cranial nerve (trigeminal nerve), which travels along with the superficial temporal vessels, posterior to the parotid, providing sensation to the temporal region. The auriculotemporal nerve also provides parasympathetic innervation to the parotid gland from the otic ganglion. After resection of the parotid salivary tissues, these fibers may form an aberrant innervation with sweat glands leading to perspiration in response to the gustatory stimuli, a phenomenon known as gustatory sweating (Frey syndrome).

Submandibular Gland

The paired submandibular glands are located in the superior aspect of the anterior neck, bounded superiorly and laterally by the body of the mandible. The platysma muscle covers the gland’s lateral border, and the hyoglossus muscle lies medial to the gland. The gland resides posterior to the lateral border of the mylohyoid muscle. The submandibular (Wharton) duct originates from the multiple smaller branches originating from the medial aspect of the gland. It courses anteriorly and superiorly first between the mylohyoid and the hyoglossus muscles and then between the sublingual gland and the genioglossus muscle. The duct is situated between the lingual and hypoglossal nerves while on the surface of the hyoglossus, but at the anterior border of the muscle, the branches of the lingual nerve cross the duct to assume a more medial position. The submandibular duct travels a total distance of ~5 cm and empties into the anterior floor of the mouth.

The facial artery provides the main blood supply to the submandibular gland. This artery courses deep to the posterior belly of the digastric muscle and travels either along the medial aspect of the gland or through the gland parenchyma and traverses the lower border of the mandible at the antegonial notch curving over the insertion of the masseter muscle into the anterior border of the mandible. Venous drainage is supplied by the anterior facial vein.

Although there is no lymphoid tissue within the parenchyma of the

submandibular gland, there are a number of pre- and postvascular lymph nodes adjacent to the facial vessels, which run over the lateral aspect of the gland, which serve as the first echelon nodes for lymphatic drainage from the lip, oral cavity, and skin of the anterior face. These lymphatics can also drain into the deep jugular chain of nodes. Enlargement of the submandibular nodes can be difficult to distinguish from a primary tumor of the submandibular gland, and a metastatic process within these nodes may also invade the adjacent gland by direct extension.

Similar to the parotid, the submandibular gland lies in anatomical proximity to the facial nerve. The marginal mandibular branch runs along the inferior border of the mandible, just deep to the platysma muscle and lateral to the fascia of the gland. Additionally, the lingual and hypoglossal nerves are located deep to the medial surface of the gland, whereas the nerve to the mylohyoid is adjacent to the superior aspect of the gland (Fig. 21.2).

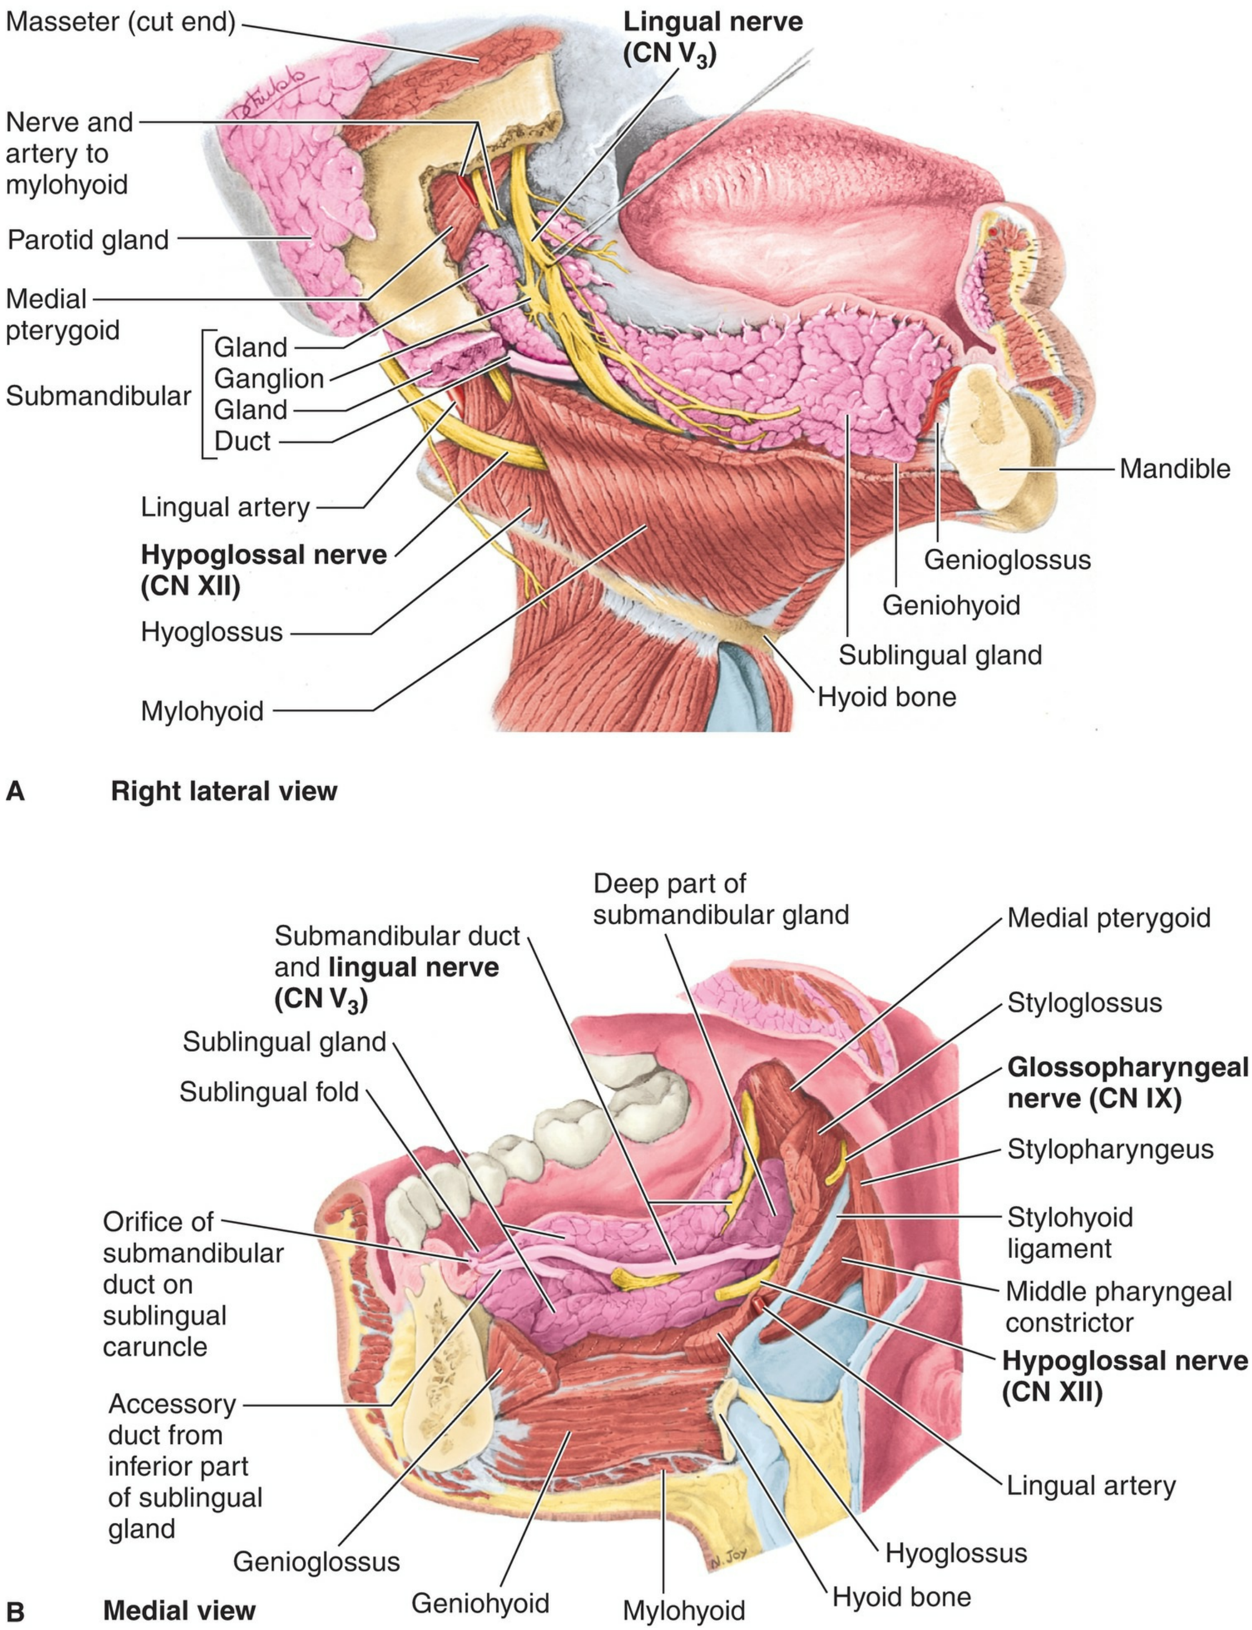

Figure 21.2. A and B: Submandibular gland anatomy. (From Moore KL, Agur AMR, Dalley AF, eds. *Clinically Oriented Anatomy*. 7th ed. Baltimore,

MD: Lippincott Williams & Wilkins; 2013.)

Sublingual Glands

The sublingual glands are also found bilaterally. They are located deep to the mucosa of the floor of the mouth and drain directly into the oral cavity through numerous small ducts. Tumors of the sublingual glands can be difficult to distinguish from those arising within the submucosal minor salivary glands of the floor of the mouth.

Minor Salivary Glands

There are over 600 minor salivary glands distributed throughout the length of the upper aerodigestive tract, and approximately half of them are located on the hard palate. Tumors can arise in these glands in such diverse sites as the oral cavity, oropharynx, larynx, pharynx, nose, nasopharynx, and paranasal sinuses. Additionally, small rests of heterotopic salivary tissue can be located within the cervical lymph nodes, mandible, thyroid gland, and the middle ear.[3]

Anatomic Tumor Classification

Over 75% of salivary gland neoplasms originate in the parotid gland (mainly in the superficial lobe), with submandibular and minor glands comprising the rest. Approximately 80% of parotid gland tumors are benign. The likelihood of a submandibular gland lesion being benign is much less, around 43%. Finally, lesions arising within the minor salivary gland lesions are more likely to be malignant (up to 60%), especially if they originate outside of oral cavity (Fig. 21.3).[4–12]

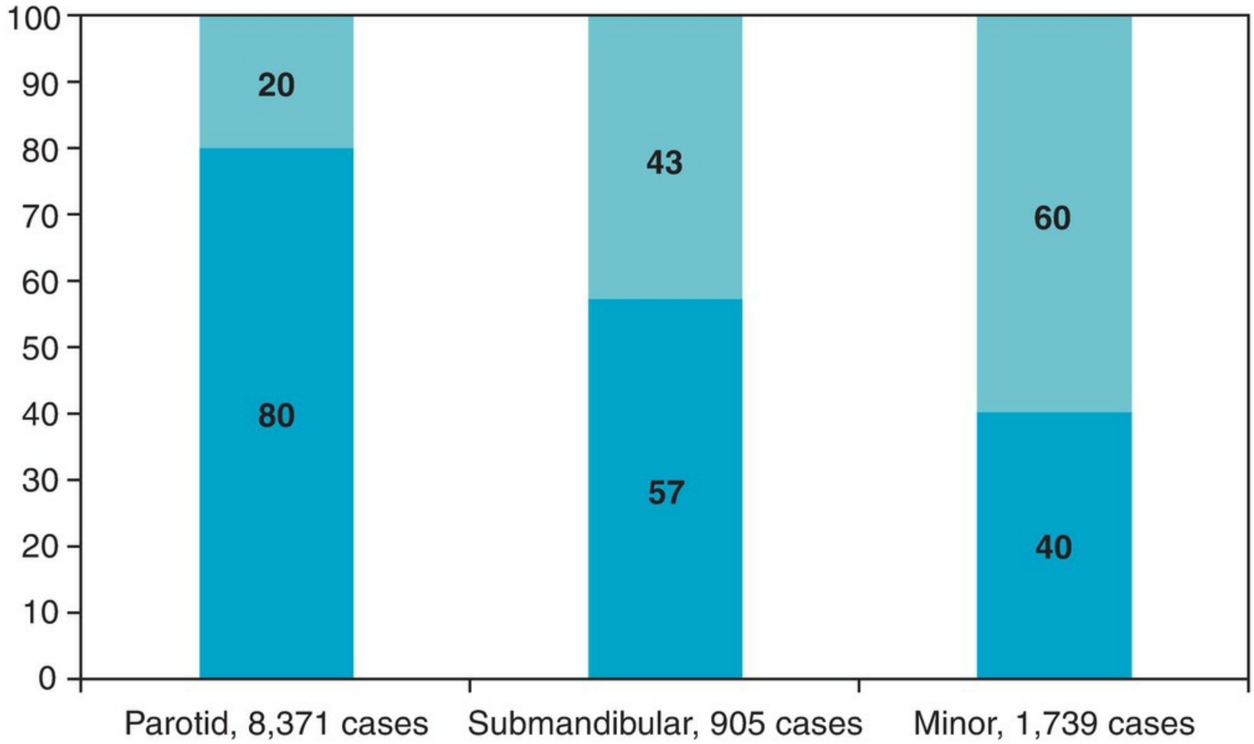

Figure 21.3. Relative ratio of benign versus malignant salivary neoplasms at various anatomic sites. (Dark blue, benign; light blue, malignant.)

Histology and Histogenesis of Salivary Gland Tumors

The salivary glands originate as ingrowths from the oral epithelium, which makes them of ectodermal descent. These ingrowths go on to form the ductal structure. The basic functional unit of a salivary gland is an acinus, made up of serous and mucinous cells. The acini release their secretions into an intercalated duct, which later becomes a larger striated duct, which eventually empties into an excretory duct. The myoepithelial cells surrounding the acini and intercalated ducts are capable of contraction and help with saliva transport (Fig. 21.4). The parotid gland is almost exclusively serous. The submandibular and sublingual glands are both mixed, but the serous component predominates in submandibular glands, whereas the mucinous element is dominant in sublingual glands.[13]

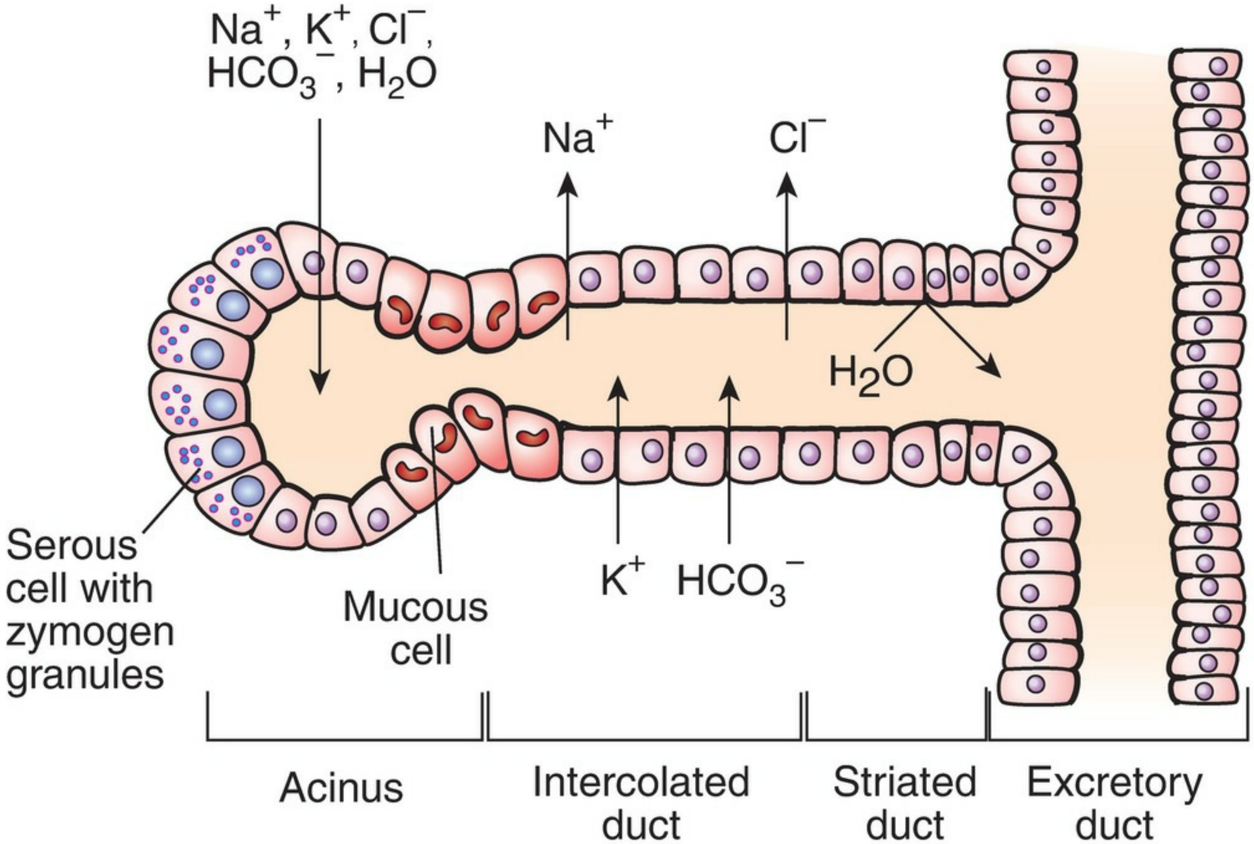

Figure 21.4. Functional unit of a salivary gland. (From Rhoades RA, Bell DR, eds. *Medical Physiology*. 4th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2012.)

There are two leading theories of the histogenesis of tumors of the salivary glands. According to the multicellular theory, each cancer arises from a particular cell type within the secretory unit.[14] For example, Warthin and oncocytic tumors are thought to arise from striated ductal cells and acinic cell tumors from acinar cells.[15] The bicellular reserve cell theory states that the development of any salivary gland neoplasm can be traced to the basal cells of either the excretory or the intercalated ducts, which are thought to be the reserve cells capable of differentiation. According to this model, pleuripotent intercalated duct basal cells give rise to salivary neoplasms of adenomatoid origin (pleomorphic adenoma, oncocytic tumors, acinic cell and adenoid cystic carcinomas). The epidermoid tumors (squamous cell and mucoepidermoid carcinomas) are then thought to be derived from the excretory duct reserve cells.[16]

Histologic Classification

Salivary gland malignancies remain a diagnostic challenge for pathologists due to the rarity of these tumors as well as the wide histopathologic diversity and heterogeneity of these cancers. The modifications to the original classification scheme described by Foote and Frazell have resulted in the current World Health Organization (WHO) classification.[17] The most recent WHO classification published in 2005 recognizes 13 benign and 24 malignant tumor subtypes, which are summarized in Table 21.1.[18]

Table 21.1 WHO Histologic Classification of Salivary Gland Neoplasms

Benign Epithelial Tumors	Malignant Epithelial Tumors
Basal cell adenoma	Acinic cell carcinoma
Canalicular adenoma	Adenoid cystic carcinoma
Cystadenoma	Adenocarcinoma, not otherwise specified
Ductal papillomas	Basal cell adenocarcinoma
Intraductal papilloma	Carcinoma ex pleomorphic adenoma
Inverted ductal papilloma	Carcinosarcoma
Lymphadenoma	Clear cell carcinoma, not otherwise specified
Myoepithelioma	Cystadenocarcinoma
Oncocytoma	Epithelial–myoepithelial carcinoma
Pleomorphic adenoma	Large cell carcinoma
Sebaceous adenoma	Low-grade cribriform cystadenocarcinoma
Sialadenoma papilliferum	Lymphoepithelial carcinoma
Warthin tumor	Metastasizing pleomorphic adenoma
	Mucinous adenocarcinoma
	Mucoepidermoid carcinoma
	Myoepithelial carcinoma
	Oncocytic carcinoma
	Polymorphous low-grade adenocarcinoma
	Sebaceous carcinoma
	Sebaceous lymphadenocarcinoma
	Salivary duct carcinoma
	Sialoblastoma
	Small cell carcinoma
	Squamous cell carcinoma

Mucoepidermoid carcinoma, adenoid cystic carcinoma, adenocarcinoma, and malignant mixed tumor are the most common malignancies of the salivary glands, whereas acinic cell carcinoma and anaplastic carcinomas are encountered less frequently.[4–12,19–22] Metastases from the skin of the scalp and face and squamous variants of mucoepidermoid carcinoma should be considered and ruled out prior to making the diagnosis of a primary salivary gland squamous cell carcinoma (SCC), as those are rare. In their review, Ying et al.[23] found that SCC of the parotid represented metastases from an identified primary site in more than half of the patients. Cutaneous

carcinomas and melanomas of the scalp and face often drain into intraparotid lymph nodes and comprise 70% to 80% of metastases to intraparotid lymph nodes. Metastases from infraclavicular primary sites are less common.[24–26]

The relative incidence rates of various malignant tumors by salivary gland subsite according to the National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) Program data from 1992 to 2006 are presented in Figure 21.5. As mentioned above, perhaps erroneous SCC designation within the database may have affected the data presented in the figure. The frequency of encountering a certain neoplasm depends on the specific anatomic subsite of interest. Mucoepidermoid carcinoma is the most commonly encountered cancer in the parotid gland, whereas the submandibular gland is more likely to give rise to adenoid cystic carcinoma. Both entities occur at approximately the same rate within the minor salivary glands, followed by adenocarcinoma.

of the cases are either intraparotid metastases or misdiagnosed high-grade mucoepidermoid carcinomas.

Incidence and Etiology

Approximately 7% of epithelial head and neck cancers (HNC) in the United States originate in the salivary glands.[27] The annual incidence varies between 0.3 and 3 cases per 100,000 population.[13] Similar numbers have been quoted in the European reports.[28]

Our current understanding of the pathogenesis of salivary gland malignancies is quite limited. The significance of both hereditary and environmental influences has been proposed. For example, a higher incidence of salivary gland tumors has been shown in some ethnic groups, such as Eskimos.[29] Ionizing radiation increases the risk of development of salivary gland malignancies, according to the multiple descriptive studies of atomic bomb survivors in Hiroshima and individuals with a history of low-dose radiation of the head and neck.[30–35] Industrial exposures to rubber and nickel have also been proposed to elevate the risk for development of salivary gland neoplasms.[36] Recent genomic characterizations of salivary tumors show a unique pattern of gene alterations in certain histologic subtypes. Despite these reports, a clear understanding of the etiology of salivary tumors remains elusive.

Clinical Presentation and Evaluation

History

Cancers of the major salivary glands present most commonly as an asymptomatic swelling and are often present for many months/years before a patient’s initial presentation for medical evaluation. The symptoms that arise from minor salivary gland tumors depend upon the anatomic regions involved. Thus, cancers of the paranasal sinuses can cause facial pain and/or

swelling, whereas cancers of the nasal cavity can lead to obstruction of the nasal passages and/or epistaxis. Cancers of minor salivary glands of the oral cavity can lead to a mass effect, which can result in ill-fitting dentures. Cancers arising in the larynx commonly present with hoarseness and/or sore throat. Sun exposure and the presence of current or previously excised skin lesions should be ascertained when squamous cancer or melanoma is found in parotid lymph nodes.

Pain is more common in patients with malignant compared to benign salivary gland neoplasms. Between 10% and 29% of patients with cancer of the parotid gland report pain, perhaps due to perineural invasion (PNI) by the cancer.[28,37–40] Pain is also reported in a few patients with benign submandibular neoplasms and up to 50% of patients with cancer of the submandibular gland.[8,41,42]

Physical Findings

As with any tumor, it is of paramount importance to document the exact location and size of the mass, as the details from this assessment dictate the staging, management, and treatment as well as follow-up.

As noted above, the majority of salivary tumors present as a palpable mass. Salivary lesions of the parapharyngeal space, however, may not be palpable; hence, the lateral pharyngeal walls should be examined transorally for asymmetry. Obviously, tumor fixation to either skin or deep structures suggests malignancy. In patients with untreated cancer of the parotid, fixation to the skin was reported in 9%, whereas fixation to the deep tissues was reported in 13% to 17% from the Memorial Sloan Kettering and MD Anderson Cancer Centers.[39,43]

Facial nerve involvement manifested by weakness of the muscles innervated by one or more branches of the nerve is also among the prominent hallmarks of physical examination for malignancy. Although facial nerve paresis or paralysis is present in fewer than a quarter of cases, it is generally associated with a poor prognosis.[43–45] Facial nerve involvement occurs most commonly in patients with adenoid cystic carcinoma, undifferentiated carcinoma, or SCC.[44,46,47]

The presence of cervical lymphadenopathy is another strong predictor of malignancy. Cervical lymph nodes are found to be positive at presentation in

~13% to 25% of patients with cancers of the parotid,[28,39,43,48] 14% to 33% of patients with cancer of the submandibular gland,[41,49,50] and 14% in patients with cancers of the minor salivary glands.[12] The histopathologic subtypes of cancer of the salivary glands most likely to metastasize to regional lymph nodes are SCC, high-grade mucoepidermoid carcinoma, high-grade adenocarcinoma, and malignant mixed tumor.[38,39,41]

Diagnostic Imaging

As a general principle, imaging studies should only be obtained if the patient management might be altered by the result. Most minor salivary gland tumors require radiographic evaluation to better delineate the extent of disease, including the involvement of adjacent structures. A thorough history and physical examination are generally sufficient to establish the diagnosis and extent of a tumor in the major salivary glands. Imaging is usually warranted to define the extent of the primary cancer as well as the presence of any regional metastases. This is particularly true of deep lobe parotid tumors extending into the parapharyngeal space.

Several imaging modalities are available as adjuncts in evaluating a tumor of the salivary glands. In expert hands, ultrasonography is an appropriate initial step in evaluation of the major salivary gland tumors and the status of the neck. It is readily available, none invasive, and cost-effective. Ultrasonography also allows for precise localization of the tumor within the gland and readily differentiates between cystic and solid components, thereby enabling accurate fine needle aspiration or core biopsy. Heterogeneous echogenicity, ill-defined margins, and extension beyond the borders of the gland with involvement of adjacent structures are ultrasonographic signs of a malignant process.[51–53] Computed tomography (CT) is the study of choice for the evaluation of involvement of cortical bone, whereas magnetic resonance imaging (MRI) better visualizes soft tissue details of the minor salivary gland lesions, deep parotid tumors, and perineural spread of tumor. Irregular borders, extraglandular extension, and hypointensity on T2-weighed images are suggestive of malignancy.[51,53,54] Additionally, in the case of sinonasal minor salivary gland tumors, MRI can assist in differentiating between a tumor and opacification of an obstructed sinus by fluid. Combined 18 F-fluorodeoxyglucose–positron emission tomography (FDG–PET)/CT has assumed an important role in head and neck

oncology. However, its applications remain limited in salivary gland neoplasms.[55] Although it has been shown to be superior to CT alone in delineating the tumor extent, nodal involvement, and distant metastases,[55–57] it is not particularly useful in distinguishing between malignant and benign neoplasms. This is due to the fact that some benign salivary gland lesions, such as pleomorphic adenomas and Warthin tumors, are capable of high glucose uptake.[58]

Fine Needle Aspiration Cytology

Unlike the minor salivary glands, open incisional biopsy is not recommended for parotid and submandibular glands due to the potential risk of tumor seeding and injury to the facial nerve or its branches. Fine needle aspiration cytology (FNAC) provides an insight into the preliminary diagnosis of a salivary gland lesion, which could be useful in the formulation of a management plan. For example, a poor surgical candidate may be observed once a benign result is obtained on FNAC. Additionally, a person with a diagnosis of lymphoma or benign lymphoepithelial disease of HIV on FNAC may avoid a diagnostic parotidectomy. Up to one-third of patients can be spared an unnecessary operation and risk to the facial nerve.[59]

In a recent meta-analysis of FNAC in salivary gland tumors by Schmidt et al., the sensitivity and specificity for diagnosis of neoplasia were 71% and 100%, respectively, and the sensitivity and specificity for diagnosis of malignancy were 76% and 97%, respectively. For differentiation between a benign and malignant salivary lesion, the positive and negative predictive values were 90% and 94%, respectively.[60] In a systematic review by Colella et al., the concordance rates between cytologic and surgical pathology diagnoses were 95.61% for benign and 79.95% for malignant salivary tumors. The concordance rates are lower for particular histologic types of salivary tumors: 63% for mucoepidermoid carcinomas and 70% for adenoid cystic carcinomas.[61] In summary, FNAC is a safe, fast, well-tolerated, and reliable procedure for distinguishing between benign and malignant lesions, though it is not as useful in differentiating between the various malignancies. The challenges encountered with FNAC include lack of histologic architecture within the sample and necessity of a cytopathologist with significant experience in salivary gland disease. Small-volume care center providers should maintain a low threshold for pathology consultation within

large academic institutions.

Core needle biopsy (CNB) technique was introduced to address some of the shortcomings of FNAC. Histologic architecture is preserved within the sample provided by the larger needle used (14 to 21 gauge). Also, larger tissue sample size eliminates the need for a cytopathologist to assess the specimen adequacy. Lastly, CNB specimens are formalin fixed and paraffin embedded, which facilitates the immunohistochemical staining. According to the recent meta-analysis by Schmidt et al., CNB sensitivity was 92% and specificity was 100%, with a 1.2% sample inadequacy rate. When compared to FNAC, CNB had a higher diagnostic accuracy. Hematoma was reported as the main complication, occurring in 1.7% patients, none of whom required aspiration or drainage. Theoretically, because of the larger diameter needle, CNB is more painful and there is a greater risk of facial nerve damage. No cases of permanent CN VII weakness have been reported thus far.[62] Regardless of the biopsy technique used, clinical judgment should be used in analyzing the results if the cytologic aspiration diagnosis is inconsistent with the clinical presentation.

Staging

Oncologic staging is critically important in the assessment of disease extent, prediction of prognosis, formulation of a treatment plan, and follow-up evaluations. It is an integral tool in communication between the treating surgeon and the patient and within the clinical and research medical communities. The current AJCC staging system used for major salivary gland cancers is presented in Table 21.2.[63] As of now, there is no separate standardized staging system for minor salivary cancers. A study from Memorial Hospital demonstrated that the staging system used for squamous carcinoma of the upper aerodigestive tract can be used in evaluation of the minor salivary gland malignancies arising in the same anatomic regions and has a similar prognostic value.[64]

Table 21.2 AJCC Staging System for Salivary Gland Cancer (7th Edition)

Primary Tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of a primary tumor
T1	Tumor ≤2 cm in greatest dimension without extraparenchymal extension
T2	Tumor >2 cm but ≤4 cm in greatest dimension without extraparenchymal extension but <4 cm
T3	Tumor >4 cm and/or tumor having extraparenchymal extension
T4a	Moderately advanced disease. Tumor invades the skin, mandible, ear canal, and/or facial nerve
T4b	Very advanced disease. Tumor invades the skull base and/or pterygoid plates and/or encases carotid artery
Regional Lymph Nodes (LN) (N)	
NX	Regional LNs cannot be assessed
N0	No regional LN involvement
N1	Metastasis in single LN <3 cm
N2a	Metastasis in single ipsilateral LN >3 cm but <6 cm
N2b	Metastasis in multiple ipsilateral LNs >3 cm but <6 cm
N2c	Metastasis in bilateral or contralateral LNs, none >6 cm
N3	Metastasis in LN >6 cm
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
Stage Grouping	
I	T1/N0/M0
II	T2/N0/M0
III	T3/N0/M0
	T1–3/N1/M0
IVA	T4a/N0–1/M0
	T1–4a/N2/M0
IVB	T4b/any N/M0

Pathology

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common cancer of salivary gland origin. The key morphologic feature is multicystic arrangement of mucous and epidermoid cells. Based on the proportion of cystic component, neural invasion, degree of anaplasia, mitoses, and presence of necrosis,

mucoepidermoid carcinomas are classified into low-grade, intermediate-grade, or high-grade categories.[64] Low-grade cancers manifest well-defined glandular architecture. They very rarely metastasize and have an excellent overall prognosis. In high-grade mucoepidermoid carcinomas, the glandular structure is less defined or may be absent altogether. These tumors have a propensity for early and aggressive spread, with a rate of regional metastasis up to 70%.[65] As the name implies, the intermediate-grade lesions contain moderate cystic components and are less clinically aggressive than their high-grade counterparts. The patients with low-grade disease have an almost negligible recurrence rate.[66] The natural history of mucoepidermoid carcinoma is less protracted than that of other salivary malignancies; hence, a 5-year disease-free interval suggests cure.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is the most common cancer of the submandibular gland, and it is as common as mucoepidermoid carcinoma in the minor salivary glands. It constitutes ~10% of all epithelial salivary tumors. It most commonly presents as a slow-growing mass and can be associated with pain, due to its propensity for neural invasion and lack of a capsule barrier.[67] Patients with adenoid cystic carcinoma must be under careful clinical surveillance indefinitely, due to its protracted natural history, with disease-related deaths having been reported even after 20 years of disease-free survival.[68,69] Despite excellent local control, adenoid cystic carcinomas result in poor long-term outcomes due to distal recurrence. The lung is the primary site for distant metastases; however, patients can often live for many years with asymptomatic pulmonary metastases that remain stable or progress slowly.[70]

Adenoid cystic carcinoma can be arranged in solid, tubular, and cribriform histologic patterns. Predominantly, tubular and cribriform lesions tend to be less aggressive than tumors with >30% solid component.[71,72] The solid histologic pattern prognosticates development of distant metastases and poor long-term survival.[71] The difference in survival based on histopathologic grading disappears at 10 years after the treatment, suggesting that the histology affects the disease-free survival, with minimum impact on the overall outcome.[73–75]

Adenocarcinoma, Not Otherwise Specified

Adenocarcinoma, not otherwise specified (NOS), is notable for its ductal differentiation.[76] Again, histologic grading affects prognosis: high-grade lesions tend to have worse outcomes. Also, the survival decreases significantly from 5 to 10 years after treatment, which warrants a long-term surveillance in these patients.[77,78]

Salivary Duct Carcinoma

Salivary duct carcinomas (SDC) are rare tumors with aggressive clinical behavior and a poor prognosis. These cancers manifest as a rapidly growing mass and occur in patients over 50 years of age, with a male to female ratio of 4:1. The majority of cases (>80%) originate in the parotid gland.[79] The rate of cervical lymphatic involvement at presentation is over 50%. Most patients present with advanced stage disease: one-third of them suffer recurrence, 46% develop distant metastases, and 65% die of the disease, usually within 4 years of diagnosis.[80]

Carcinoma Ex Pleomorphic Adenoma

As the name implies, carcinoma ex pleomorphic adenoma originates in the setting of a pleomorphic adenoma. The malignant component usually features a poorly differentiated adenocarcinoma or an undifferentiated carcinoma. The proportions of benign and malignant components vary. This cancer is classified into noninvasive, minimally invasive, or invasive.[81] Noninvasive variants display indolent behavior similar to that of pleomorphic adenomas, whereas the invasive variants are more aggressive, with recurrence of 23%, regional metastatic rates between 49% and 56%, and distal metastatic rate up to 40%.[82,83]

Acinic Cell Carcinoma

Acinic cell carcinoma affects all age groups and is almost never seen outside of the parotid gland. Due to its indolent course, it is considered a low-grade cancer. However, high-grade papillary–cystic variants exist. Despite its overall good prognosis, the potential of local recurrence or distant metastases exists, especially in advanced stage or improperly treated tumors.[84,85] In the

review of prognostic factors by Neskey et al.,[86] older age and larger tumor size were found to correlate with poor overall survival. Also, distant metastases were prognostic of disease-specific death.

Squamous Cell Carcinoma

Primary salivary SCC of the salivary glands is rare. Time and care should be taken to distinguish it from the more common high-grade mucoepidermoid carcinoma or metastatic SCC from a cutaneous malignancy of the face, ear, or scalp. In the review by Ying et al.,[23] over 60% of patients with SCC of the parotid had a known primary cutaneous malignancy (most commonly, auricle). Only a quarter of the patients were found to have the primary salivary SCC. Both groups had high rates of cervical node involvement and poor disease outcome.

Lymphoma

Up to 85% of salivary gland lymphomas are of the non-Hodgkin type. Lymphomas of the salivary glands arise either from intraglandular lymph nodes (nodal) or from the nondiscrete lymphoid tissue within the gland parenchyma (extranodal). Although extranodal lymphomas affect salivary glands in only ~5% of cases, the overwhelming majority of these occur in the parotid gland. Lymphoma of the salivary glands either can be the only manifestation of the disease in primary cases or can also be a part of a disseminated lymphomatous process. Primary lymphomas of the salivary glands are usually associated with Sjögren syndrome.[87] Those associated with Sjögren syndrome have a significantly worse prognosis, compared to lymphomas arising in normal salivary glands. The risk of the development of the lymphoma in patients with Sjögren syndrome is 44-fold higher than that in the general population.[88]

Secondary (Metastatic) Cancers

The majority of metastases to the salivary glands involve the parotid gland and are due to intraparotid lymph node spread from the cutaneous malignancies of the face, ear, and scalp. Approximately 40% of these are

SCCs and 40% are melanomas. The majority of metastatic parotid SCCs appear within the first year of treatment. Therefore, every patient with a parotid mass with cutaneous histology should undergo careful examination of the skin of the head and neck.

Involvement of the salivary glands by the distant infraclavicular metastatic cancers is extremely rare. When it does occur, the parotid gland is most commonly affected, and the most common sites giving rise to these metastases are the lung, kidney, and breast.[89]

Grading of Malignant Salivary Gland Neoplasms

The diverse anatomic and histopathologic origins of the salivary gland cancers make them a diagnostic challenge. In order to guide the prognostic and management decision making, it was proposed to grade salivary tumors based on their clinical behavior. The association between tumor histology and local, regional, and distal control and overall outcomes has been demonstrated.[90] However, there are clinical "outliers," proving that the relationship is not absolute and constant. Seethala states that due to the rarity of cancers of the salivary glands, the grading is not standardized, which makes it less reproducible across different centers or individual pathologists with varying levels of experience in reviewing cases of cancer of the salivary glands. Also, cancers perceived as "high risk" historically, such as SDC or SCC, are not graded at all.[91]

To add to the complexity, heterogeneity even exists within the histologic groups themselves, and there are aggressive variants within the low-risk cancers as well as indolent variants among the high-risk cancers. For instance, grading is the most important consideration in prognosis and management of mucoepidermoid carcinoma. Surgical excision is sufficient for low-grade cancers, rendering an overall 5-year survival of over 90%. However, for high-grade cancers, overall survival drops below 50% and adjuvant radiation and neck dissections are required.[90,91]

The latest WHO classification of cancer of the salivary glands published

in 2005 categorizes them into low- and high-risk groups, based on the histology and grading (Table 21.3). To fine-tune the existing system, Jouzdani et al.[92] demonstrated a separate intermediate-risk category. Based on the constructed Cox models, this intermediated group has an individual prognostic value: One step elevation from low- to intermediate- to high-risk level resulted in 2.3 increase in the risk of disease recurrence and 2.6 increase in risk of nonspecific death. This three-tier histologic classification is presented in Table 21.4.[92]

Table 21.3 Risk Classification of Cancer of the Salivary Glands by the WHO

Low Risk	High Risk
Acinic cell carcinoma Adenocarcinoma NOS and cystadenocarcinoma, low grade[a] Basal cell adenocarcinoma Carcinoma ex pleomorphic adenoma (intracapsular/minimally invasive or with low-grade histology) Clear cell carcinoma Epithelial–myoepithelial carcinoma Low-grade mucoepidermoid carcinoma[a] Low-grade salivary duct carcinoma (low-grade cribriform cystadenocarcinoma) Myoepithelial carcinoma Oncocytic carcinoma Polymorphous low-grade adenocarcinoma Sialoblastoma	Adenocarcinoma and cystadenocarcinoma, NOS, high grade[a] Adenoid cystic carcinoma[b] Carcinoma ex pleomorphic adenoma (widely invasive or high-grade histology) Carcinosarcoma High-grade mucoepidermoid carcinoma[a] Large cell carcinoma Lymphoepithelial carcinoma Metastasizing pleomorphic adenoma Mucinous adenocarcinoma Sebaceous carcinoma and lymphadenocarcinoma Squamous cell carcinoma Small cell carcinoma Salivary ductal carcinoma

[a]For these tumors, intermediate-grade classification is controversial. For mucoepidermoid carcinoma, it depends on the grading system employed. For adenocarcinoma NOS (not otherwise specified), intermediate grade should be placed in the high-risk group.

[b]All adenoid cystic carcinoma grades are high risk for local recurrence, but only solid high-grade adenoid cystic carcinoma is high risk for nodal metastasis.

Table 21.4 Three-Tier Histologic Classification of Cancers of the Salivary Glands by Jouzdani et al.

Low Risk	Intermediate Risk	High Risk
Acinic cell carcinoma Basal cell carcinoma Clear cell carcinoma Cystadenocarcinoma Epithelial–myoepithelial carcinoma Low-grade cribriform cystadenocarcinoma Low-grade mucoepidermoid Polymorphous low-grade adenocarcinoma Mammary analogue secretory carcinoma	Mucinous adenocarcinoma Myoepithelial carcinoma Intermediate-grade mucoepidermoid Tubular and cribriform adenoid cystic carcinoma	Adenocarcinoma NOS Carcinosarcoma Dedifferentiated acinic cell carcinoma Dedifferentiated basal cell adenocarcinoma High-grade mucoepidermoid Large cell carcinoma Lymphoepithelial carcinoma Oncocytic carcinoma Salivary duct carcinoma Sebaceous carcinoma Small cell carcinoma Squamous cell carcinoma Undifferentiated, solid adenoid cystic carcinoma

NOS, not otherwise specified.

Molecular Alterations in Salivary Malignancy

The goal of analysis of molecular oncologic details is to identify diagnostic biomarkers and markers prognostic of clinical behavior and to broaden the spectrum of potential therapeutic targets and therapies. HER2 is a transmembrane glycoprotein receptor involved in cell growth and differentiation that has been very well studied in breast oncology due to its overexpression in aggressive breast carcinoma. HER2 was commonly found to be overexpressed in cancers of the salivary gland of excretory duct origin, such as SDC and mucoepidermoid carcinoma.[93–96] Cancers with HER2 overexpression have a propensity for regional lymphatic spread and were shown to have a worse overall survival.[97] Unfortunately, the clinical benefit of HER2-targeted therapy has not yet been demonstrated.[98,99]

The epidermal growth factor receptor (EGFR) is another transmembrane receptor involved in signal transduction. Its expression has also been correlated with aggressive malignant behavior.[100] EGFR is commonly encountered (>50% frequency) in both mucoepidermoid carcinoma and SDC but is not seen as commonly in adenoid cystic carcinoma.[41,97,101–181]

C kit is a protooncogene responsible for encoding a transmembrane receptor–type tyrosine kinase, which is involved in growth stimulation and differentiation. Its expression has been demonstrated in adenoid cystic carcinomas.[102,103] Absence of C kit expression is a poor prognostic factor.[100]

Additionally, a number of genetic alterations were identified in cancer of the salivary glands over the last decade. Translocation t(11:19)(q21;p13) results in the MECT1–MAML2 fusion gene, which disrupts the NOTCH pathway in mucoepidermoid carcinoma, and its presence carries a favorable prognosis.[104] Translocation t(6;9)(q22-23;p23-24) produces a fusion of transcription factors MYB and NFIB in adenoid cystic carcinoma and has been correlated with worse outcomes.[105]

More recently, complete genomic profiling of adenoid cystic carcinoma revealed extensive mutational diversity of this disease, providing some answers to the questions of oncogenesis and tailored treatment. For example, mutations in genes responsible for chromatin-state regulators were identified, which may suggest chromatin deregulation as the inciting event for carcinoma development.[106,107] Additionally, multiple "actionable genomic alterations" (sequences known to impact targeted oncologic treatment) were identified in over 40% adenoid cystic carcinoma tumor samples.[108]

Treatment: Surgery

Surgery remains the gold standard of treatment of salivary gland malignancies. The next few paragraphs will review the details of surgical management for both major and minor salivary glands, indications for neck dissection, and usefulness of intraoperative frozen section analysis.

Parotid Gland

A general thought process when considering treatment options for patients with cancer of the salivary glands is summarized in Table 21.5. Surgery remains the primary treatment modality for primary and/or regionally metastatic cancer of the parotid gland. The minimum operation appropriate for early-stage cancers is lateral or superficial parotidectomy with dissection and preservation of the facial nerve. More extensive cancers may require more extensive operations with resection of adjacent structures, such as portions of the mandible, zygoma, temporal bone, overlying skin, and facial nerve. In general, these radical procedures are associated with poor oncologic outcomes.

Table 21.5 General Algorithm for Management of Cancer of the Salivary Glands

Surgery: Primary Site Only	Low-grade histology Low T stage (T1 or T2)
Primary Site and Neck Dissection	Pathologic cervical LNs N0 neck in setting of: High-grade histology High T stage (T3 or T4)
Surgery and Adjuvant XRT	Close (<2 mm) or positive margins High-grade histology High T stage (T3 or T4) Pathologic cervical lymph nodes Perineural invasion
Chemotherapy	Distant metastasis or unresectable disease

The introduction of radiation has altered our approach to the management of the facial nerve in surgical treatment of parotid cancers. Unless there is gross infiltration of the nerve by the tumor, every attempt at preservation should be made.[109] Radiotherapy in the adjuvant setting is intended to control any microscopic residual disease. When planning the management of the facial nerve, histologic characteristics of the cancer must be taken into consideration. This is particularly true of cancers with a propensity for PNI and spread, such as adenoid cystic or SCC. Per review by Iseli et al.,[110] better 5-year disease control and a trend for improved 10-year survival were observed in patients with adenoid cystic carcinoma who underwent facial nerve sacrifice. As expected, this came at the expense of quality of life.[110] If the main trunk of the nerve or its major branches must be sacrificed and primary anastomosis is not feasible, cable grafting with the greater auricular or sural nerves should be performed in the same setting. As mentioned above, over 60% of patients with facial nerve grafting are able to achieve the best outcome, defined as House-Brackmann Grade III. Most Grade III and Grade IV recoveries occur within 6 months.[111] Positive nerve margins do not affect the postoperative facial nerve function after immediate grafting in the review by Wax and Kaylie; hence, the repair is recommended even when perineural margins are suspected to be positive.[112] According to Brown et al.,[113] a

comparison of radiated and unradiated grafts revealed no significant difference with respect to the best facial nerve function achieved.

Submandibular and Sublingual Glands

En bloc resection of the entire submandibular triangle for cancer of the submandibular gland has been popularized in the earlier literature.[41] Currently, the extent of resection is being individualized to the tumor and patient characteristics. For small early-stage cancers confined to the submandibular gland, a simple excision of the gland may be adequate. For a more extensive cancer, a more anatomically aggressive operation may be needed with resection of the adjacent lymph nodes, overlying skin, nearby muscles, lingual and/or hypoglossal nerve(s), bone, and the floor of the mouth.

With respect to sublingual glands, en bloc resection is preferred. The extent of such resection is a balance between optimal oncologic result and optimal functional outcome. In general, the principles of SCC management are followed.

Minor Salivary Glands

The surgical approach to the management of cancer of minor salivary origin is location specific. Again, the principles of management of SCC of the upper aerodigestive tract are followed. An individualized and tailored to the patient and tumor characteristics surgical approach and operation are chosen.

Neck Dissection

Metastases of cancer of the salivary glands to the regional lymph nodes have an adverse impact on prognosis.[114] A recent analysis of the anatomical distribution of cervical lymph node involvement in cancer of the parotid concluded that unilateral cervical lymph nodes in levels II and III are at greatest risk for metastasis.[115] The risk of cervical metastases depends on the tumor location, size, and grade. For cancers of the major salivary glands, the reported rates of cervical lymphatic involvement are between 14% and 25%.[116–119] This range is much broader for cancers of the minor salivary glands. Although cervical metastases are present in 10% of cancers arising within minor salivary glands of the oral cavity, this number rises to 33% for

pharyngeal and laryngeal sites of origin.[120] Larger cancers have a higher incidence of cervical lymphatic involvement: the rate of occult cervical metastases is 20% in patients with a cancer >4 cm in size and only 4% in those with smaller lesions.[118] Finally, the rates of positive cervical lymph nodes are between 32% and 62% in high-grade cancers of major salivary glands and 40% in minor salivary gland cancers.[116–120] Low-grade histopathology tumors of both minor and major salivary glands harbor cervical lymph node metastases in <15% of cases.[116–121]

Although there is a clear indication for cervical lymphadenectomy in patients with palpable neck disease, there are no uniformly accepted guidelines for management of a clinically negative neck. The histology of the cancer and its anatomic dimensions determine the rate of occult metastases. Zbaren et al.[122] demonstrated that patients who underwent an elective neck dissection versus observation for parotid carcinoma had lower recurrence rates (12% vs. 26%) and better 5-year disease-free survival (86% vs. 69%). Herman et al.[120] treated 59 clinically N0 high-grade cancer of the salivary gland with surgery and postoperative radiation to the primary site and elective neck dissection or neck irradiation. After a 5.2-year follow-up, the rates of recurrence and cause-specific survival were similar.[120] This suggests that elective neck treatment, surgical or with irradiation, should be offered to patients with large and high-grade cancers.

Intraoperative Frozen Section Analysis

Advocates of the intraoperative use of frozen section pathologic analysis in surgery for cancer of the salivary glands find it useful in planning of the extent of local resection and the need for elective neck dissection. A recent meta-analysis of 13 studies with over 1,800 cases by Schmidt et al.[123] demonstrated sensitivity of 90% and specificity of 99% for frozen section analysis. The accuracy of the analysis was found to be consistent across a number of study centers.[123] However, the accuracy of frozen section is histopathology dependent: it is somewhat lower for malignant lesions at 85.9%, compared to 98.7% in benign pathology cases. The most common overdiagnosed benign tumor is pleomorphic adenoma. Mucoepidermoid carcinoma is the most frequently encountered entity in the false-negative category.[13] In summary, frozen section pathologic analysis may be useful in operative decision making in challenging settings. However, the findings of the analysis should be considered in light of the clinical picture and caution should be taken if there is a discrepancy.

Results of Surgical Treatment

For patients treated with surgery alone, failure at the primary site has been a challenge. Prior to the introduction of adjuvant radiation, the reported rates of locoregional recurrence were 49%, 60%, and 65% for parotid, submandibular, and minor salivary gland primary sites, respectively. Isolated failure in the neck was quite rare.[4]

Overview of Surgery and Complications for Cancer of the Parotid and Submandibular Glands

Superficial Parotidectomy

The patient should be prepped and draped in such a way that half of the face

is exposed, so that facial motion can be monitored during the procedure. Muscle paralysis should be avoided for the same reason. A modified Blair incision is outlined: anterior to the tragus, around the earlobe, and into the submandibular crease or into the hairline. Markings should be made at the site of earlobe attachment, which would facilitate closure later. The skin is elevated over the parotid containing the mass, taking care to preserve the adequate flap thickness. The parotid gland is elevated off of the ear canal and the anterior border of the SCM muscle. The main trunk of the facial nerve is identified between the insertion of the digastric muscle and tragal pointer. Each of the branches of the facial nerve is dissected, elevating the parotid gland substance off of the nerve. The face should be cautiously monitored for movement. Every effort should be made to preserve the facial nerve, except for the cases where preoperative facial paralysis exists. Postoperative hemostasis and facial nerve function need to be confirmed. The wound is closed in layers over a suction drain. The further surgical details and descriptions of more extensive procedures are beyond the scope of this chapter.

Submandibular Gland Excision

Adequate exposure can be achieved by cervical extension. The patient should be prepped and draped in such a way that the lower lip is exposed, so that facial motion can be detected during the procedure. Muscle paralysis should be avoided for the same reason. A horizontal incision is made within the natural neck crease approximately at the level of hyoid bone. The incision is carried through skin, subcutaneous tissues, and platysma muscle to the most inferior extent of the submandibular gland. The glandular fascia is incised and elevated off the gland. Facial vein is encountered and ligated. Vein retraction and fascia elevation will protect marginal mandibular nerve, which is superficial to both of these structures. The superior portion of the gland is dissected off of the mandible bluntly. The anterior portion of the gland is identified and separated from the anterior belly of digastric muscle. Once the mylohyoid muscle is identified, it is skeletonized to its most posterior extent and retracted medially to expose the duct and lingual and hypoglossal nerves. Only once both nerves are exposed, and in view, the duct is divided. The rest of the gland is delivered from the neck quite easily. The wound is closed in layers over a suction drain. The further surgical details and descriptions of more extensive procedures are beyond the scope of this chapter.

Complications of Parotidectomy

Injury of the facial nerve is the most feared and devastating complication of parotidectomy. To establish the baseline presence and degree of weakness, facial function should be assessed once the patient is extubated and able to follow commands. Some degree of facial weakness is expected in 13% to 100% of patients undergoing parotidectomy, depending on the underlying pathology and its location within the gland, extent of operation, and whether it is a reoperative setting.[124] Most cases of facial nerve dysfunction are a result of stretching, entrapment, compression, and thermal and ischemic injuries.[125] The factors predictive of postparotidectomy facial nerve paresis are extent and duration of operation, close proximity of the tumor to the facial nerve, histologic makeup, and the size of the lesion.[126,127] Fortunately, the rate of permanent paralysis is below 5%, with most cases of facial nerve weakness recovery occurring within 12 months of operation.[124,126,127] Should the facial nerve be transected, inadvertently or as a planned step, primary tension-free repair with fine permanent interrupted sutures under magnification should be attempted first.[128] If tension-free repair is not feasible, greater auricular or sural nerves can be used as the interposition grafts. Over 60% of patients with facial nerve grafting are able to achieve facial symmetry at rest, which is the best outcome obtainable after grafting. Most paretic nerves recover within 6 months.[111] Eisele et al.[125] found that the majority of the otolaryngologists/head and neck surgeons in the United States and the United Kingdom routinely use nerve monitoring during parotid surgery. Although it can be of great benefit in technically demanding situations, such as a reoperative setting, radiated field, distorted anatomy, or minimally invasive procedures, there is minimal evidence supporting its routine use in all cases of parotid gland tumor surgery.[125] To reduce the risk of facial nerve injury, alternative dissection techniques should be considered in challenging operative situations. The facial nerve can be identified in the mastoid bone in cases of tumor extension into the region of the stylomastoid foramen. Alternatively, a retrograde dissection should be performed if the main trunk of the facial nerve cannot be dissected in a safe manner.

Hemorrhage is another serious perioperative complication. Most occur within 24 hours and are typically due to failure to achieve adequate

intraoperative hemostasis.[129] Prescription and over-the-counter agents may produce anticoagulation and antiplatelet activity, which increases the risk of bleeding and should be discontinued a sufficient time period before the surgery. Once the diagnosis of the hematoma is established, urgent exploration and evacuation must be performed.

Sialocele, another type of surgical bed collection, may occur after parotid surgery. The transected edge of the parotid gland may secrete saliva and collect under the skin (sialocele) or drain through the skin (fistula). As expected, the intensity of drainage is correlated to gustatory stimuli. The incidence of this bothersome complication is between 4% and 14%.[130,131] The condition is usually self-limited and resolves with repeated needle aspiration and compression dressings. Oral anticholinergics may be useful and should be considered for their suppressive effect on the salivary flow. Should the conservative measures fail, more radical surgical interventions, such as tympanic neurectomy, botulinum toxin A injection, and completion parotidectomy, should be explored.[132]

Frey syndrome (gustatory sweating) is a common occurrence after a parotidectomy. It results from the aberrant healing of transected parasympathetic secretomotor fibers supplying the parotid gland and sympathetic fibers supplying the cutaneous sweat glands and blood vessels, which in turn produces sweating and flushing with gustatory stimuli. The incidence of the condition varies according to the method of detection used. For instance, between 43% and 96% of patients who have had a parotidectomy test positive with a starch–iodine (Minor) test. However, only 14% to 43% of patients report clinical symptoms, most on average within 5 months postoperatively. Less than 10% of postparotidectomy patients experience intractable gustatory sweating.[133,134] Once the syndrome is diagnosed, it can be managed with topical antiperspirants or superficial botulinum toxin A administration.[135] However, most surgeons aim for prevention of clinically evident disease. Intraoperative techniques, such as SMAS, superficial temporal artery fascial (STAF) and SCM flaps, and AlloDerm interpositional grafts, have been described.[136–139] A recent meta-analysis by Curry et al.[140] confirmed the benefit of preventive intraoperative techniques.

Hypoesthesia of the greater auricular nerve is a consequence, not a

complication of parotidectomy. The numbness of the ear lobe and surrounding area resolves to a various degree within 1 year of the operation. Preoperative counseling regarding this sequela of surgery is recommended. Suggestions of preservation of the posterior branches of the greater auricular nerve have been made in hopes of a faster and more complete recovery.[141]

Alteration of the lateral facial contour as a result of parotid excision is of esthetic importance. Again, it is an expected consequence of the operation, not a complication; nonetheless, it can be quite disturbing to the patient. A variety of flaps (SMAS, STAF, SCM), grafts (AlloDerm and dermofat), and lipofilling techniques have been shown to reduce the postparotidectomy depression in the preauricular and over the angle of mandible.[136–139,142] Unless a radical procedure was performed, the majority of the defects take on a more natural contour in a course of a few months.

Complications of Resection of the Submandibular Gland

As with parotid surgery, operations on the submandibular gland place the facial nerve at risk of injury; the marginal mandibular branch is the most commonly affected. The clinical manifestation of the injury ranges between a minor cosmetic asymmetry with movement of the corner of the mouth and poor oral competence. The incidence of transient and permanent weakness is ~9% and <1%, respectively.[143] As mentioned earlier, other nerves in the proximity are the lingual and hypoglossal. A theoretical possibility of injury exists at the time of Wharton duct ligation. Transient lingual nerve paresthesia was noted in 2% by Preuss et al.[143] in their 15-year experience.

Treatment: Radiation Therapy

Traditionally, salivary gland cancers were thought not to be amenable to radiation, but over the last two decades, evidence of the opposite was revealed and radiation became an important treatment modality in both primary and adjuvant settings.[144] Radiotherapy has been shown to improve local–regional control and disease-free survival postoperatively in high-grade and/or advanced stage tumors and those with close or involved margins. Evidence regarding the effect of radiation on the overall survival remains inconclusive. In cases of recurrence after radiation, distant metastasis is the predominant site of failure.[145–147] The Head and Neck Service at Memorial Sloan Kettering Cancer Center performed a matched pair analysis of patients treated with and without adjuvant radiotherapy. Patients with stage III and IV cancer who received postoperative radiation had improved local control and better survival. Patients with early-stage cancer did not benefit from the adjuvant radiation.[148] The summary of current indications for postoperative radiotherapy in the treatment of salivary cancer is presented in Table 21.6.

Table 21.6 Indications for Adjuvant Radiotherapy

High-grade histology
Advanced stage
Close/positive margins
Perineural invasion
Recurrent disease
Pathologically confirmed positive cervical lymph nodes

An alternative beam energy, fast neutron radiation, offers a biologic advantage specific to the treatment of adenoid cystic carcinoma. It has been used for recurrent or residual disease in anatomically challenging to access locations, such as the skull base. Morbidity related to neutron therapy remains an area of investigation and a significant concern, and the initial enthusiasm for its use in the primary treatment of cancer of the salivary glands has waned.[149,150]

In addition to its important role as an adjunct, radiotherapy has been used in the primary setting for patients who are in inoperable or medically unstable. The radiation doses used range between 57 and 74 Gy. Complete responses at 12 months have been reported in a sizeable proportion (64.7%) of patients.[151] Longer follow-up, however, has demonstrated 10-year local control, overall and metastasis-free survival rates of 57%, 46%, and 67%, respectively.[152]

The toxicities of radiation therapy include xerostomia, dysphagia, osteoradionecrosis, and skin and soft tissue fibrosis. In addition, patients treated for cancer of the parotid appear to be particularly prone to sensorineural hearing loss and cochlear damage as a result of adjuvant or primary radiation. Intensity-modulated radiotherapy (IMRT) has been shown to reduce the radiation dose delivered to the cochlea as compared to the conventional three-dimensional conformal radiotherapy (3DCRT).[153] A phase III study of cochlear-sparing IMRT is now open in hopes to compare IMRT and standard 3DCRT with the hearing loss as the primary endpoint.[154]

Treatment: Chemotherapy

Systemic therapy for salivary gland malignancies is used in a palliative setting in patients with bothersome symptoms or rapid disease progression. The available data are limited to some phase II trials in adenoid cystic carcinoma and retrospective reports from individual institutions. There are no phase III trials.[155]

Monotherapy usually involves cisplatin or 5-fluorouracil. Most analyses include a very small number of patients encompassing a variety of histologies. The response rates vary widely between 10% and 70%, and they are typically short-lived.[155] The largest phase II study included 25 patients treated with cisplatin. The response rates were between 16% and 21% in patients without distant site involvement. The rates in the patients with metastatic disease were even lower. The response duration was limited to between 5 and 9 months.[156] Adenoid cystic carcinoma appears to be sensitive to 5-fluorouracil. The response rates and duration reported between 30% and 46% and between 5 and 24 months, respectively.[157,158]

Combination chemotherapy has been shown to result in better response rates, but there has been limited survival benefit. In very symptomatic patients, initial platinum and doxorubicin combination is preferred. Licitra et al.[159] reported the overall response of 27% in their phase II study of 22 patients treated with cyclophosphamide/doxorubicin/cisplatin combination.

The results of molecular targeted therapy have been rather disappointing thus far. There have been no objective responses noted with tyrosine kinase inhibitors (imatinib, gefitinib, lapatinib), monoclonal antibodies (cetuximab, trastuzumab), or proteasome inhibitor bortezomib.[99,160–165] In the best response cases, disease stabilization for a few months was achieved.[155] Thus far, there have been no trials comparing conventional and novel chemotherapy agents as of yet. Currently, over 100 trials are actively recruiting patients with cancer of the salivary gland.[166]

Treatment: Chemoradiation

Although surgery remains the standard of care for treatment of salivary gland malignancies, concurrent chemoradiation options have been explored in patients with locally advanced and unresectable tumors. Rosenberg et al.[167]

report 2-year overall survival and disease-free survival of 67% and 44%, respectively, in patients with advanced high-grade disease (mostly mucoepidermoid carcinoma). Patients undergoing chemoradiation for adenoid cystic cancers seem to be doing even better, with 5-year overall survival and local progression-free survival of 87% and 61%.[168]

Prognostic Factors

Clinical stage is the strongest predictor of prognosis in both major and minor salivary gland cancers.[47] Similar results have been reported by other major centers internationally. The multivariate analysis from the United Kingdom confirmed clinical stage as the most important independent prognostic factor, with 10-year survival rates of 96%, 70%, 47%, and 19% in patients with AJCC stage I through IV disease, respectively.[169] A study from Denmark of patients with parotid cancer revealed similar survival rates of 85%, 69%, 43%, and 14% for UICC stage I through IV, respectively.[28]

Prognosis and treatment outcome strongly correlate with the tumor histopathologic type and grade.[42,148,169] In general, patients with high-grade histologic type present with advanced stage lesions, so histologic grade is at least partially reflected in the clinical stage. Patient with acinic cell carcinoma tend to do very well with a 5-year survival of 76% to 100%.[84,85,170] In patients with mucoepidermoid carcinoma, 5-year survival drops from 76% to 100% in patients with low-grade lesions to 22% to 49% in patients with high-grade lesions.[171–176] In adenoid cystic carcinoma, 5-year survival ranges between 50% and over 80%, with solid component histology having worse outcomes.[68–75,177–180] Long-term survival is dramatically worse: 10-year survival is between 29% and 67%, and 15-year survival is at 25%.[68,69] The overall 5-year survival for patients with salivary adenocarcinoma is 76% to 85% but falls to 34% to 71% after 10 years.[76]

Patient demographic details, such as gender and age, are also important prognostic factors. Males tend to have a worse outcome.[181] Increasing age negatively affects the outcome prognosis.[42,136]

Summary

Salivary gland malignancies are a relatively rare and histologically heterogeneous group. Arising from both major and minor salivary glands, they present at various anatomical sites and demonstrate a wide range of clinical behaviors. Both diagnostic imaging and fine needle aspiration help to establish the plan of care. Prognostic factors include clinical stage, histopathologic type and grade, age, and gender. Although surgery, in form of excision of the primary tumor with or without cervical lymphadenectomy, remains the gold standard, other modalities (such as definitive radiation or concurrent chemoradiation) are available options in unresectable cases.

22 Tumors of the Parapharyngeal Space

Zhen Gooi, Matthew J. Kruse, David W. Eisele, Jeremy D. Richmon

The evaluation and treatment of tumors of the parapharyngeal space (PPS) have evolved over the past few decades. Successful management of tumors in this region is now a multidisciplinary endeavor encompassing a broad range of medical and surgical subspecialty knowledge. There is an increasing awareness of the need to balance the benefits of surgical resection with the anticipated functional deficits and subsequent morbidity that can occur following surgical intervention. An intimate understanding of the anatomy of this region remains the key factor in surgical planning and successful management of tumors involving this anatomic region.

ANATOMY

The PPS is a potential space deep in the neck, shaped like an inverted pyramid. The borders delineating this space are made up of both immobile and distensible tissues, which has implications on the directions of growth and eventual clinical presentation of tumors occurring in this space. At its superior limit, representing the base of the inverted pyramid, is a small region of the temporal and sphenoid skull base including the carotid canal, jugular foramen, and hypoglossal foramen. The inferior limit representing the apex is at the level of the greater cornu of the hyoid bone. The medial borders of this space are the pharyngeal constrictor muscles of the oropharynx, a distensible plane that enables tumor expansion. The medial pterygoid muscle, ramus of the mandible, and the deep lobe of the parotid gland represent the lateral borders, whereas the prevertebral fascia and cervical vertebrae make up the posterior border. The superior, lateral, and posterior borders are relatively

immobile barriers, and as such, tumor growth typically occurs in either the medial or inferior direction leading larger tumors involving these areas to manifest as a pharyngeal mass or cervical mass.

The PPS has traditionally been divided into prestyloid and poststyloid compartments by the fascial band connecting the styloid process and skull base to the tensor veli palatini muscle (Fig. 22.1). The prestyloid space, positioned anterolaterally, is a potential space composed of adipose tissue, lymph nodes, minor salivary glands, branches of the mandibular division of the trigeminal nerve, internal maxillary artery, and the pharyngeal venous plexus. The poststyloid space, positioned posteromedially, contains the carotid artery, internal jugular vein (IJV), cranial nerves IX to XII, the sympathetic chain, and lymph nodes. In relation to other neck spaces, both the masticator and parotid spaces are located anterolaterally, whereas the retropharyngeal space is located posteromedially. Recently, a suggested update to the nomenclature of the PPS refers to the prestyloid space as the true PPS, whereas the poststyloid space is referred to as the vascular space.[1]

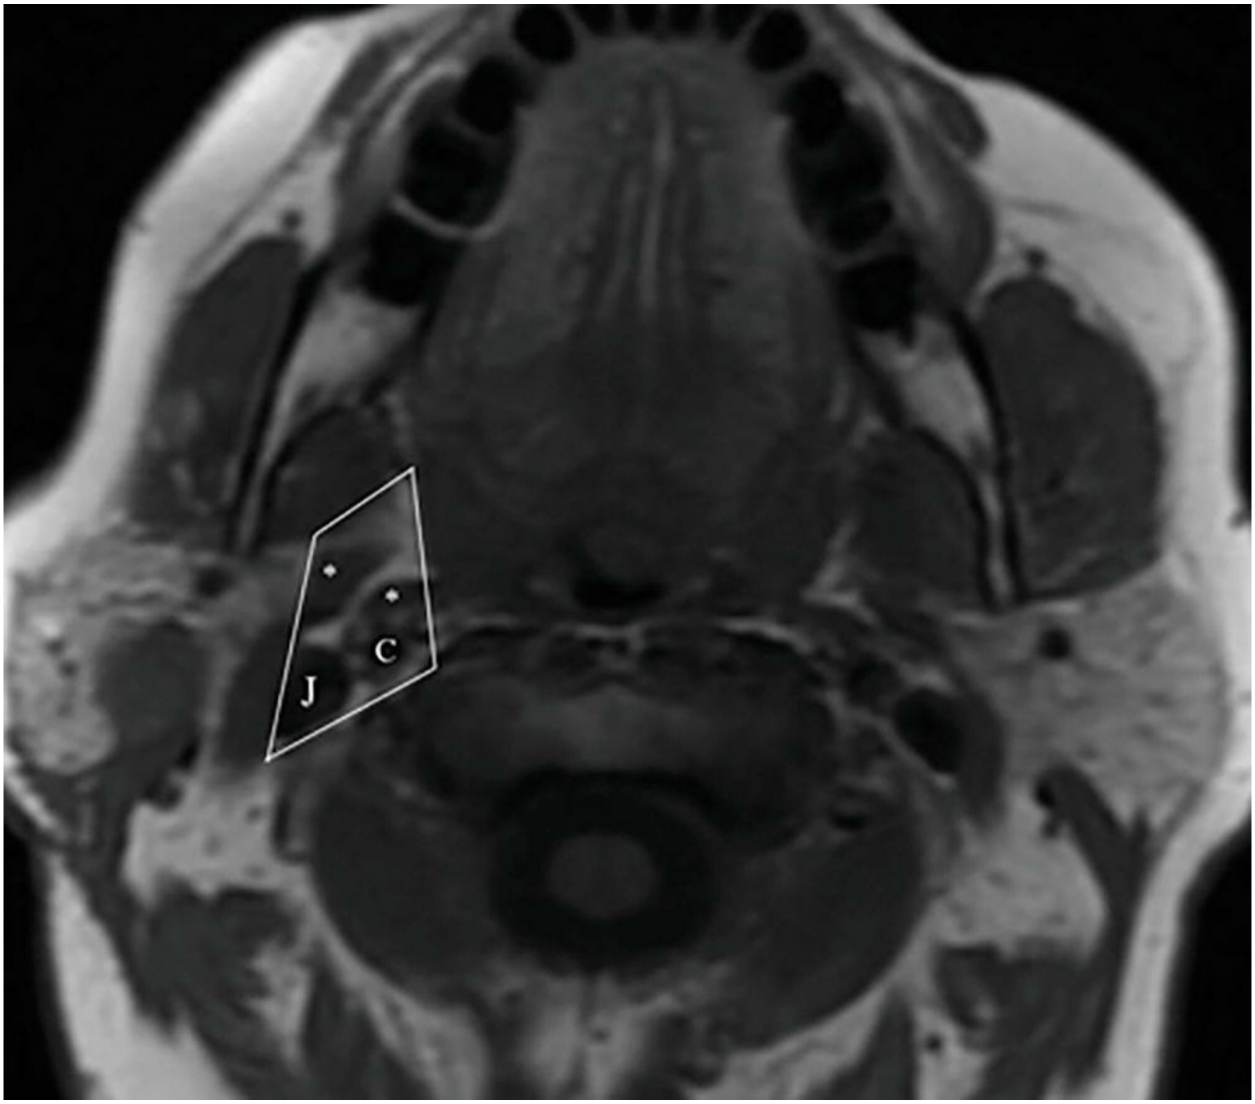

Figure 22.1. Normal anatomy. The PPS is separated into a prestyloid and poststyloid compartment by the styloid process and styloid musculature (*asterisk*). The prestyloid compartment is primarily composed of adipose tissue, which demonstrates high signal intensity on this T1-weighted MR image. The poststyloid compartment contains the carotid sheath and its contents, the internal jugular vein (*J*), and carotid artery (*C*). The poststyloid compartment is also referred to as the carotid space or vascular space.

CLINICAL PRESENTATION

The vast majority of patients with a mass in the PPS have little to no symptoms until the size of the mass is sufficiently large. This is due in part to the relatively slow growth of tumors that arise in this area. Therefore, it is not

surprising that many of these masses are found as incidental findings on imaging studies performed for other reasons. Nonetheless, there are multiple symptoms that may be related to tumors arising within the PPS reflecting the diverse pathology that can arise from within this region. These can be categorized broadly into symptoms related to tumor mass effect or tumor invasion such as functional deficits from cranial nerve involvement. Natural expansion of tumor along the path of least resistance along the medial boundary leads to displacement of the lateral pharyngeal wall and tonsil that may manifest as dysphagia, dysarthria, new-onset snoring, voice changes, or an ill-fitting maxillary denture due to soft palate displacement of the tumor. Tumors narrowing the oropharyngeal region may lead to symptoms of obstructive sleep apnea.[2,3] Hearing loss can arise from middle ear effusion by compression of the cartilaginous portion of the eustachian tube, whereas the presence of trismus implies infiltration of the pterygoid musculature or impingement on the coronoid process of the mandible. Tumors arising in the superior portion of the PPS in close proximity to the skull base may cause manifestations of a jugular foramen syndrome characterized by nerve palsies of cranial nerves IX, X, and XI. Extension of tumor along an inferior plane can lead to a palpable cervical mass posterior and inferior to the angle of mandible or tail of the parotid. Involvement of cranial nerves or the cervical sympathetic chain may cause symptoms of dysphonia from vocal cord paralysis or paresis, dysarthria from tongue weakness, or Horner syndrome.

DIAGNOSTIC CONSIDERATIONS

Diagnostic Imaging

As mentioned above, many PPS masses are discovered incidentally on imaging studies that include the head and neck region. However, the preferred radiologic modality in the assessment of PPS tumors is magnetic resonance imaging (MRI) with gadolinium enhancement as it allows for precise localization of tumors in relation to surrounding neurovascular and muscular structures, thus helping to differentiate between benign and malignant masses. T1 sequences are useful for defining the interaction between the tumor and surrounding fat planes, whereas T2 sequences delineate the relationship between tumor and adjacent muscle. Postcontrast T1 imaging allows for assessment of perineural spread. The use of particular

MRI sequences including phase contrast angiography, time of flight, and MR angiography have been shown to increase the diagnostic sensitivity and specificity of PPS lesions.

Although MRI remains the preferred modality, newer multidetector CT scanning has a number of advantages including quicker scanning times, improved spatial resolution up to 0.082 mm^3 (compared to 4.4 mm^3 for T1-weighted images and 1.1 mm^3 for time of flight MR angiography), and ability for multiplanar reconstruction of images.[4] Quicker scanning times of <30 seconds make images less susceptible to motion artifacts compared to MRI and should be a consideration in patients who are not candidates for MRI or experience claustrophobia. There are considerable cost savings with CT scan compared to MRI as well. Ultrasound is an inexpensive, noninvasive, nonionizing radiation diagnostic modality that has the added advantage of enabling radiologic guidance for fine needle aspiration biopsy (FNAB).

The diagnosis of a tumor within the PPS can be predicted based on a distinction made on its location within either the prestyloid or poststyloid space. The majority of tumors found within the prestyloid compartment are of salivary gland origin, whereas in the poststyloid compartment, tumors of neural origin constitute the majority of lesions. The determination of whether a tumor is located in the prestyloid or poststyloid space is based on a number of factors including tumor position relative to the carotid artery, styloid process, medial pterygoid muscle, and parapharyngeal adipose tissue plane. In prestyloid masses, the carotid artery is posteriorly displaced, the medial pterygoid muscle is anterior in relation to the tumor, and the parapharyngeal adipose tissue plane will be located along its medial aspect. In poststyloid masses, the carotid artery is displaced anteriorly, whereas the parapharyngeal adipose tissue is displaced in an anterolateral direction (Fig. 22.2). As a poststyloid mass expands laterally, it will extend posterior to the styloid process.

muscle (*MP*) slightly anteriorly and the prestyloid parapharyngeal adipose tissue (outlined) medially, whereas the carotid artery (*C*) is posteriorly located. **B:**Poststyloid vagal paraganglioma displaces the carotid artery (*C*) anteriorly and the prestyloid parapharyngeal fat (outlined) anterolaterally. (*C*, carotid artery; *J*, internal jugular artery; *asterisk* denotes styloid musculature.)

Fine Needle Aspiration Biopsy

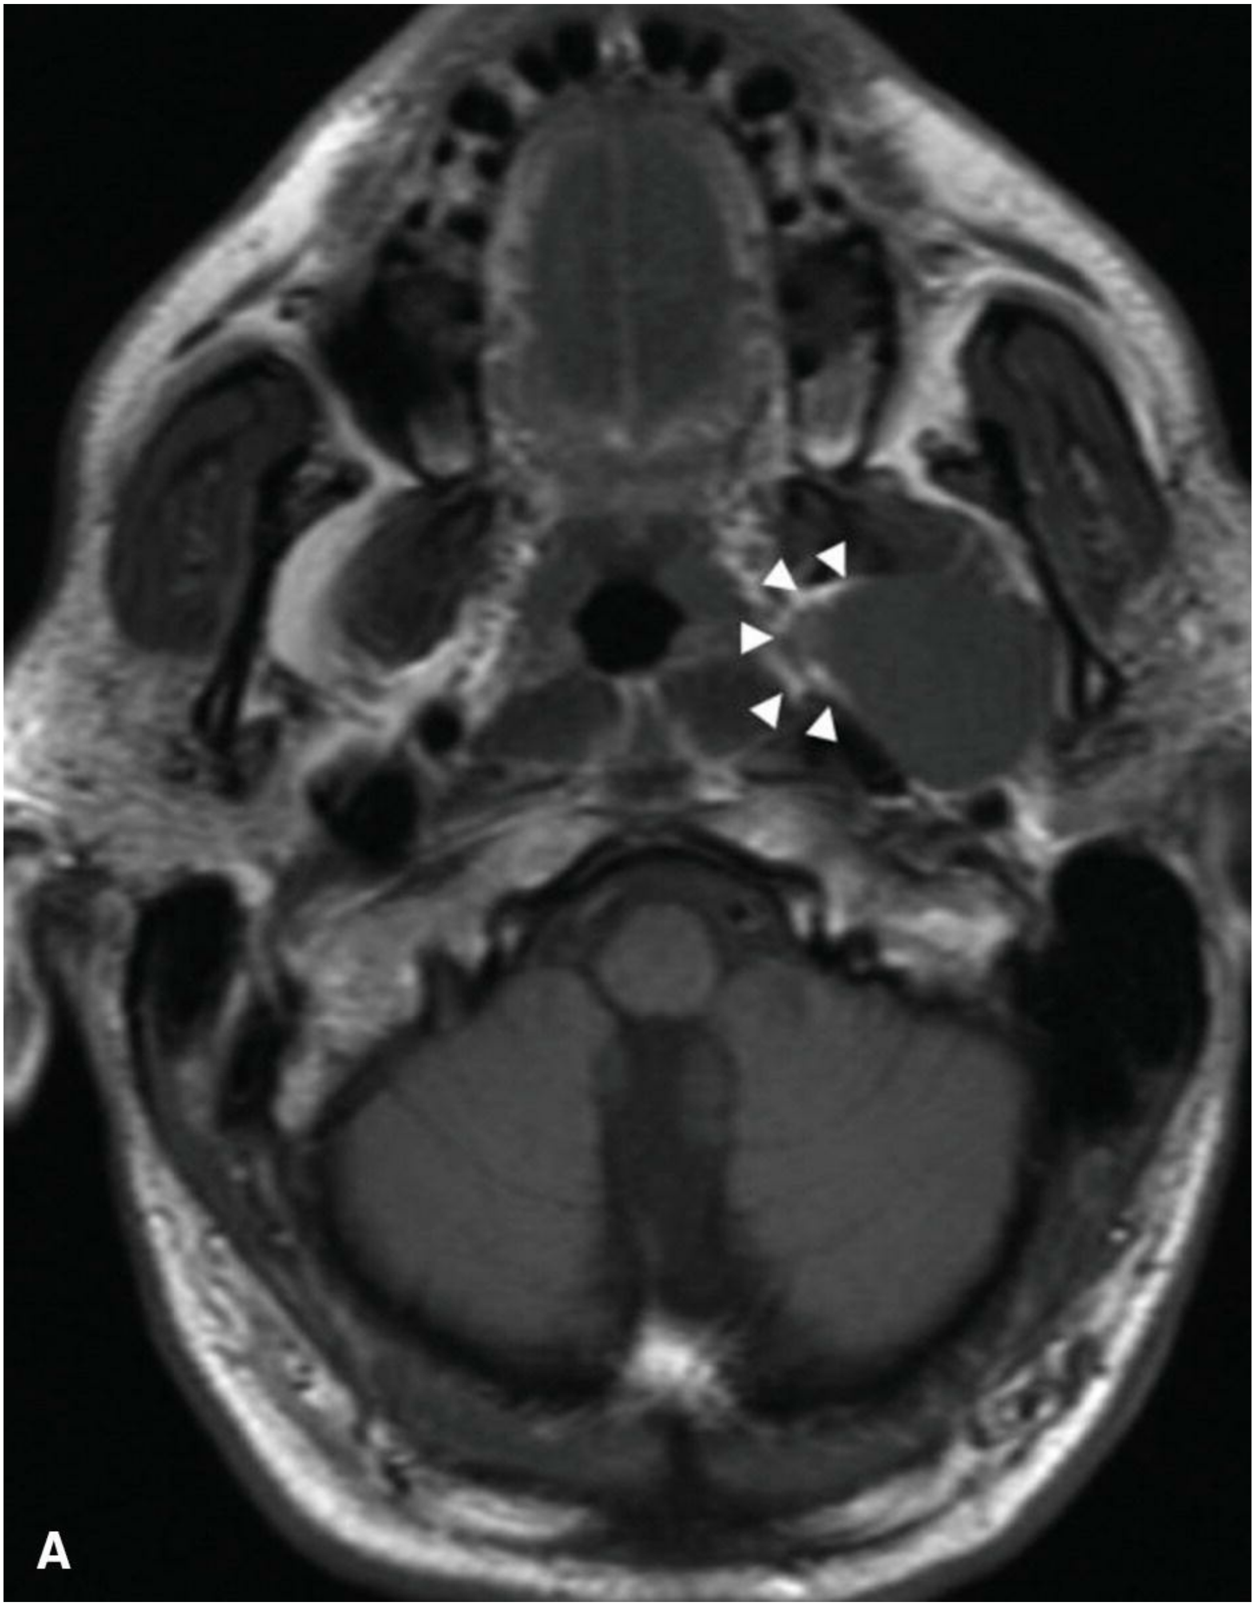
Proper imaging is usually sufficient to determine the type of tumor in the PPS in most cases. Due to this, the use of FNAB for diagnosis is selective. Imaging studies may help differentiate tumors that require surgical resection from those that do not. Also, the extent of operation is infrequently altered by the FNAB results. Nonetheless, FNAB may be used as a diagnostic adjunct for preoperative evaluation of PPS tumors and to aid in treatment planning and patient counseling, in particular if a malignant diagnosis is suspected or in cases of uncertain radiologic interpretation. A number of case series has shown that FNAB confers a diagnostic accuracy of >87% for malignant lesions.[5–8] The overall diagnostic accuracy of FNAB for all tumor types when compared to histopathologic analysis of resected surgical specimens has ranged from 36% to 61%.[5,6,8] A recent study has highlighted a significant improvement in diagnostic accuracy when liquid-based cytology is employed in the place of conventional smear preparations.[5] Coordination of care with a cytopathologist at the time of FNAB can help to ensure a satisfactory specimen quality especially in cystic lesions.

COMMON PARAPHARYNGEAL SPACE TUMORS

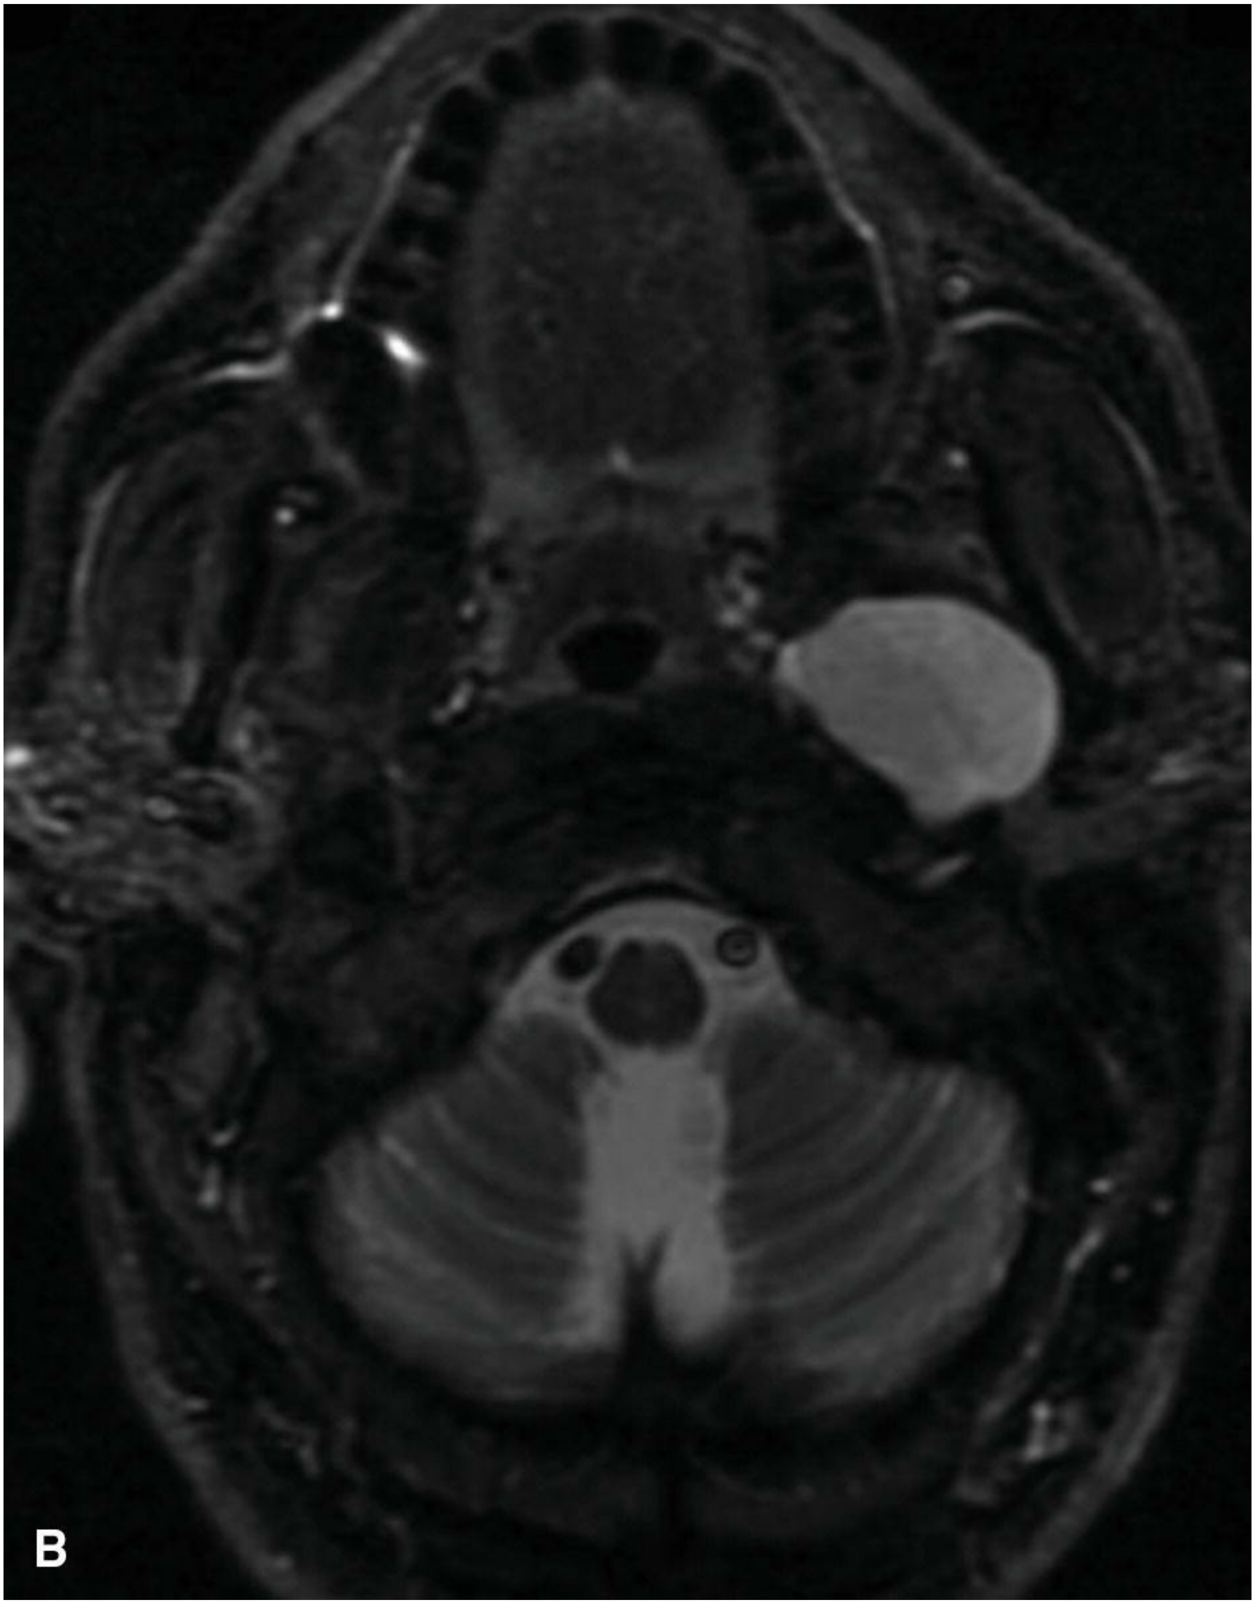
Salivary Tumors

Salivary gland tumors within the PPS can arise from the deep lobe of the parotid gland or from ectopic salivary gland tissue within the PPS itself, and they constitute the most common PPS tumors. Distinguishing between these two entities is not possible on physical examination. Radiologically, deep lobe parotid tumors extending into the PPS are observed to be contiguous with the parotid gland, whereas de novo tumors have a clear plane of

separation with the overlying parotid tissue. Consequently, the overlying parotid tissue can be spared in the excision of de novo tumors although this is not often possible for contiguous tumors of the parotid deep lobe. A comprehensive discussion of salivary tumors is covered in Chapter 21. However, here we aim to present the key imaging characteristics of these tumors. Pleomorphic adenomas are the most common tumors arising from the prestyloid PPS.[9–11] There is a degree of heterogeneity observed on CT and MRI, depending on the size of the tumor with more uniform characteristics observed in smaller tumors. On MRI, smaller tumors are usually well circumscribed with a low-intensity T1 signal that enhances homogenously on postcontrast imaging with a hyperintense T2 signal (Fig. 22.3). Larger tumors are often lobulated and may demonstrate areas of hyperintense or hypointense signal intensity attributed to calcification, necrotic, or hemorrhagic areas within the tumor (Fig. 22.4).[12] Malignant degeneration can occur in pleomorphic adenomas giving rise to carcinoma ex pleomorphic adenoma or carcinosarcoma. These malignancies are associated with a high frequency of metastasis to regional lymph nodes and can also metastasize to the lungs, bone, and brain.



A



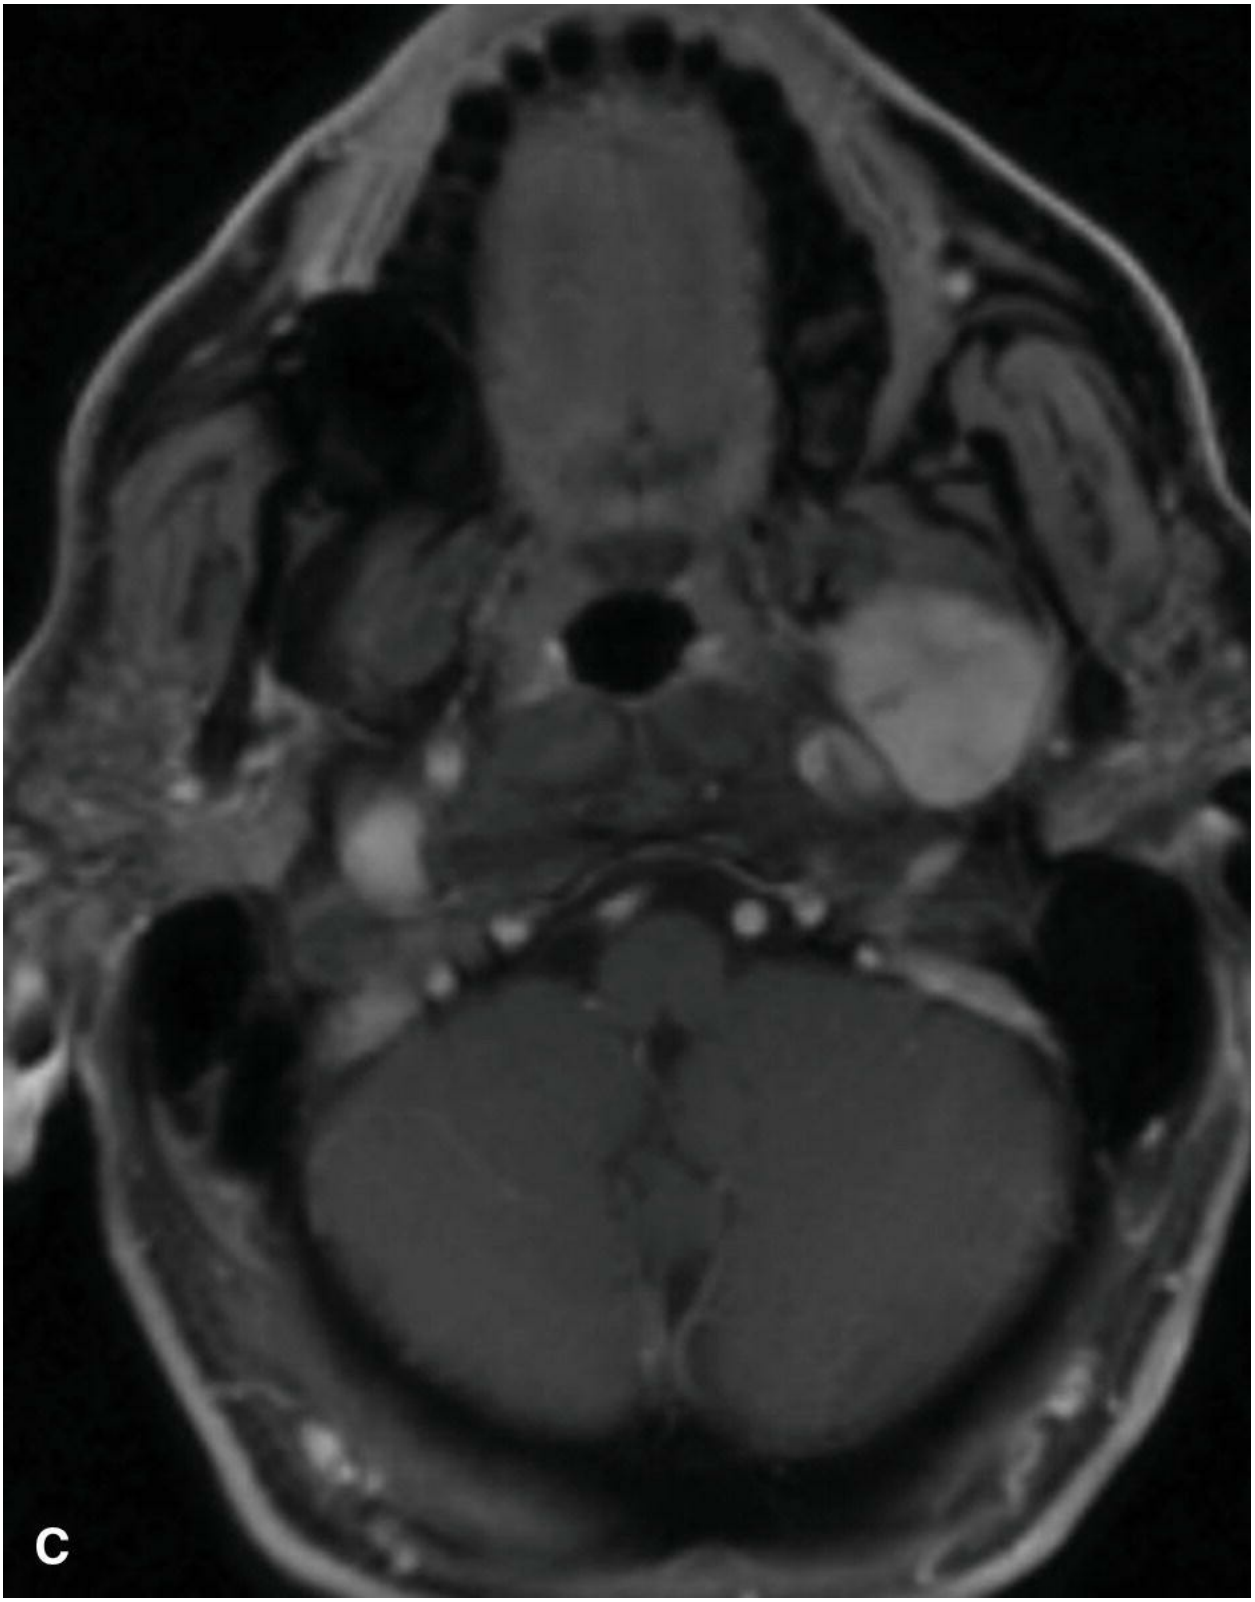


Figure 22.3. Pleomorphic adenoma. T2 hyperintense well-circumscribed homogeneously enhancing mass arises from the prestyloid PPS. Note

anteromedial displacement of the prestyloid parapharyngeal fat (*arrowheads*, high signal intensity on T1-weighted image). The mass homogeneously enhances on postcontrast images. These tumors arise from ectopic salivary gland tissue in the prestyloid PPS or from medial extension of the deep lobe of the parotid gland. **A:** T1-weighted image. **B:** T2 STIR image. **C:** T1-weighted postcontrast image with fat suppression.

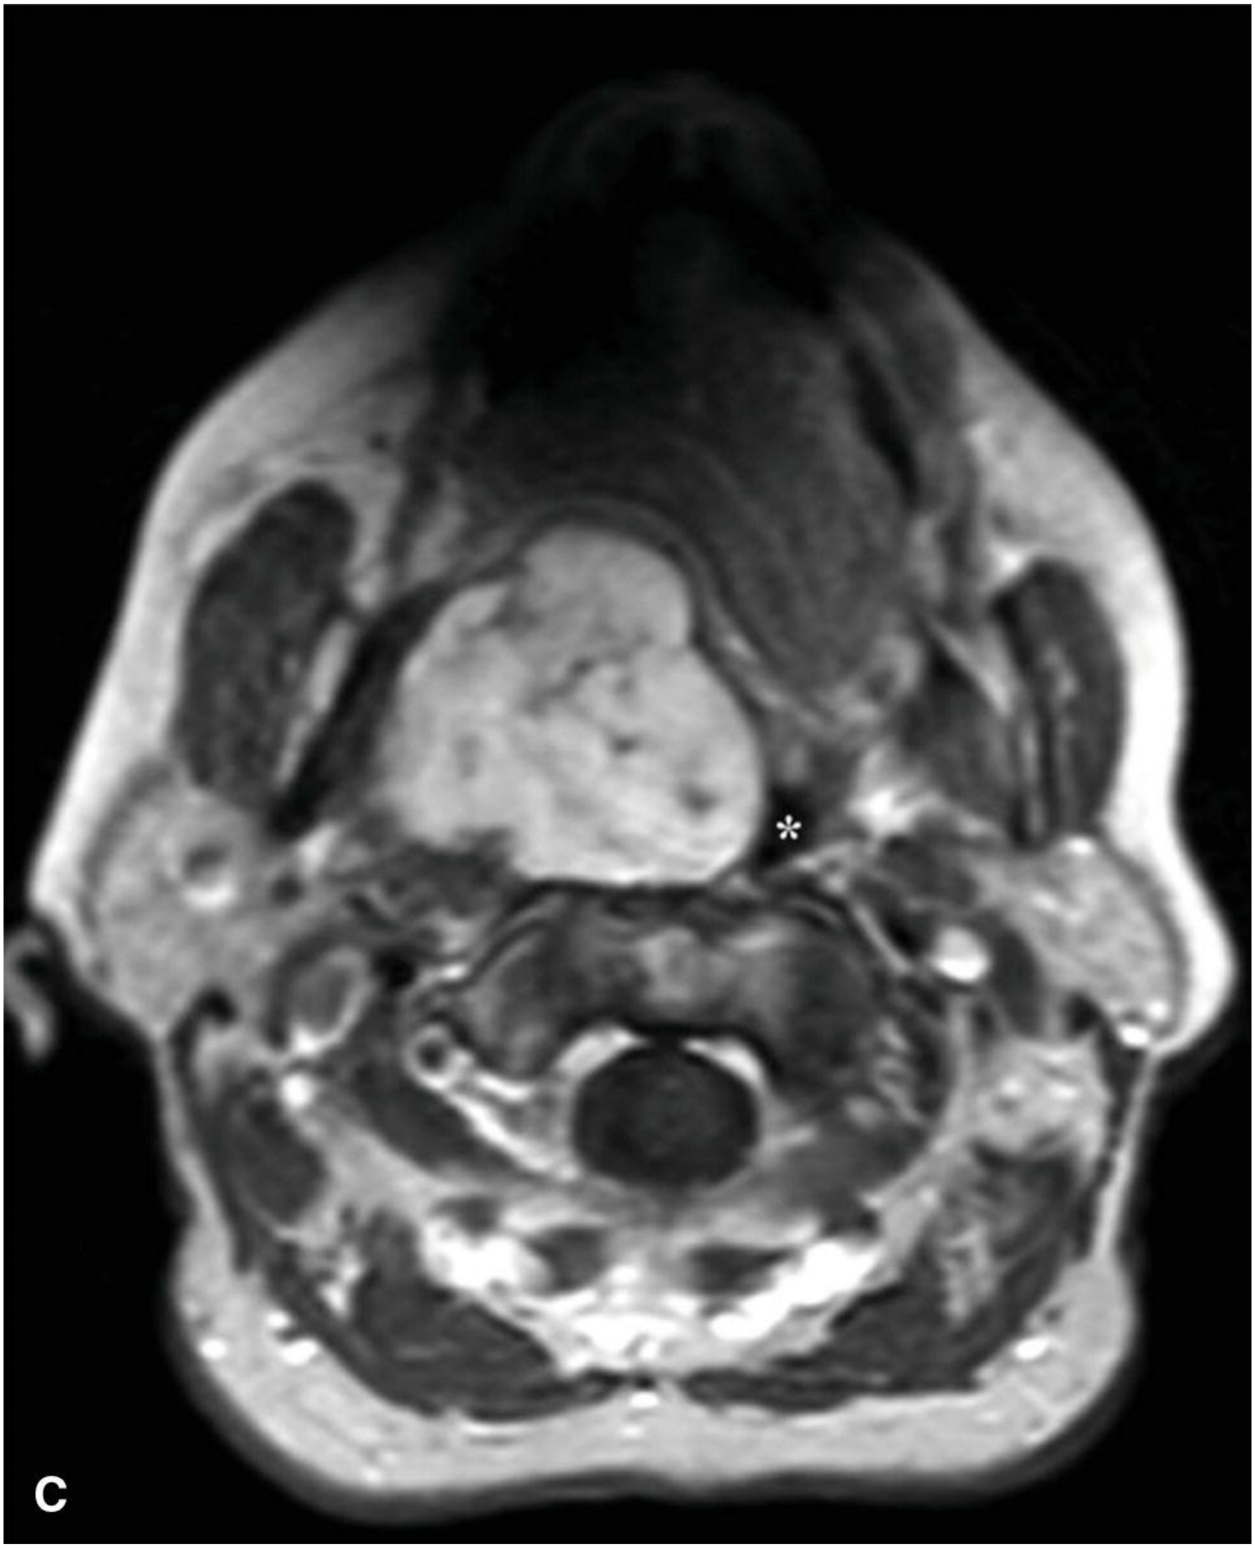

Figure 22.4. Large pleomorphic adenoma in a 77-year-old woman found to have deviation of the uvula on dental examination. Large lobulated mass in the right prestyloid PPS demonstrating heterogeneously intense T2 signal and

avid heterogeneous enhancement with flow voids. Note anterolateral displacement of the medial pterygoid muscle (*MP*) on the right, indicating lack of involvement of the masticator space. The mass abuts the deep right parotid gland. There is mass effect on the base of the right tongue with narrowing of the oropharynx (*asterisk*). (*C*, internal carotid artery; *J*, internal jugular vein.) **A:** T1-weighted image. **B:** T2-weighted STIR image. **C:** T1-weighted postcontrast image.

Mucoepidermoid carcinoma is the most common malignant tumor of the parotid gland, and imaging findings on MRI vary depending on tumor grade. Lower-grade tumors can exhibit similar features to pleomorphic adenoma with low to intermediate signal on T1 images, intermediate to high signal on T2 imaging correlating with the increased mucin-secreting cellular component, and heterogenous enhancement on postcontrast T1 images. High-grade tumors demonstrate low to intermediate signal on both T1 and T2 images with ill-defined margins.

As a general principal, features of salivary gland neoplasms on MRI that have been shown to be indicative of malignancy include low signal intensity on T2-weighted imaging, ill-defined margins on postcontrast images, and perineural involvement. The radiologic features of benign parotid tumors and low-grade malignancies share similarities on MRI, and definitive diagnosis based on imaging studies alone can be a challenging task. The use of dynamic contrast MRI with analysis of peak contrast enhancement and subsequent time frame of contrast washout can assist in distinguishing between Warthin tumor and malignant lesions.[13,14] The comparison of various apparent diffusion coefficient (ADC) of tumors on diffusion-weighted MRI has also been analyzed, with higher ADCs being associated with pleomorphic adenomas and Warthin tumors and lower ADCs associated with malignant tumors (Fig. 22.5).[15,16] The use of fluorodeoxyglucose positron emission tomography (FDG PET) for the diagnosis of salivary gland tumors is limited owing to the nonspecific nature of FDG uptake, with some benign tumors such as Warthin tumor demonstrating intense FDG uptake and other malignant tumors such as adenoid cystic carcinoma showing little FDG avidity.

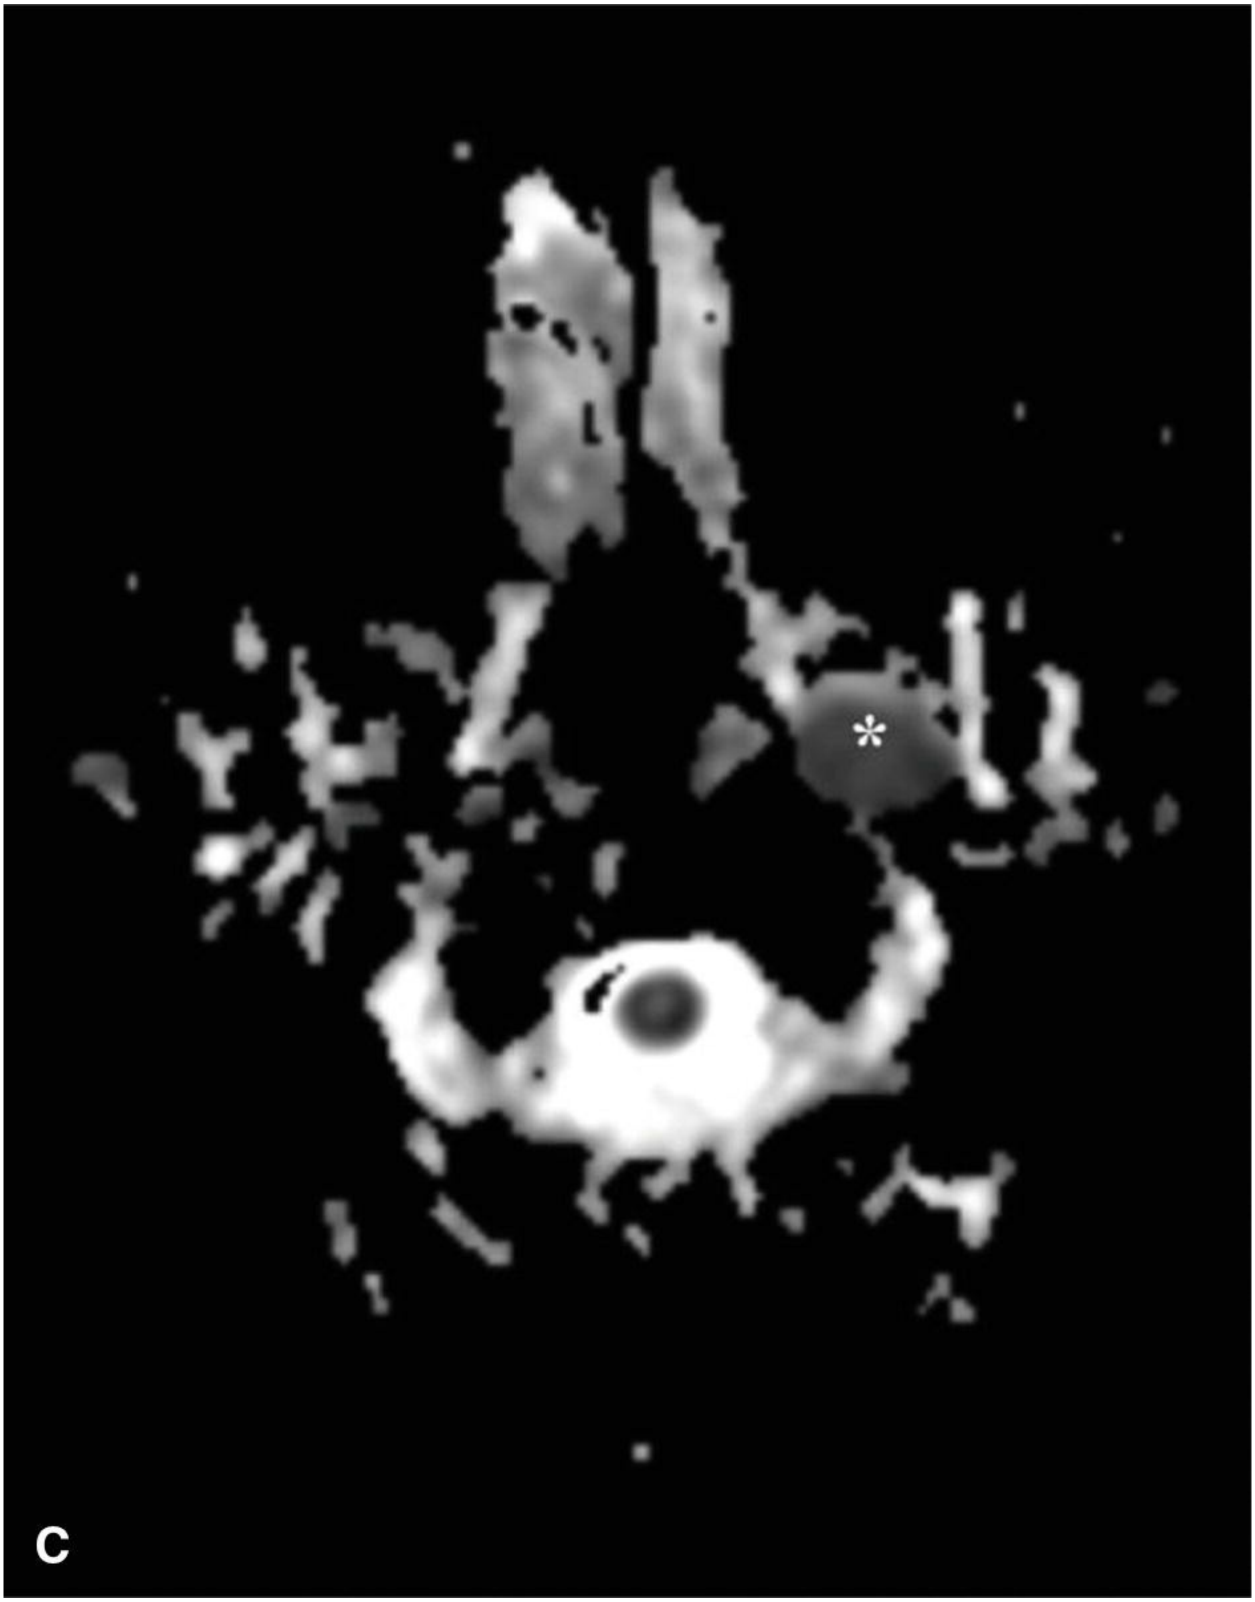

Figure 22.5. Acinic cell carcinoma. Well-circumscribed T2 hyperintense avidly enhancing mass (*asterisk*) in the left prestyloid PPS, anterior to the

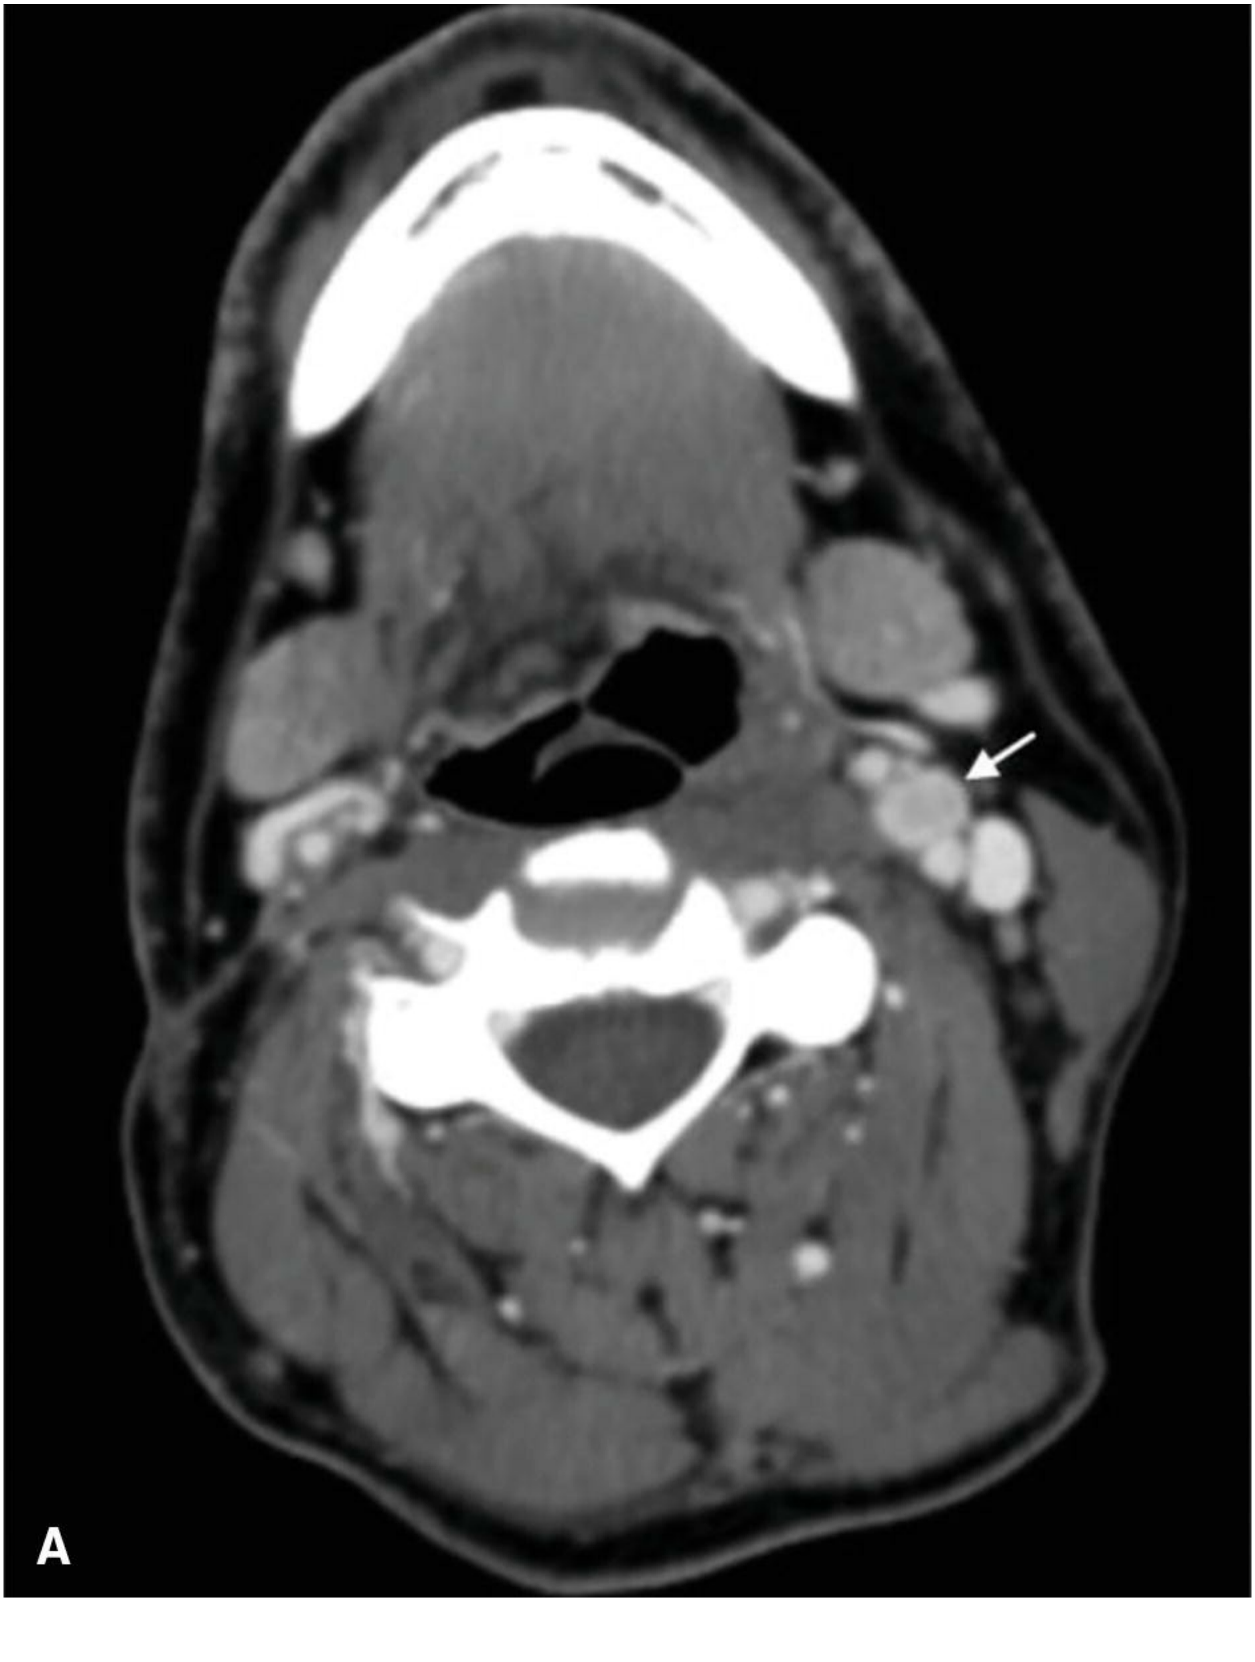
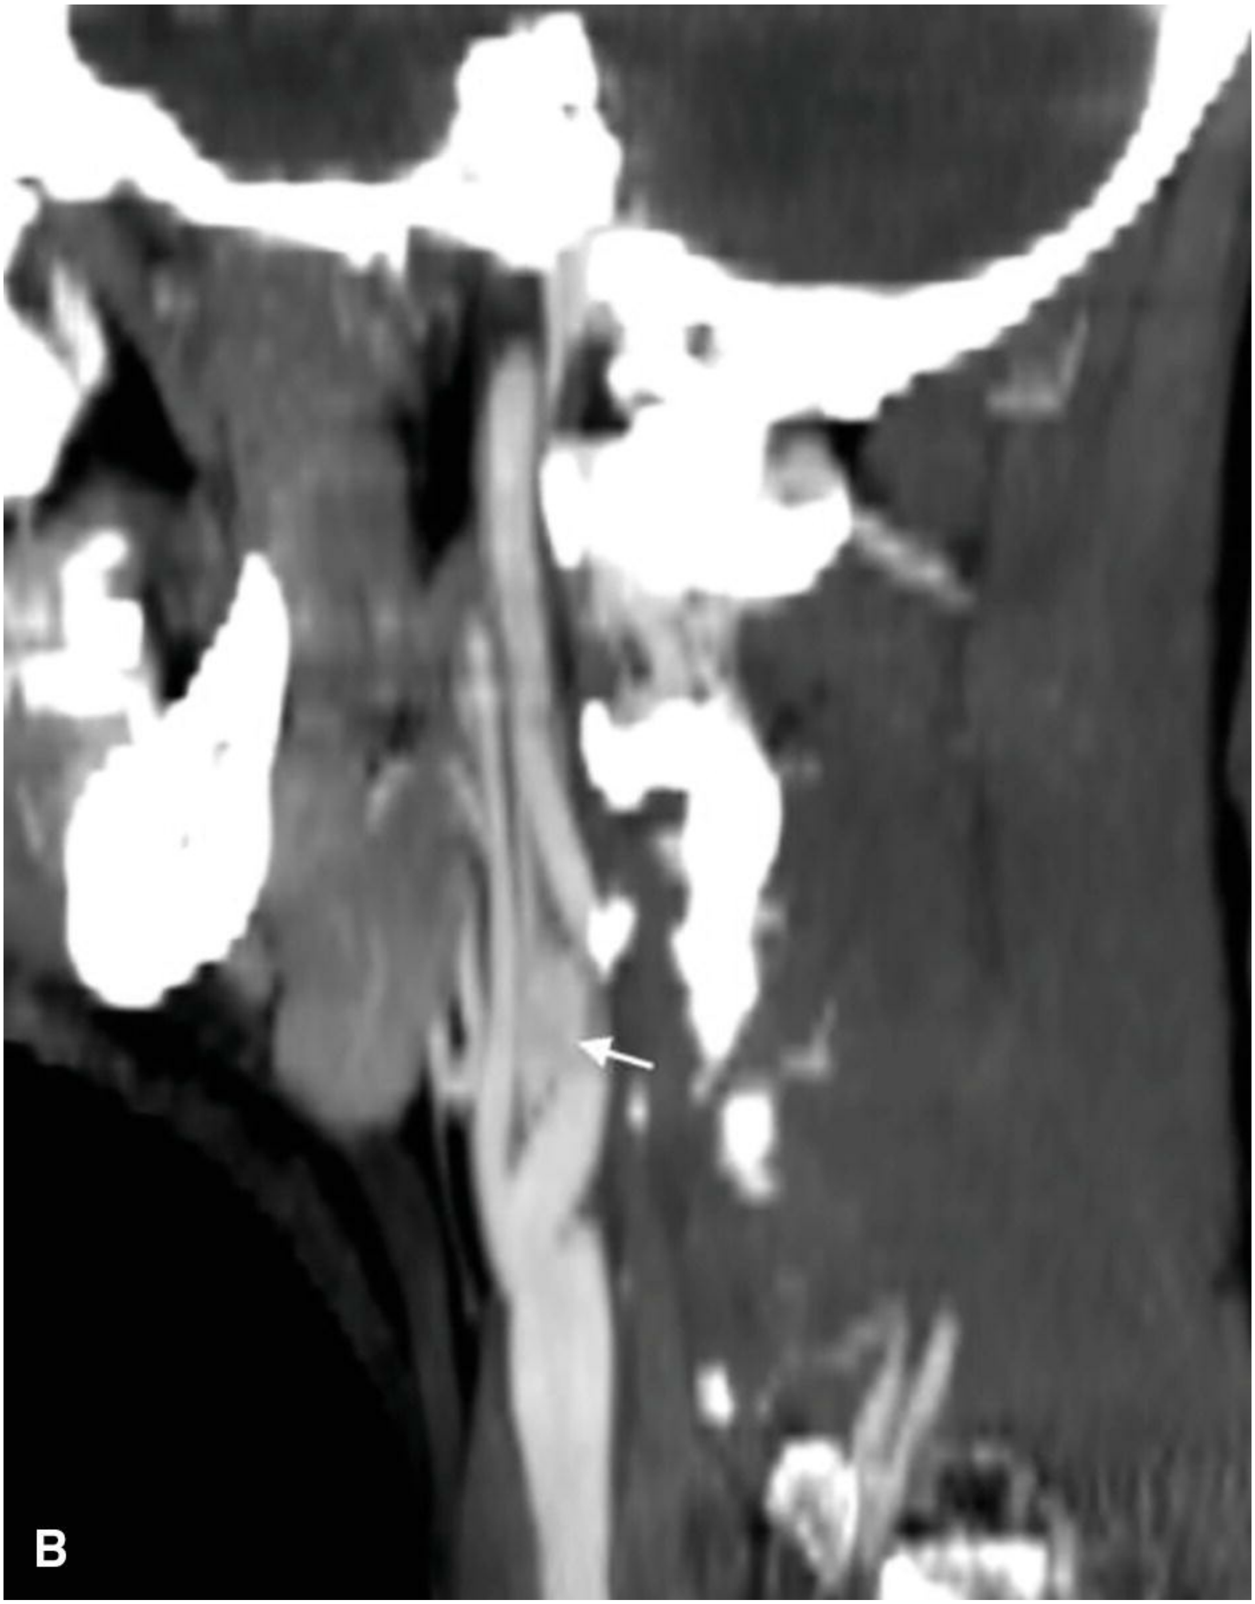
carotid arteries (*arrowheads*), and internal jugular vein (*arrow*). In this location, a pleomorphic adenoma is the most common diagnosis; however, it is noted that there is restricted diffusion of the mass (low ADC value), which may be indicative of high cellularity. Pathology demonstrated acinic cell carcinoma. **A:** T2-weighted image. **B:** T1-weighted postcontrast image. **C:** ADC map.

Paraganglioma

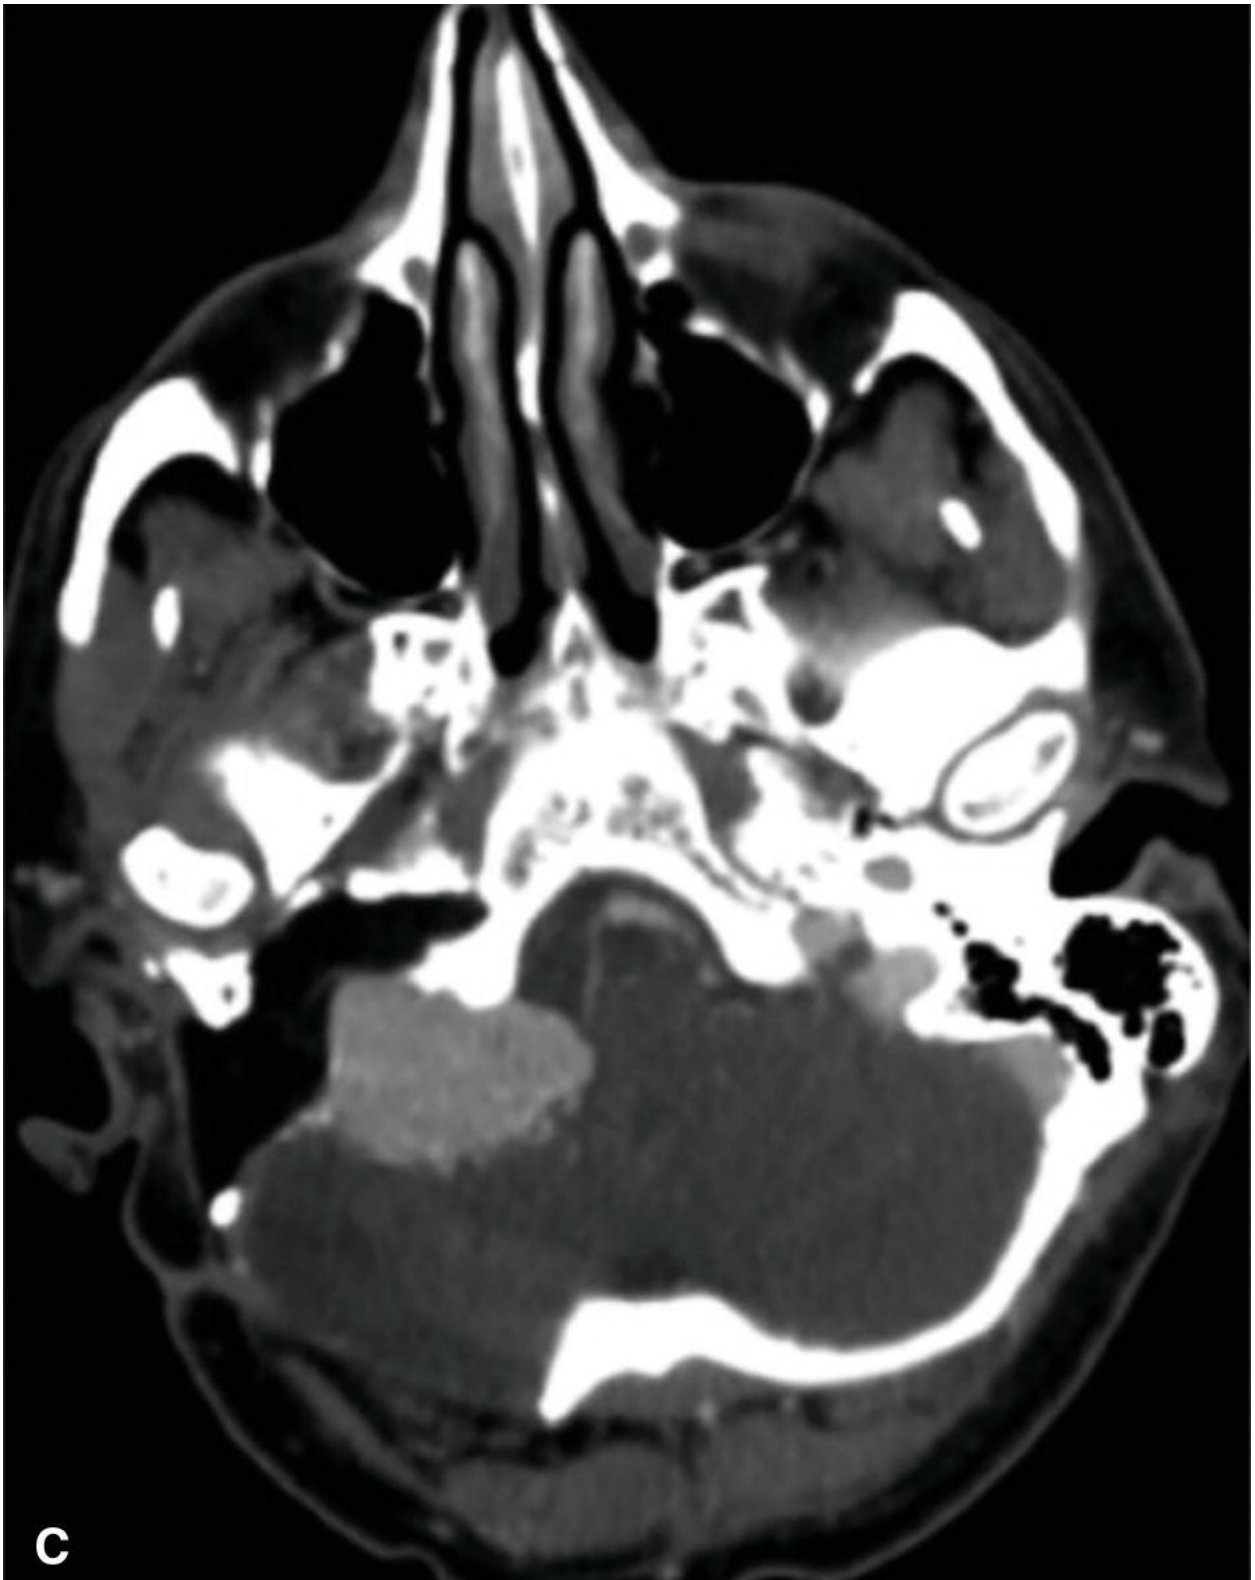
Paragangliomas, also known as glomus tumors, are tumors of neural crest origin that have a chemoreceptor function and most commonly arise at the carotid body bifurcation (glomus caroticum), the jugular foramen (glomus jugulare), along the course of the vagus nerve (glomus vagale), and within the middle ear space (glomus tympanicum). In contrast to paragangliomas arising from the lower mediastinum, abdomen, or pelvis, the vast majority of head and neck paragangliomas do not secrete catecholamines. Paragangliomas can rarely occur in association with genetic syndromes such as von Hippel-Lindau syndrome, neurofibromatosis type I, MEN2A, and MEN2B. Nonsyndromic paragangliomas occur more frequently and may be caused by genetic mutations involving the hereditary paraganglioma (PGL) genes that code for the succinate dehydrogenase (SDH) enzyme. Genes that have been identified include SDHD gene 1 (PGL1) on chromosome 11q23, SDHB gene (PGL4) on chromosome 1p35-p36, SDHC gene (PGL3) on chromosome 1q21, and the PGL2 gene, of which the exact location on chromosome 11 remains unknown. PGL3 and PGL4 are inherited in an autosomal dominant form, whereas PGL1 and PGL2 are subject to maternal imprinting. As such, children inheriting the PGL1 and PGL2 genes only express the phenotype if the diseased gene is inherited from the father.[17] SDHD and SDHB mutations show an age-related penetrance showing 86% and 77% penetrance by age 50, respectively.[18] SDHD mutation carriers manifest head and neck paragangliomas and multifocal disease more commonly (Fig. 22.6), whereas SDHB carriers have an increased frequency of malignant paragangliomas in addition to a predisposition toward thyroid cancer and renal cancer.[18,19]



A



B



C

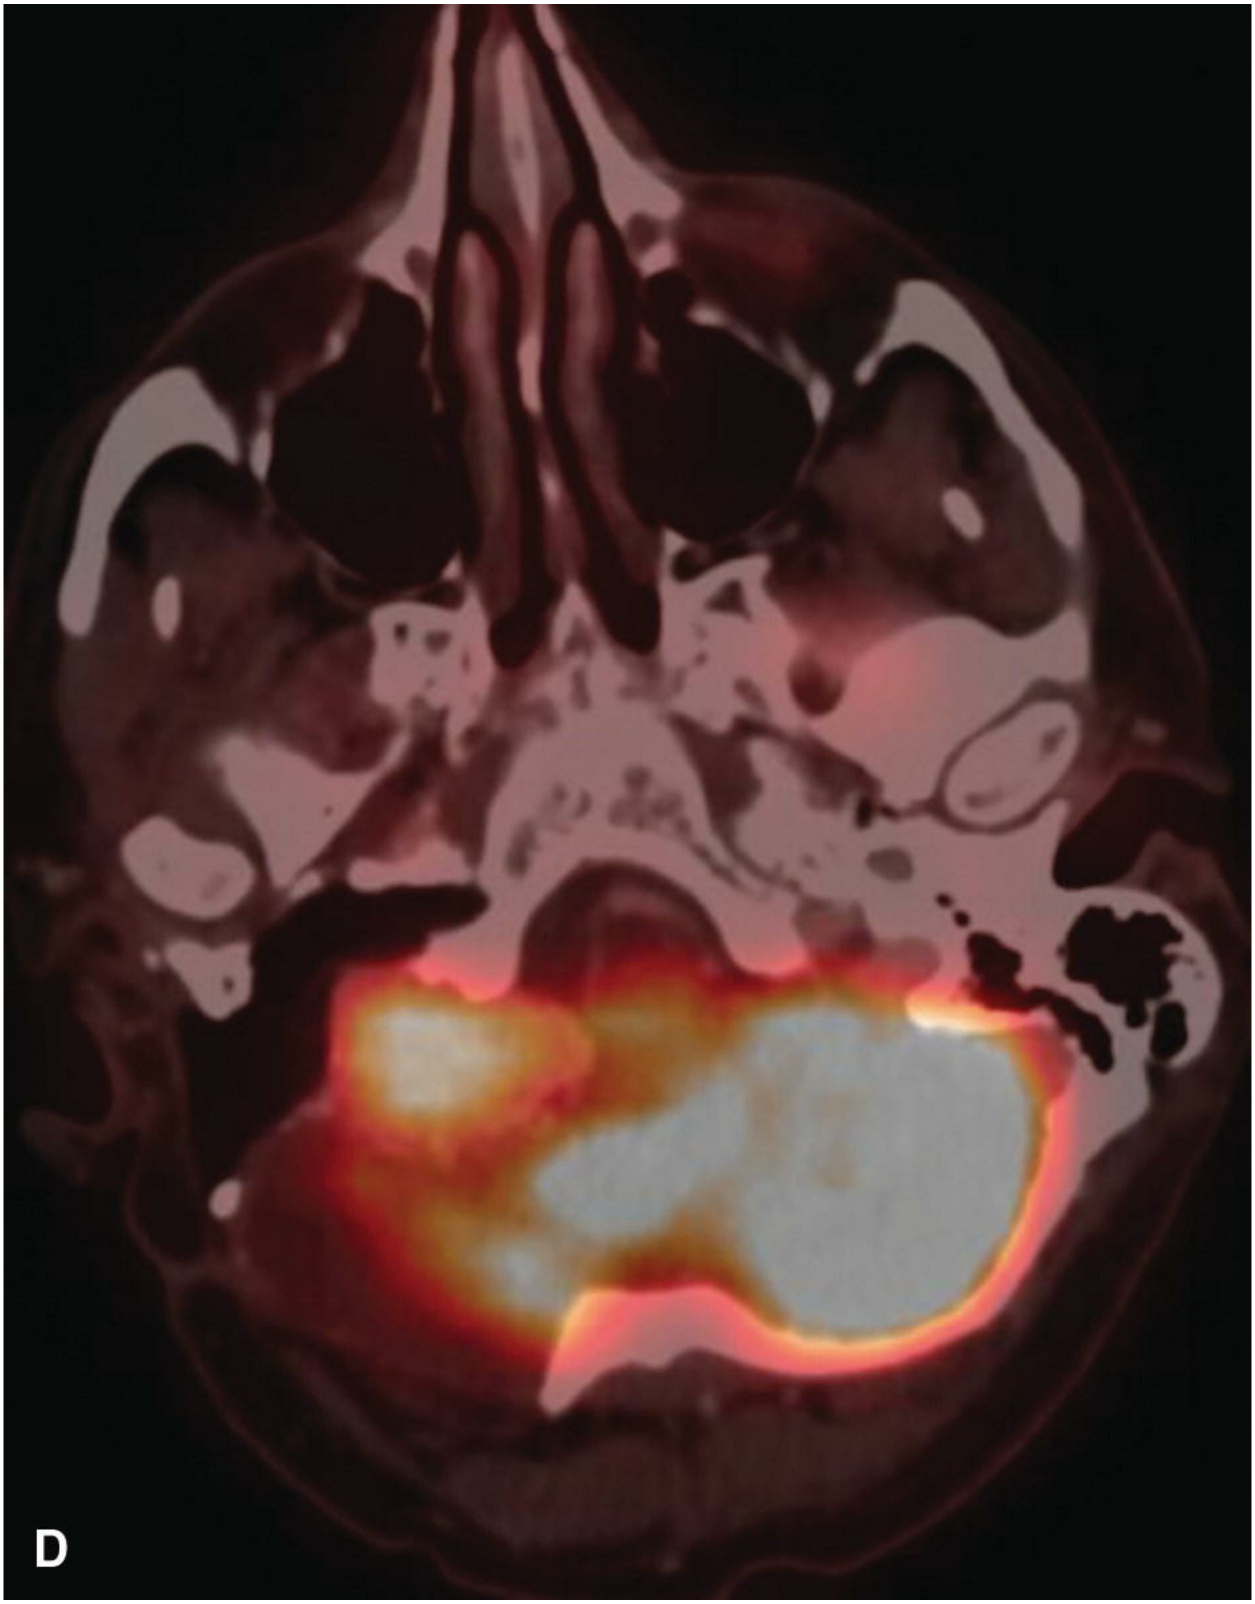


Figure 22.6. Small carotid body tumor (Shamblin type I). Thirty-nine-year-old man with history of succinyl dehydrogenase D mutation and multiple

paragangliomas. Axial **(A)** and sagittal **(B)** contrast-enhanced CT images demonstrate small enhancing mass (*arrows*) at the left carotid bifurcation with mild splaying of the internal and external carotid arteries. This patient also has large enhancing mass extending from the right jugular foramen at the cerebellopontine angle (glomus jugulare tumor) with prior right occipital and petrous temporal decompressive surgery **(C)**. Both lesions were intensely FDG avid on PET–CT **(D)**.

Screening for SDH mutations should be carried out in family members of patients with a clinical history of familial paraganglioma, those with an age of presentation below 45 years, and those with multiple synchronous or metachronous tumors. SDHB mutation testing should be considered in all patients with a malignant tumor. In individuals known to have familial paraganglioma, genetic testing should commence at age 10 or at least 10 years before the earliest age of diagnosis in relatives affected. Periodic clinical, biochemical, and imaging surveillance has been recommended to include 24-hour urinary excretion of fractionated metanephrines and catecholamines and MRI or CT scan imaging of the skull base every 2 years and MRI or CT imaging of the thorax, abdomen, and pelvis every 4 years.[20] Meta-iodinated benzylguanidine (MIBG) scintigraphy has traditionally been used to detect paragangliomas or metastatic disease not visualized on CT scan or MRI with sensitivities between 77% and 90% and specificity between 88% and 96%, with the addition of SPECT improving sensitivities to between 88% and 96%.[21] Over the past decade, there has been an increasing interest in the use of positron emission tomography (PET) as an alternative to MIBG scintigraphy, with PET imaging shown to have a higher sensitivity in detecting distant metastasis in patients with SDHB mutations.[22,23]

Histologically, paragangliomas consist of two different cell types organized into clusters separated by a fibrovascular stroma pathognomonically known as Zellballen (“cell balls” in German). Type I cells, also known as chief cells, have a polygonal shape and eosinophilic cytoplasm and are concentrated in the center. Type II, or sustentacular cells, are spindle shaped and surround the periphery of the Zellballen. Rarely, paragangliomas can secrete catecholamines and may present with headaches, palpitation, tremor, and profuse sweating. Patients with these symptoms should be tested for 24-hour urinary collection of metanephrine,

normetanephrine, and vanillylmandelic acid (VMA) and plasma free metanephrines.

These tumors have a lobulated, ovoid appearance on MRI with well-defined margins. On T1 sequences they have signal intensity similar to that of muscle, whereas on T2 sequences they are mildly hyperintense. They enhance rapidly and intensely with gadolinium contrast and larger tumors possess punctuate areas of flow voids, which may confer the classic “salt-and-pepper” appearance (Figs. 22.7 and 22.8). Surgical biopsy of these lesions should be avoided, as they are highly vascular. A mass splaying the internal and external carotid arteries at the bifurcation (i.e., lyre sign) is highly suggestive of a carotid body tumor.

Figure 22.7. "Salt-and-pepper" appearance of paraganglioma. Fifty-nine-year-old man presenting with fullness in the left neck. T1-weighted image

(A) demonstrates “salt-and-pepper” appearance of mass splaying the internal (*I*), external (*E*) carotid arteries and (*J*) internal jugular vein. Low-intensity foci (“pepper”) indicate flow voids due to tumor vascularity (also seen on postcontrast image, **(B)**). High-intensity foci (“salt”) may represent areas of slow flow or hemorrhage. Thin **(C)** and thick **(D)** section multiplanar reformations of MR angiography in this patient demonstrate the carotid body tumor splaying the carotid vessels on the left as well as an additional paraganglioma just lateral to the right internal carotid artery (*asterisks*).

Serpiginous flow voids indicating tumor vascularity can be seen (*black asterisk*). **C:** Another patient with a paraganglioma demonstrating prominent flow voids on postcontrast T1-weighted MRI. Presence of flow voids differentiates paraganglioma from schwannoma.

Shamblin's classification of carotid body tumors based on their relationship to the internal carotid artery (ICA) has recently been correlated with MR imaging. In type I tumors, the area of contact with the ICA is ≤180 degrees, type II tumors contact the ICA 180 to 270 degrees, and type III tumors have an area of contact >270 degrees.[24] Larger type II or type III tumors have been shown to have an increased rate of intraoperative ICA sacrifice, and preoperative balloon occlusion testing is therefore recommended to assess the integrity of collateral circulation to the brain and plan for possible carotid artery replacement preoperatively. In retrospective reviews of patients who experienced intraoperative ICA disruption without undergoing balloon occlusion testing, it is shown that 26% suffered a stroke with a subsequent mortality rate of 12%, compared to a 4.7% stroke rate alone with no mortalities for patients who passed a total balloon occlusion test.[25,26] A wide variety of methods incorporating CT imaging and MRI of cerebral blood flow during balloon occlusion testing and interpretation criteria have been used to assess the adequacy of cerebral blood flow during balloon occlusion testing. No one technique has been demonstrated as being superior in predicting the incidence of permanent neurologic deficit following ICA sacrifice.

Vagal Paraganglioma

The most common origin of paragangliomas of the PPS is from the vagus nerve (Fig. 22.9). Vagal paragangliomas are more closely adherent to the nerve compared to schwannomas, such that at the time of presentation between 20% and 50% of patients have vagal nerve functional deficits.[27] Surgical separation of the tumor from the vagus nerve is not usually feasible, and surgery reliably leads to a complete vagal nerve palsy. Therefore, consideration should be given to serial imaging and observation of tumors with minimal or no growth. In the presence of bilateral vagal paragangliomas or preexisting contralateral vagal nerve palsy, radiation therapy should be considered as an alternative to surgical resection in order to avoid the

morbidity of bilateral vagus nerve deficits.

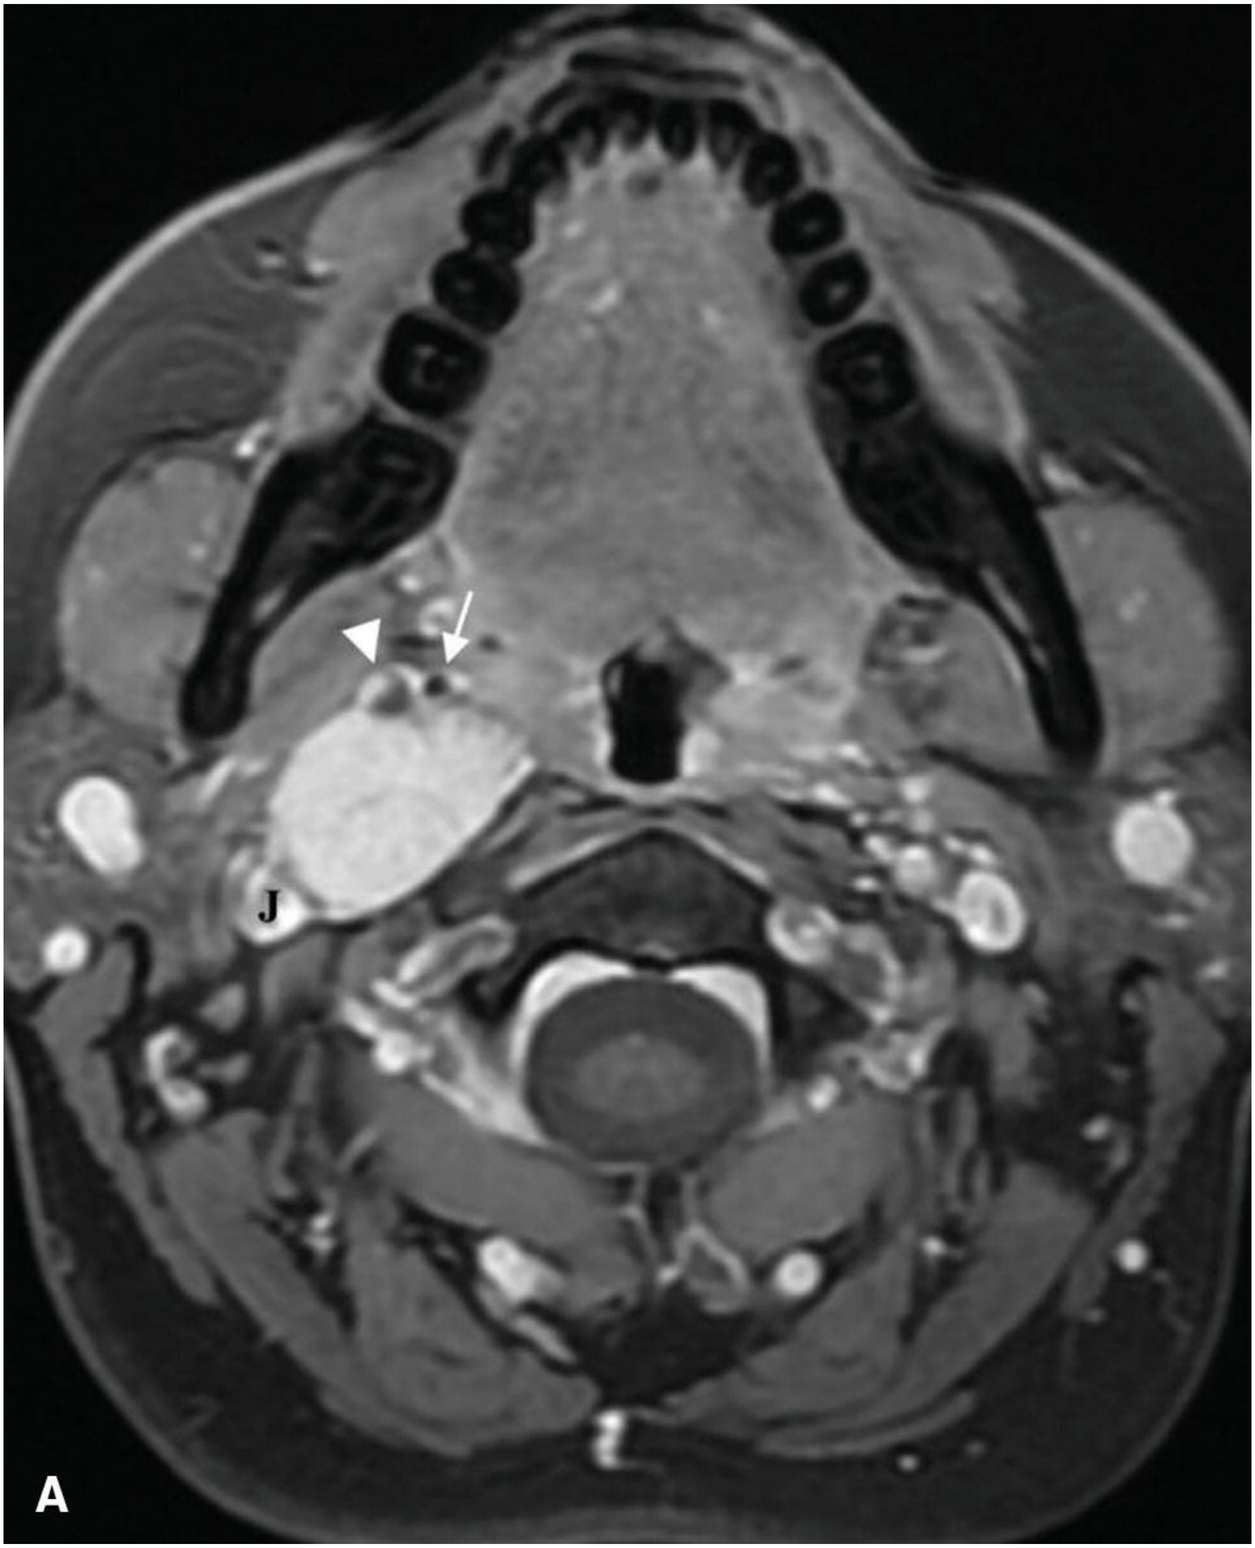

Figure 22.9. Vagal paraganglioma. T1-weighted postcontrast axial **(A)** and sagittal **(B)** images demonstrate a avidly enhancing lesion in the carotid space displacing the internal carotid artery (*arrowheads*) anteriorly away from the

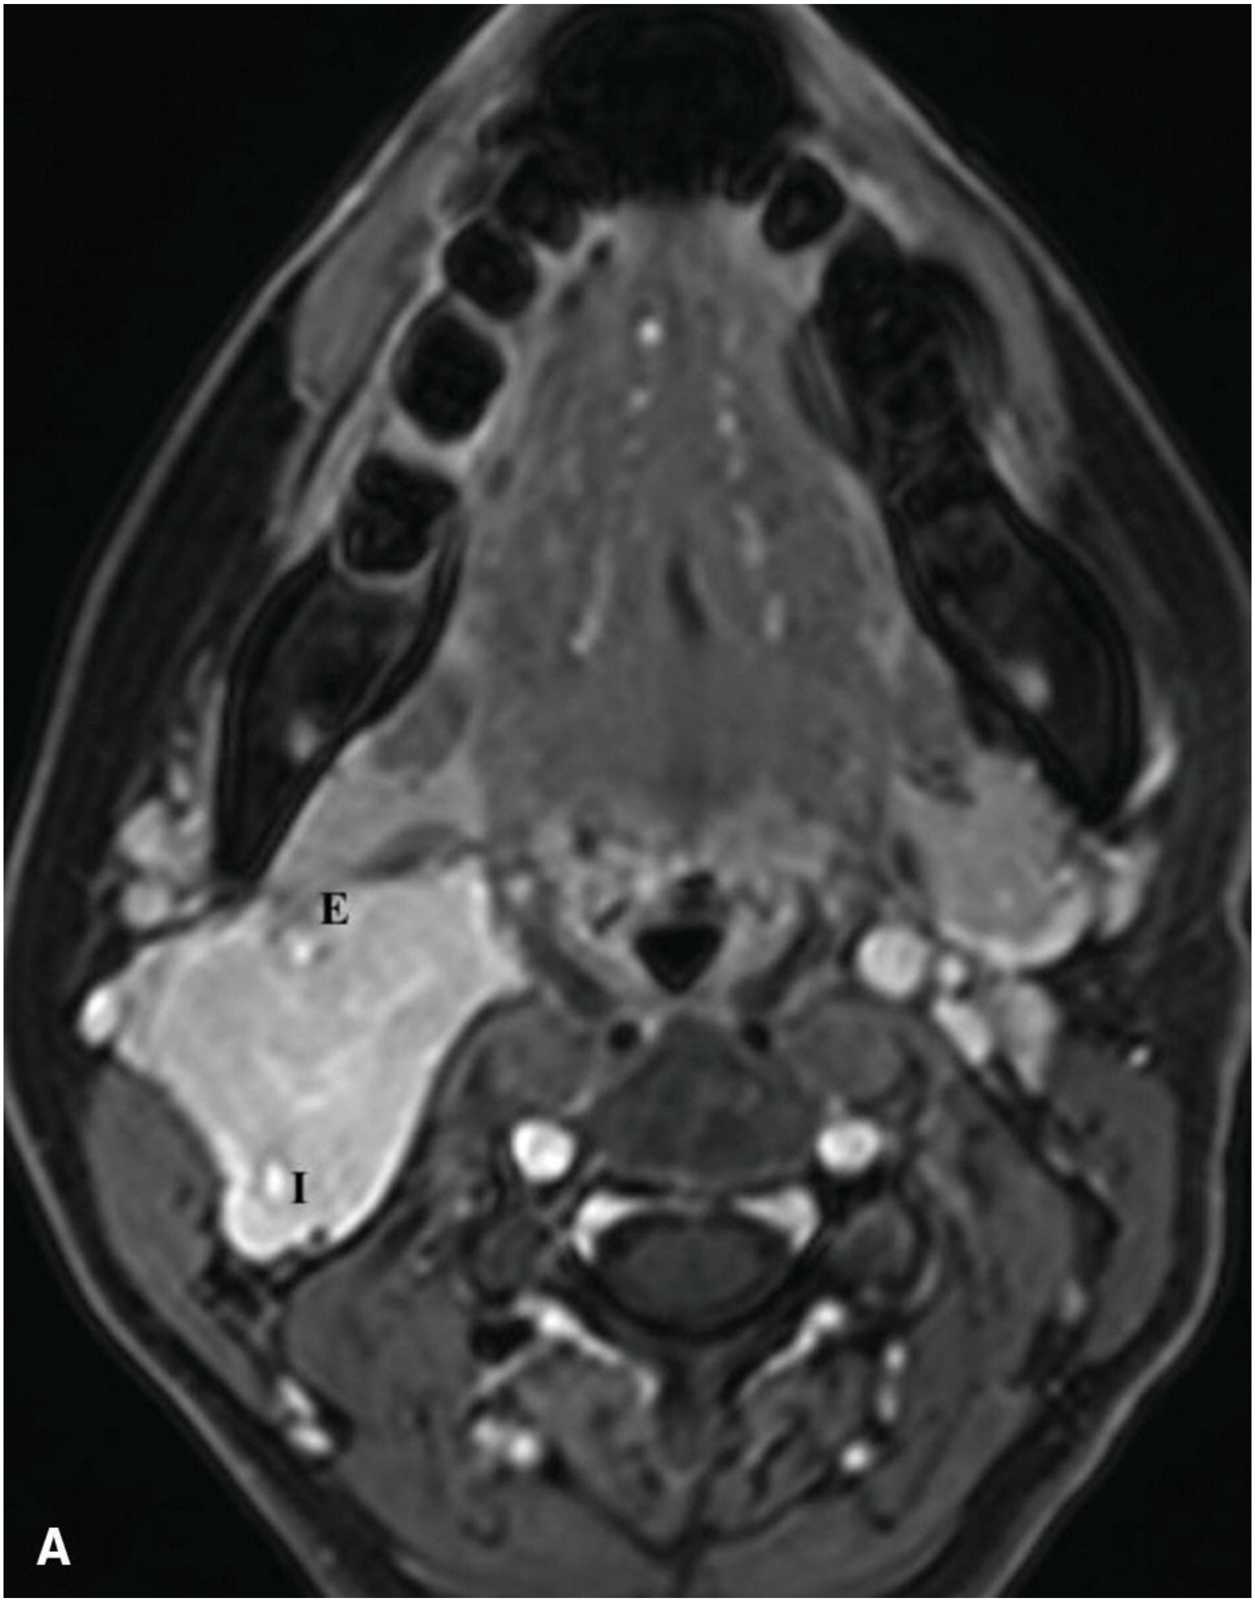
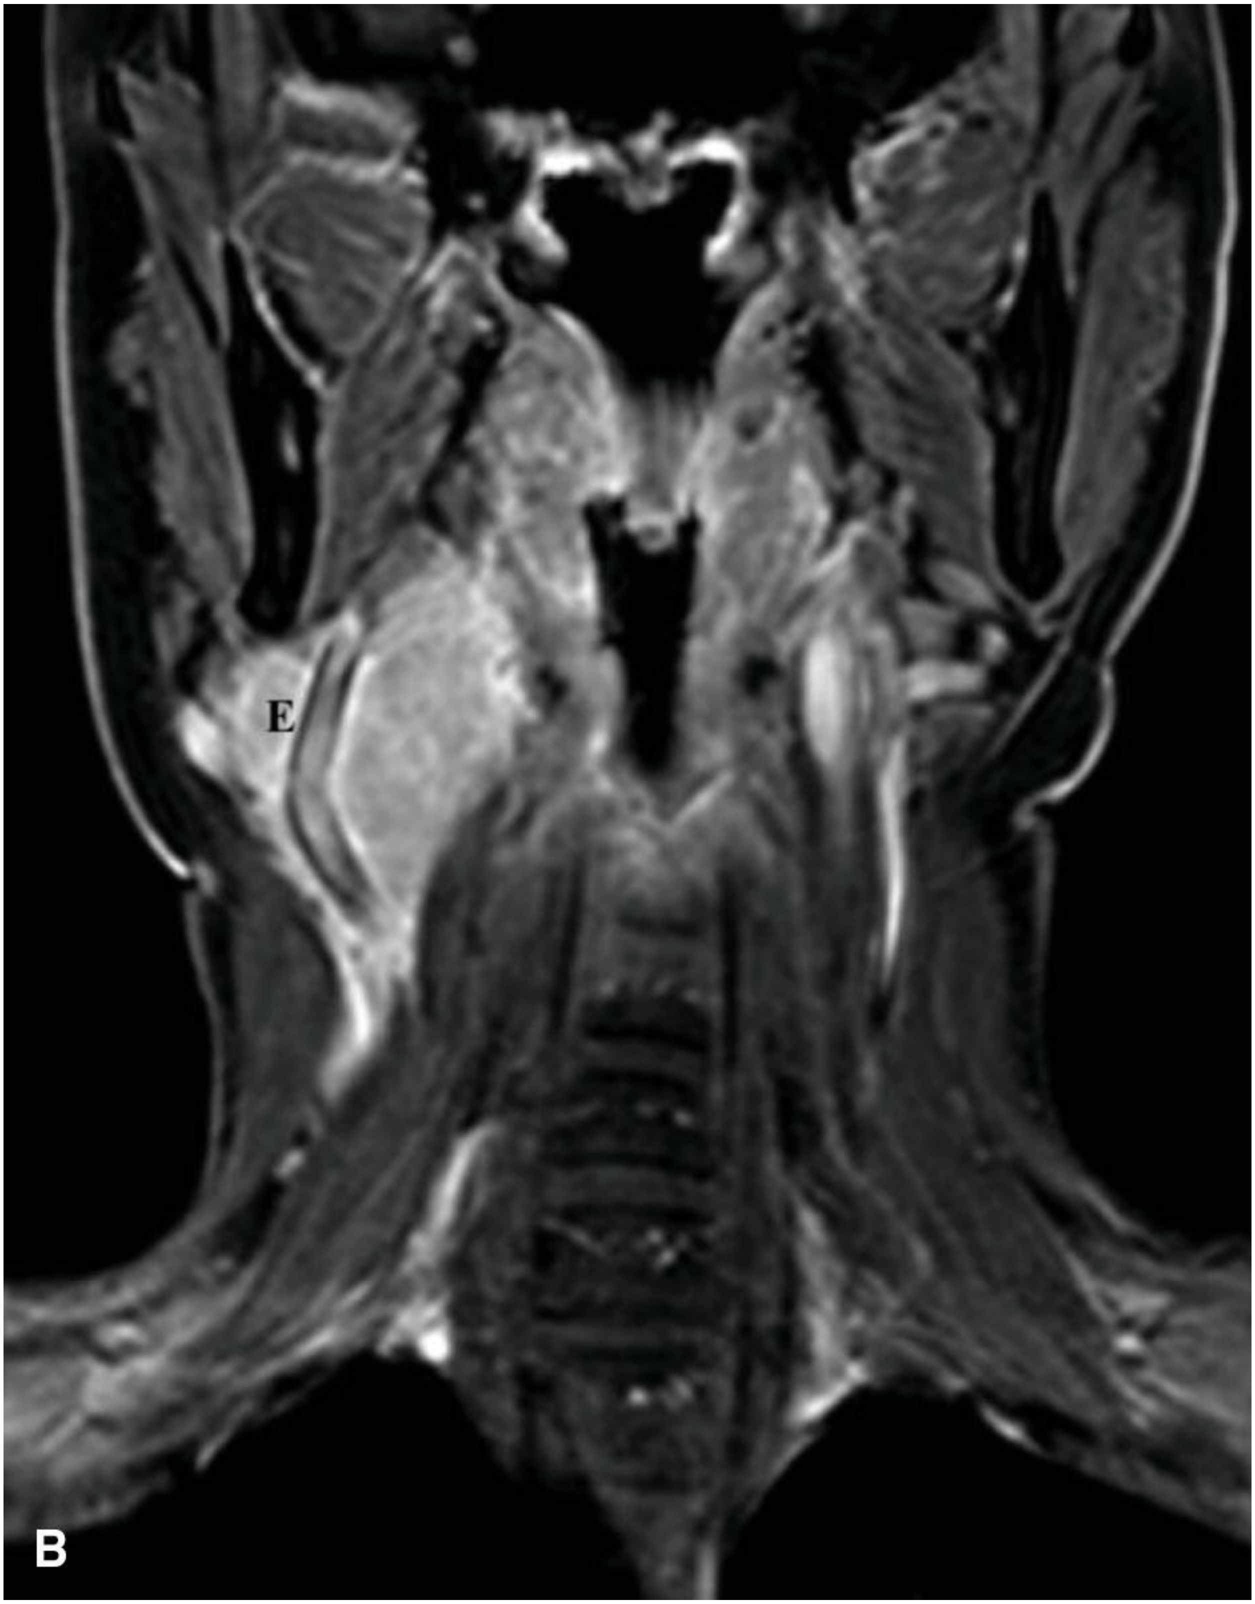
internal jugular vein (*J*). Displacement of both internal and external carotid arteries (*arrow*) anteriorly suggests vagal paraganglioma over carotid body tumor.

Carotid Body Tumors

Carotid body tumors are the most commonly encountered paraganglioma in the lower neck. A large carotid body tumor can extend superiorly into the PPS (Fig. 22.10). On physical examination, these tumors manifest as a mass in the neck that on palpation responds to manipulation in the lateral plane, but not in a cephalocaudad direction as they are tethered to the carotid artery.



E
I
A



E
B

Figure 22.10. Large carotid body tumor (Shamblin type III). T1-weighted postcontrast MRI axial images demonstrate large avidly enhancing mass in

the right carotid space, splaying the external carotid artery (*E*) anteriorly and the internal carotid artery (*I*) posteriorly **(A, B)**. Angiography image **(C)** in right lateral view shows widening of the carotid bifurcation by vascular tumor (i.e., Lyre sign) supplied by multiple hypertrophied vessels, predominantly arising from the external carotid artery (*E*).

Treatment decisions for paragangliomas are challenging and require the input from a multidisciplinary team of specialists familiar with these tumors. Treatment may include observation, surgery, or radiation therapy. Although traditionally these tumors have been treated with surgery, both conventional radiation therapy and stereotactic radiation therapy have been shown to be effective in either stabilization or decreasing tumor volume.[28,29] Long-term local control rates in excess of 94% have been reported, and overall survival is comparable to that of surgical excision.[28] Reported complications following radiation therapy have included headaches, xerostomia, mucositis, transient cranial nerve palsies, hearing loss, and dysequilibirum.[28] The distinction between malignant and benign paragangliomas can only be made on the basis of nodal or distant metastasis, as there are no distinguishing histopathologic features at the primary site. On this basis, about 7% of paragangliomas meet the criteria for malignancy.[30,31] On sequential radiologic imaging, between 25% and 40% of paragangliomas in the head and neck have been shown to remain stable in size, whereas those that enlarged grew at a median rate of ~1 to 2 mm/year, which makes observation a reasonable option for select patients.[32,33]

In those patients undergoing surgery with tumors generally larger than 3 cm, arteriography with preoperative embolization of carotid body tumors has been used as a treatment strategy to minimize intraoperative blood loss (Fig. 22.11). In one study, 131 patients with Shamblin class II and III tumors were divided into a presurgery embolization group and nonembolization group. Presurgery embolization was shown to reduce intraoperative blood loss and the need for intraoperative ICA clamping but did not reduce the rates of cranial nerve injury, stroke, or death.[34] No significant differences in the distribution of tumor size were found to exist between groups. The optimal timing for surgical resection following embolization has not been determined, but surgical resection following embolization should generally occur within 24 hours.[35] The preoperative management of catecholamine-secreting carotid

body tumor (CBT) should also include endocrinologists and anesthesiologists for a comprehensive cardiac workup and titration of alpha-adrenergic blockade. Surgical principles for excision of carotid body tumors include proximal and distal control of the carotid artery and identification and preservation of the spinal accessory and hypoglossal and vagus nerves prior to dissection of the tumor in a subadventitial plane (Fig. 22.12).

Nonsurgical options for management of metastatic paraganglioma that have been used include ^{131}I-MIBG therapy, combination chemotherapy with cyclophosphamide, vincristine and dacarbazine, and sunitinib, a tyrosine kinase inhibitor.[36,37] A recent meta-analysis of studies using ^{131}I-MIBG therapy for treatment of metastatic paraganglioma and pheochromocytoma in 243 patients demonstrated stable disease in 50% of patients over a mean duration follow-up period of between 24 and 62 months.[38] Eligibility for ^{131}I-MIBG therapy is dependent on demonstration of adequate radiotracer uptake on pretreatment scintigraphy.

Neurilemmoma

Nonvestibular neurilemmomas, also known as schwannomas of the head and neck, most frequently occur in the PPS. These benign tumors arise from the neuroectodermal nerve sheath of a peripheral nerve. Histologically, they exhibit two different patterns as described by Antoni in 1920. In the “Antoni A” pattern, a distinctive pattern of spindle-shaped cells known as Verocay bodies is arranged in a stacked palisading pattern alternating with anuclear zones containing cellular cytoplasm. In the Antoni B pattern, cells are arranged in a random pattern within a loose myxoid stroma. On immunohistochemistry, these tumors stain intensely for the S100 protein. Within the PPS, most schwannomas are of either vagal or cervical sympathetic chain origin, and although the vast majority of these tumors are benign, malignant degeneration has been described. It is difficult to determine the nerve of origin based solely on the patient’s history and clinical examination alone due to the nonspecificity of the presenting symptoms.

With regard to their radiologic appearance, they are ovoid to fusiform in shape with smooth, well-defined margins. On MRI T1 sequences, neurilemmomas most commonly have low signal intensities, whereas on T2 sequences, these tumors have a higher intensity compared to surrounding muscle. With administration of contrast, they show uniform enhancement but

do not demonstrate flow voids and are less vascular compared to paragangliomas. Determining the nerve of origin is possible by identifying the relationship of the tumor to the ICA and the IJV. In vagus nerve schwannomas, the tumor usually causes separation of the ICA and IJV (Figs. 22.13 and 22.14), whereas in a cervical sympathetic schwannoma, both ICA and IJV are typically displaced together without separation.[39,40] Splaying of the ICA and external carotid artery by a cervical chain sympathetic schwannoma has also been described.[41] This can be explained by the posteromedial relation of the cervical sympathetic trunk to the ICA at the level of the carotid bifurcation, with nondistensible boundaries of the cervical vertebra column medially and the longus capitis muscle posteriorly, whereas vagal nerve fibers course lateral to the ICA.

Figure 22.13. Schwannoma (cystic). A 57-year-old woman a with PPS mass incidentally noted on spinal MRI. Ring enhancing, a primarily cystic mass

lesion arising within the right poststyloid PPS with its superior margin at the inferior jugular foramen. The mass displaces the internal (*arrow*) and external carotid (*arrowhead*) arteries anteriorly away from the internal jugular vein (*J*). Imaging characteristics are most suggestive of a suprahyoid vagus nerve schwannoma. When noncystic, schwannoma may be differentiated from vagal paraganglioma by lack of flow voids and less rapid enhancement on dynamic imaging. **A:** T2-weighted image. **B:** T1-weighted axial postcontrast image. **C:** T1-weighted coronal postcontrast image.

Figure 22.14. Schwannoma (noncystic). Circumscribed T2 hyperintense enhancing mass in the right poststyloid PPS. This tumor displaces the internal carotid artery (*I*) laterally, a pattern atypical for schwannoma. **A:** T1-

weighted postcontrast image without adipose tissue suppression demonstrates displacement of the prestyloid parapharyngeal adipose anteriorly (*arrowheads*). **B:** Coronal T1-weighted postcontrast image.

These tumors are relatively radioresistant, so that complete surgical resection is the definitive treatment, although given the slow rate of growth and noninvasive nature of these tumors; observation with serial imaging is another management option. Intracapsular tumor excision is a surgical technique that allows for preservation of nerve continuity, although structural nerve continuity following complete tumor excision does not always equate to normal functioning. The epineurium of the nerve is incised longitudinally, and blunt dissection is carried out parallel to nerve fibers teasing the tumor from within the nerve. Alternatively, microdebrider or coblation may be employed to decompress the tumor and facilitate excision. Preservation of nerve function following this technique has been reported to range from 78% to 85% in two recent case series.[42,43]

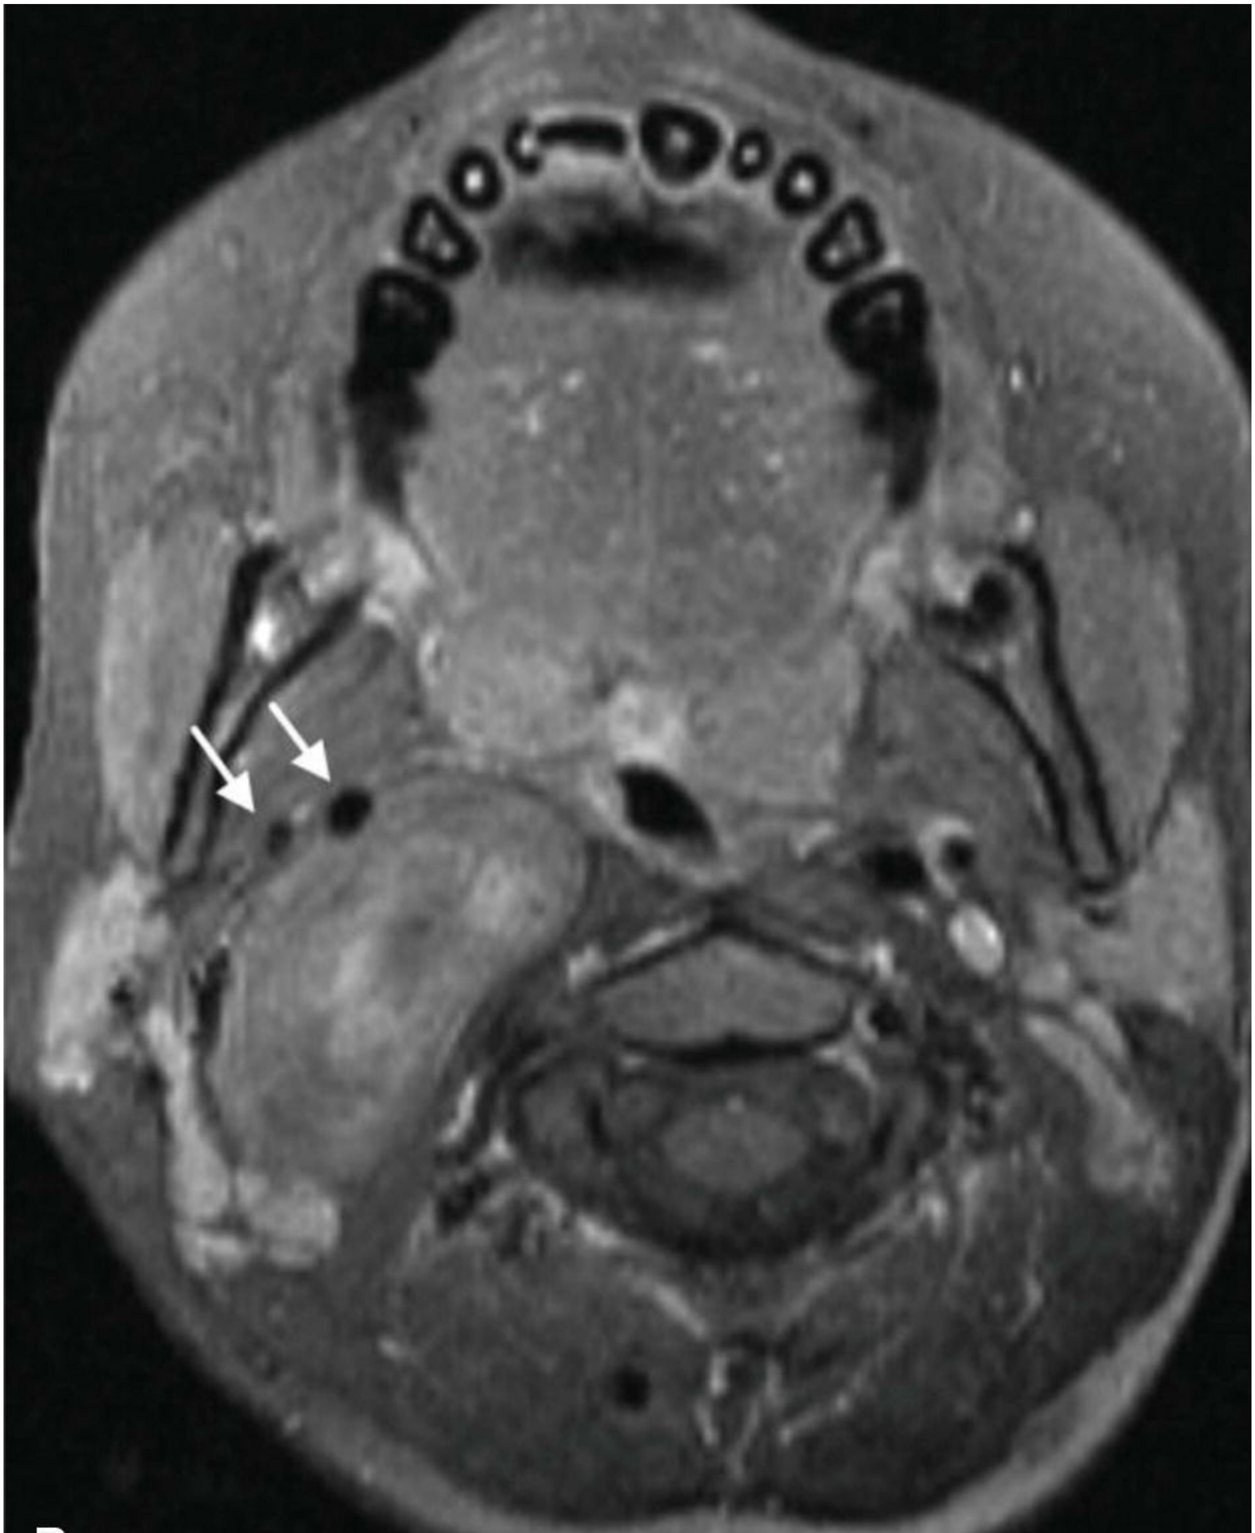
Neurofibroma

Neurofibromas are benign peripheral nerve tumors arising from nonmyelinating Schwann cells. Histologically, the neoplastic cells, which have elongated wavy, twisted nuclei, are intimately involved with axons in a myxoid matrix containing thin walled vessels, mast cells, and fibroblasts. Neurofibromas stain for S100 protein, neurofilament protein, and myelin basic protein. A clear histologic distinction between neurofibromas and schwannomas is sometimes difficult, although schwannomas exhibit an Antoni A or Antoni B pattern, have a more diffuse staining pattern for the S100 protein, and do not usually stain for neurofilament protein.

Radiologically, neurofibromas have similar imaging characteristics as other neural crest-derived tumors including schwannomas and ganglioneuromas, appearing hypo- to isointense on T1-weighted images and hyperintense on T2-weighted images. Distinguishing between these tumors is often difficult on radiologic interpretation alone, as demonstrated on Figure 22.15. Features that have been proposed to distinguish neurofibromas from schwannomas include a “target sign” on T2-weighted imaging, manifesting as a hypointense central area in an otherwise hyperintense periphery and tumor bulk occupying a central position within the nerve of origin, in contrast

to schwannomas, which more frequently have an eccentric relation to the nerve of origin.[44]

A



B

Figure 22.15. Ganglioneuroma. A heterogeneous T2 hyperintense mass with heterogeneous enhancement arising from the poststyloid PPS, displacing both

carotid vessels anteriorly (*arrows*) just above the bifurcation. Imaging characteristics are similar to neurofibroma, but pathology on excision demonstrated ganglioneuroma. **A:** T2-weighted MRI. **B:** axial T1-weighted postcontrast image. **C:** Coronal T1-weighted postcontrast image.

Multiple neurofibromas occur in association with von Recklinghausen disease (neurofibromatosis type I), an autosomal dominant inherited disorder with low penetrance occurring in 1 per 3,000 births. Mutations in the NF1 gene, which is a tumor suppressor gene involved in the production of neurofibromin, have been attributed to this disease. Clinical characteristics of neurofibromatosis Type I include multiple café au lait spots, Lisch nodules, and optic gliomas. Malignant degeneration occurs more commonly in neurofibromatosis type I and is rare in patients with solitary neurofibromas. Histologic features of malignancy include pleomorphic nuclei, increased mitotic activity, and hypercellularity, whereas clinical features include rapid increase in size, cranial nerve deficits, and metastasis. Similar to schwannomas, neurofibromas are relatively radioresistant, and surgical excision versus observation are the major management options.

OTHER TUMORS OF THE PARAPHARYNGEAL SPACE

The lymphatics within the PPS receive drainage from the oral cavity, oropharynx, nasopharynx, and thyroid gland. As such, metastasis from these regions has been described including papillary thyroid cancer, medullary thyroid cancer, squamous cell carcinoma, and nasopharyngeal carcinoma (Fig. 22.16). Non-Hodgkin lymphoma occurs very rarely in the PPS and is treated primarily with radiotherapy or concurrent chemoradiation, depending on the stage of the tumor.[45] Lipomas are also rare benign tumors of mesenchymal origin that show a characteristic well-defined, lobulated, nonenhancing hyperintense signal on T1-weighted imaging.[46] Management options for these tumors are surgical excision versus observation. Congenital lesions such as 2nd branchial cleft cysts can manifest in the PPS (Fig. 22.17), with MRI findings showing well-marginated, cystic masses showing mild hyperintensity on T1-weighted imaging and mild hypointensity on T2-weighted imaging compared to cerebrospinal fluid.[47]

displaced laterally. This is most likely a branchial cleft cyst, with differential also including laryngocele and rare pharyngeal/esophageal duplication cyst.

SURGICAL APPROACHES

The general principles that should be adhered to in the resection of PPS tumors are maximization of intraoperative exposure to allow for safe dissection of the tumor with adequate margins, visualization of critical neurovascular structures, and minimization of functional and cosmetic morbidity.

Transcervical Approach

This is the most commonly used surgical approach to the PPS (Fig. 22.18).[9,48,49] The advantages to this approach include clear visualization of major blood vessels and nerves, no oral flora contamination, maintenance of sterility, and cosmesis with the incision placed in a natural skin crease. The limitations to this approach include poor visualization of the superior and medial aspect of tumors in close proximity to the skull base and inability to identify and protect proximal facial nerve branches in tumors involving the deep lobe of the parotid gland. The skin incision is most commonly placed in a natural skin crease several fingerbreadths below the mandible. Subplatysmal flaps are raised, followed by identification and preservation of the marginal mandibular branch of the facial nerve. The anterior border of the sternocleidomastoid muscle and digastric and stylohyoid muscles is then identified. Access to the PPS is obtained through superior retraction of the mandibular body and inferior retraction of cervical tissue. Exposure to the PPS through this route can be improved through division of the stylomandibular ligament and digastric and stylohyoid muscles. Removal of the submandibular gland is not usually necessary.

A

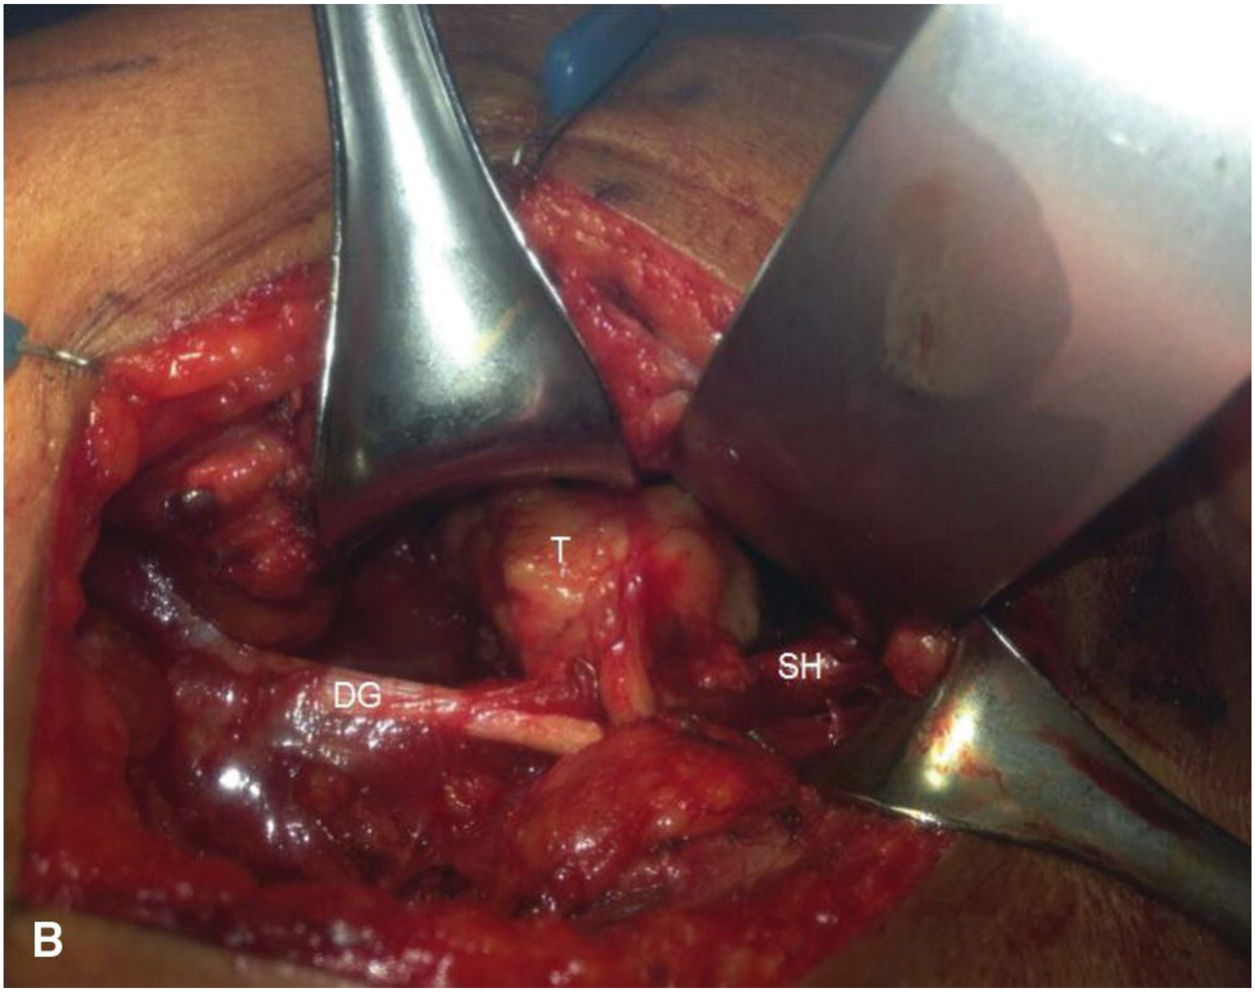

Figure 22.18. Transcervical approach for resection of a deep lobe pleomorphic adenoma. **A:** Planned cervical incision in a natural skin crease below the inferior edge of the mandible. **B:** Subplatysmal flaps have been elevated, the submandibular gland is retracted anteriorly, the posterior belly of the digastric (*DG*) and stylohyoid (*SH*) muscle has been identified, and superior retraction of the mandibular body after sectioning the stylomandibular ligament reveals the pleomorphic adenoma (*T*).

Postoperative complications with this approach include temporary pain in the jaw and transient marginal mandibular nerve weakness.[48] Visualization within the PPS from a transcervical approach can be facilitated using endoscopes, especially along the superomedial dissection. A visible cervical scar can also be avoided by using a hairline incision or facelift approach.

Transcervical–Transparotid Approach

The transcervical–transparotid approach is used for deep lobe parotid neoplasms extending into the prestyloid PPS (Fig. 22.19). A key feature of this approach is formal identification and preservation of the main trunk of the facial nerve to enable safe dissection of the tumor medial to the nerve. A modified Blair incision is carried out in a preauricular skin crease and extended inferiorly to incorporate a natural cervical skin crease. Anterior and posterior flaps are raised in a fashion similar to a parotidectomy. The anterior border of the sternocleidomastoid muscle in level II is skeletonized, allowing for identification of the posterior belly of the digastric muscle, which establishes the approximate depth of the facial nerve. Dissection in a broad plane separating parotid tissue from the tragal cartilage enables identification of the tragal pointer and tympanomastoid suture line that are useful landmarks to find the facial nerve. Once the facial nerve is identified, branches of the facial nerve are traced distally and dissected away from the underlying tumor capsule. Anterior retraction of the submandibular gland allows mobilization of the inferior aspect of the tumor. Division of the stylomandibular ligament and mandibulotomy are additional steps to improve tumor access.

Mandibulotomy Approach

The benefits of mandibulotomy to improve visualization of larger tumors in close proximity to the skull base, malignant tumors, recurrent tumors, and vascular tumors have to be balanced against the risks of malocclusion, temporomandibular joint dysfunction, inferior alveolar nerve damage, and infrequent need for tracheostomy. Regardless, patients with larger PPS tumors should always be counseled on the possibility of mandibulotomy and tracheotomy if necessary for complete tumor resection. The use of mandibulotomy in the resection of PPS tumors varies between 10% and 30% in a number of large case series.[10,11,50] A number of mandibulotomy approaches that preserve the integrity of the inferior alveolar nerve have recently been described. Jungehuelsing et al.[51] performed a single vertical osteotomy technique perpendicular to the mandibular symphysis through an intraoral approach by floor of mouth mucosal incisions. Smith et al.[52] carried out a transcervical vertical subsigmoid osteotomy posterior to the lingula, thus sparing the inferior alveolar nerve and a second mandibular osteotomy anterior to the mental foramen between the canine and first premolar teeth. Kolokythas et al.[53] utilized either a single paramedian osteotomy between the canine and first premolar alone or in combination with a horizontal osteotomy above the lingula. Prior to any osteotomies, it is essential that reconstruction plates be adapted to the contour of the native mandible through predrilled holes to ensure an accurate reconstruction during closure, thus preventing malocclusion.

Transoral Approaches

Transoral approaches for resection of PPS tumors have traditionally not been viewed favorably due to the risks of tumor rupture, incomplete tumor resection, and major neurovascular injury secondary to poor visualization.[54,55] Ducic et al.[56] in 2006 reported en bloc resection of eight nonsalivary benign tumors in the superomedial compartment of the PPS through a transoral approach with no tumor rupture. The authors used an incision extending from the posterior edge of the hard palate passing along

the lateral margin of the soft palate into the nasopharynx. Early identification and proximal and distal control of the ICA was obtained prior to tumor dissection. Combined transoral and transcervical approaches are advantageous in the resection of tumors requiring partial resection of the pharynx. In tumors that have previously undergone intraoral incisional biopsy (often ill-advised), a cuff of mucosa surrounding the site of previous incisional biopsy is incorporated in the resection of the main tumor specimen to reduce the risk of tumor spillage and subsequent multifocal recurrence within the PPS (Fig. 22.20).

Newer developments to enhance visualization during dissection of the

PPS have included the use of endoscopic techniques and transoral robotic surgery (TORS).[57,58] TORS provides a magnified, three-dimensional high-resolution view using angled scopes, greater range of movement with robot arms, and lack of a transcervical scar. There has been growing enthusiasm for resection of PPS neoplasms through a TORS approach. Chan et al.[59] recently performed a literature review of 44 patients and reported unintended tumor capsule violation or tumor fragmentation in 24% of patients undergoing TORS resection for pleomorphic adenomas. The authors question if the approach is truly “minimally invasive.” Disadvantages include the need for an incision through the superior constrictor and soft palate muscles, the inability to safely grasp the tumor capsule with sharp robotic instrumentation, lack of haptic feedback, limited space to manipulate the tumor, awkward angulation as dissection proceeds laterally deep into the PPS, and lack of carotid artery protection. Caution must be exercised using this technology, especially for pleomorphic adenomas, as the rupture rate is unacceptably high.

MANAGEMENT OF SURGICAL COMPLICATIONS

Cranial nerve injuries involving CN IX, CN X, and CN XII during resection of PPS tumors can result in speech and swallowing difficulties. CN X paralysis following resection of either a vagus nerve schwannoma or a paraganglioma should be anticipated and requires careful management to minimize morbidity. Immediate vocal fold medialization at the time of operation can assist in improving voice quality and reducing aspiration. Speech and language pathologists should be engaged to provide assessment of swallowing function and institution of swallowing therapy if required. If poor postoperative swallowing function is anticipated, alternative means of providing nutritional support via a nasogastric tube or percutaneous endoscopic gastrostomy tube should be considered. CN XI injuries incur weakness of the sternocleidomastoid and trapezius muscles and potential long-term adhesive capsulitis of the shoulder joint. Patients should receive postoperative physical therapy for range of motion shoulder exercises to rehabilitate trapezius muscle function if postoperative weakness is detected. Complete transection of CN VII results in impaired eye closure and increases

the risks of exposure keratopathy and corneal ulceration that warrants an aggressive regimen of eye lubrication with artificial tears and ointment. The most commonly used surgical strategies for treatment of lagophthalmos resulting from CN VII injury include placement of eyelid weight, canthoplasty, and canthopexy, although a whole host of other dynamic and static treatment options exist, which are beyond the scope of this chapter.

Mandibulotomies incur the risk of malocclusion, nonunion, tooth loss, and temporomandibular joint dysfunction. The risk of impaired bony union across osteotomy sites is increased with the use of adjuvant radiation. Proper attention to alignment of osteotomy segments during plating and placement of osteotomies in between tooth roots reduces these complications.

A particular complication related to resection of PPS tumors include first bite syndrome, manifested as recurrent severe pain in the parotid region with initial oral intake that subsides with subsequent chewing. Dissection within the PPS, deep lobe parotid resection, and sympathetic chain sacrifice have been shown to be strong independent risk factors for the development of this syndrome.[60] Denervation supersensitivity of the myoepithelial cell receptors following sympathetic denervation of the parotid gland has been proposed as the pathophysiology underlying this syndrome.[61,62] Severe pain related to first bite syndrome has been treated with gabapentin, pregabalin, or transcutaneous injection with botulinum toxin.[61–64] Ptosis, miosis, and anhidrosis constituting Horner syndrome can occur following disruption of the cervical sympathetic chain during surgical dissection. Velopharyngeal dysfunction following vagal injury can be ameliorated by the use of palatal prosthesis or a palatal adhesion procedure.[65]

CONCLUSION

The optimal evaluation and management of PPS tumors require a multidisciplinary team approach. A comprehensive history and physical examination allow for identification of familial tumors that may warrant further genetic counseling. An appreciation of the anatomical features of this space combined with knowledge on the commonly occurring tumors allows for accurate interpretation of radiologic imaging and treatment planning. The treatment approach of PPS tumors should take into consideration existing patient comorbidities and anticipated sequelae of surgical intervention

allowing for an informed discourse with patients on the risks, benefits, and alternatives of surgical excision. In patients who choose to undergo surgical excision, understanding of the anatomical features of this space is once again a key component allowing for maximization of intraoperative access while concurrently minimizing the risks of intervention.

23 Ear and Temporal Bone Cancer

Paul W. Gidley

The external ear is a relatively common location for skin cancers. The external ears are susceptible to sun exposure accounting for the relatively high rate of skin cancer occurrence. Squamous cell carcinoma (SCC) of the outer ear is notorious for a relatively high metastatic rate and a higher death rate than other cutaneous sites.

Whereas the anatomic location of the ears makes them susceptible to sun-related skin cancers, the temporal bone is rarely the site of primary malignancy. Untreated external ear and periauricular skin cancers, on the other hand, can invade into the ear canal, mastoid, or stylomastoid region. Furthermore, tumors of the parotid gland, temporomandibular joint, and infratemporal fossa also erode into the ear canal and middle ear and can require a temporal bone approach for management. This chapter will present an overview of ear and temporal bone cancers.

INCIDENCE

External Ear

In the United States, approximately one million persons develop cutaneous malignancies every year.[1] The incidence of nonmelanoma skin cancer is highest in Australia with an annual occurrence of 1,200/100,000 population.[2] In a population-based study, SCC occurred on the ear as the site of first cancer in 12/100,000 men and 0.6/100,000 women.[3] The mortality rate of nonmelanoma skin cancer has been calculated to roughly 0.44/100,000.[4]

Generally speaking, external ear cancers occur in older, Caucasian men usually in their sixth and seventh decades of life.[5–9]

Cutaneous SCC is up to 17 times more common in men than in

women[10–12]. Whereas SCC of the outer ear makes up somewhere between 11% and 25% of skin cancer in men, SCC of the outer ear is found in only 0.2% to 3% of women.[3,10,13] Differences in occupation and the female style of wearing long hair may be protective.[14]

Right and left sides are equally affected, with only minor differences seen in individual studies. In comparing the incidence of left to right, these differences range from 62% to 38% to 47% to 53%.[11,15–18] Bilateral disease is found in around 10% of patients.[17] Nearly 18% of patients develop either multiple lesions or bilateral lesions during their clinical course.[8]

Temporal Bone

Primary tumors that affect the temporal bone are rare and account for only about 0.2% of all head and neck cancers.[19] Primary ear canal cancers or middle ear cancers occur at an estimated rate of one person per million people per year.[20–22] It is estimated that cancer is the underlying cause in only one in every 5,000 to 20,000 patients with an otologic complaint.[23] The temporal bone is more likely to be affected secondarily from advanced cancers of the external ear, periauricular skin, or the parotid gland (**Fig. 23.1**).[24,25]

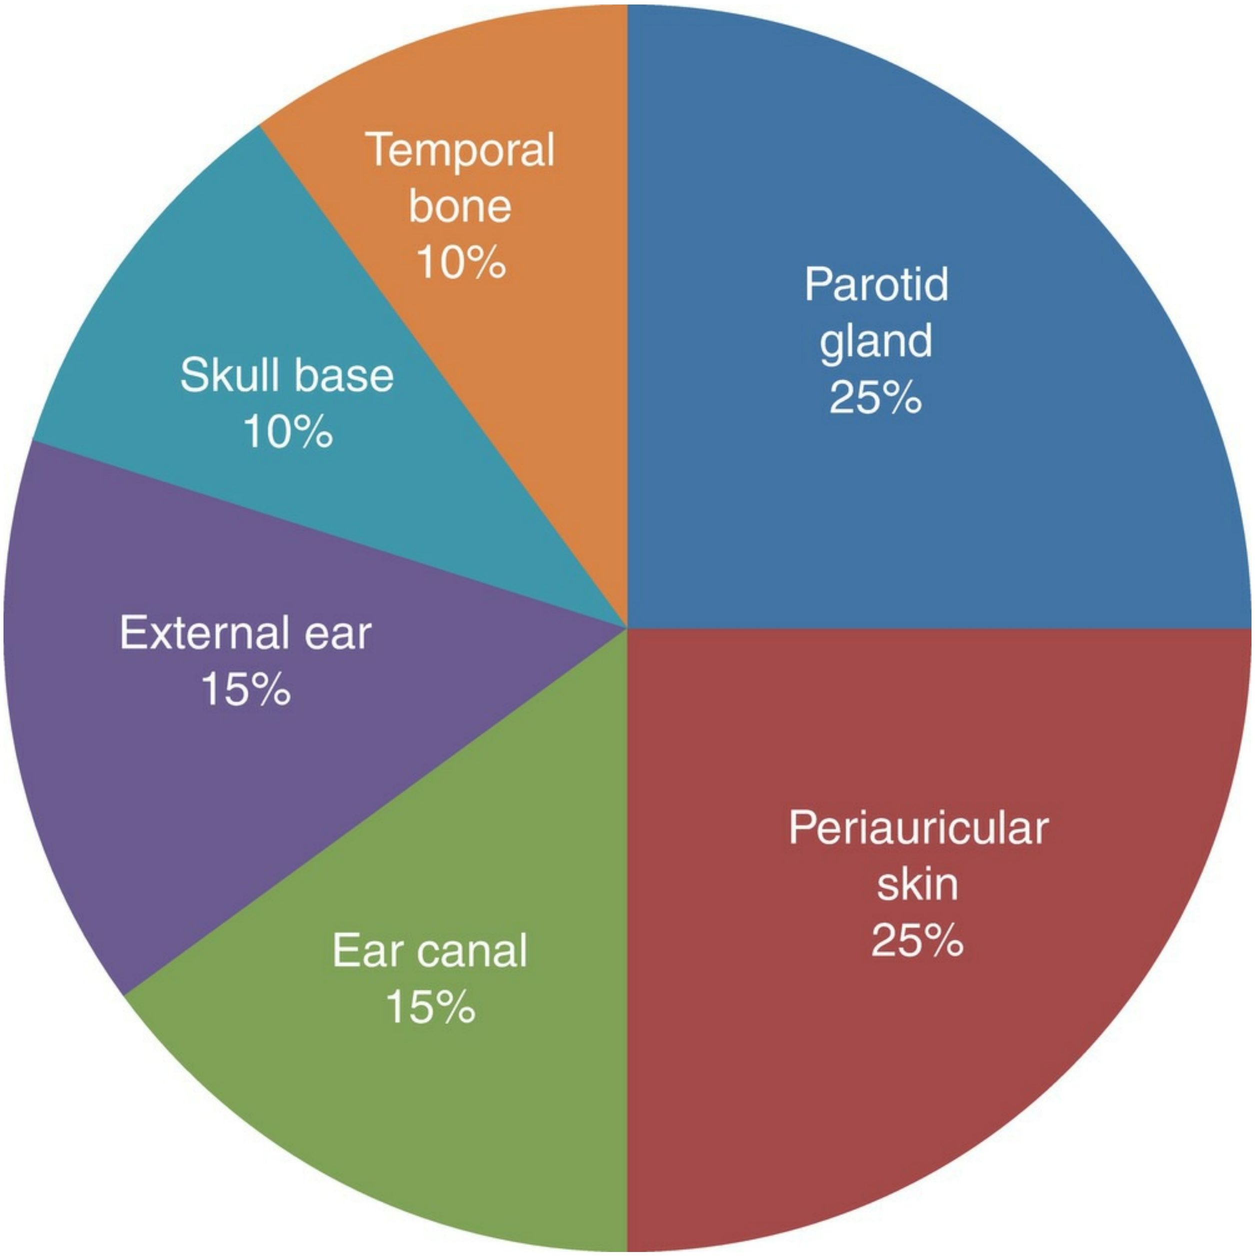

Figure 23.1. Pie chart representation of location of temporal bone primary tumors. (Used with permission, Department of Head and Neck Surgery, MD Anderson Cancer Center.)

Tumors affecting the temporal bone can occur in all age groups but typically occur in older patients, especially in men. In a large series of temporal bone cancers, 75% of patients were men, and the average age was 65 years.[26] The tumor histologies tend to trend with age, so that younger patients are likely to have sarcomas and older patients are likely to have carcinomas.

ETIOLOGY

Overwhelmingly, the leading cause of external ear cancer is ultraviolet solar radiation.[27] In the sun-drenched parts of the United States, cancer of the external ears is a common clinical entity. The prominent location of the external ear makes it vulnerable to sun exposure. Radiotherapy has also been implicated as a risk factor for development of SCC. According to Conley and Schuller,[28] SCC is also found in patients with burn chondritis and chronic scarring lupus erythematosus.[29]

Radiotherapy has been linked with squamous cell cancer of the middle ear and ear canal.[30–32] Some authors have linked chronic otitis media and cholesteatoma to ear canal and middle ear cancer,[30,33–36] but this etiology probably accounts for only a small number of tumors in most modern studies. HPV16 has been found in only a small number of temporal bone SCCs.[37]

HISTOLOGIC TYPES

External Ear

Basal and squamous cell carcinoma are far and away the most common malignancies to affect the outer ear and its surrounding skin.[12] The outer ear is estimated to make up 5% to 10% of all skin cancers.[9,38,39] For the head and neck, the external ear is the second most common site of cutaneous SCC.[10] In the subset of patients with metastatic spread of cutaneous SCC in the head and neck, the outer ear accounts for 20% of the primary sites; and this rate is higher than for lip (15%) or cheek (12%) primary sites.[40]

Although basal cell carcinoma (BCC) is almost four times more common than SCC as a cutaneous malignancy in other body sites,[41–43] an analysis limited to the outer ear found that their incidence is nearly equal (1.3 BCC:1 SCC).[14] In another study of 780 patients with external ear cancer, SCC was found to affect 55% of patients.[5] In reviewing the literature, SCC made up 55% to 67% of malignancies affecting the outer ear, whereas BCC made up 28% to 32% and melanoma was 1% to 5%.[17]

Unlike most cutaneous SCCs, which have a low rate of metastatic spread

to regional lymph nodes (range 0.5% to 5%),[6,44–46] SCC from the ear has a much higher rate, ranging from 10% to 16%.[7,8,15,47]

Overall, when compared to other cutaneous sites, SCC from the auricle has the highest death rate, nearly 47% in one study.[4] It has been estimated that cancers originating from the ear are responsible for more than 25% of deaths caused by nongenital, nonmelanoma skin cancers.[48]

Given all the features and facts listed above, the ear is considered a high-risk area for BCC and SCC as documented in the latest National Comprehensive Cancer Network (NCCN) guidelines[49,50] and AJCC staging.[51]

Melanoma of the external ear is a unique disease in its own right. The external ear is involved relatively infrequently with melanoma. In the United States, roughly 1% of the 48,000 new cases of melanoma involve the outer ear.[52] While approximately 20% of melanomas occur in the head and neck[53], the external ear accounts for approximately 7% to 15% of melanoma cases in head and neck sites.[53,54] Of the four subtypes of melanoma described, superficial spread and nodular melanoma are the most common to be found on the external ear.[54] For melanoma of the external ear, the rate of metastatic spread to regional lymph nodes is very high. Byers et al.[54] noted an overall incidence of clinically positive nodes in 42 of 102 patients. The presence of metastatic neck disease was found to be a significant correlate for survival.[54]

A recent review of the incidence of external ear cancers seen at the University of Texas MD Anderson Cancer Center is listed in **Table 23.1**. In our patient population, BCC was slightly more common than SCC and its variants. Our patient cohort has nearly as many malignant melanoma patients as SCC probably owing to the fact of our location in the southern US Sunbelt and due to referral bias as a comprehensive cancer institution.

Table 23.1 Histologic Types of External Ear Cancers at University of Texas MD Anderson Cancer Center Between 1990 and 2006

Cancer Type	No. of Patients	%
Basal cell carcinoma	527	30.1%
Basosquamous carcinoma	70	4.0%
Squamous cell carcinoma	388	22.2%
Squamous cell carcinoma in situ	41	2.3%
Squamous cell carcinoma, adenoid variant	25	1.4%
Squamous cell carcinoma, spindle cell variant	5	0.3%
Carcinoma in situ, Bowen disease	8	0.5%
Melanoma, malignant	386	22.1%
Melanoma arising in melanotic freckle	64	3.7%
Melanoma in situ	22	1.3%
Malignant neoplasm unclassifiable	158	9.0%
Carcinoma, NOS	20	1.1%
Merkel cell carcinoma	15	0.9%
Atypical fibrous histiocytoma	6	0.3%
Angiosarcoma	3	0.2%
Unusual tumors[a]	10	0.6%
	1,748	100.0%

[a]Unusual tumors occurring in two or fewer patients during this time include adnexal carcinoma (1), apocrine carcinoma (1), adenocarcinoma (1), adenoid cystic carcinoma (1), papillary squamous carcinoma (1), sarcomatoid carcinoma (1), sebaceous gland carcinoma (1), atypical fibroxanthoma (2), and angiomatoid fibrous histiocytoma (1).Used with permission, © Paul Gidley, MD 2009.

Temporal Bone

Perhaps as a result of its location in the lateral skull base, the temporal bone is affected by a long list of tumor types (**Table 23.2**).[26] Squamous cell and BCC account for more than 50% of the tumors if all primary tumor sites are considered. When primary locations outside the temporal bone are excluded, SCC accounts for 60% to 80% of the tumors that arise in the ear canal, middle ear, or mastoid cavity.[55–57] BCC and adenoid cystic carcinomas (ACCs) are the next two most common tumors found in the ear canal.[58]

Table 23.2 List of Malignant Tumor Types Found Affecting the Temporal Bone

Epithelial
Squamous cell carcinoma
Basal cell carcinoma

Hemangiopericytoma
Neuroendocrine carcinoma
Peripheral nerve sheath tumor

ANATOMY

Embryologically, the auricle arises from the six hillocks of His. These hillocks each give rise to one or more of the structures of the outer ear. The area in front of the ear, at the sideburn in men, marks an area of embryologic fusion plane.[59] These fusion planes are thought to play a role in the depth of invasion of tumors and perhaps contribute to the insidious and profound invasion that is a notorious hallmark for this anatomic site.[5] Equally, the embryologic compartments from each hillock might explain why tumor spread is limited in the early stages of the disease.[59]

Anatomically, the outer ear can be described by its parts: helix, antihelix, tragus, antitragus, lobule, concha, and scapha (**Fig. 23.2**).[60] The conchal bowl can be further subdivided into a concha cavum and a concha cymba. The scapha is divided by branching of the antihelix, thus creating a fossa triangularis. The ear stands out from the scalp creating a posterior, or sometimes called medial, surface.

Figure 23.2. Anatomic subdivision of the external ear. (AH, antihelix; AI, anterior incisura; AT, antitragus; CC, conchal cavum; CH, crus of helix; FT, fossa triangularis; H, helix; II, intertragic incisures; L, lobule; S, scaphoid fossa; T, tragus.) (From Gidley PW. Special considerations: periauricular lesions. In: Weber RS, Moore BA, eds. *Cutaneous Malignancy of the Head and Neck: A Multidisciplinary Approach*. San Diego, CA: Plural Publishing, Inc.; 2011:155–172, with permission.)

The skin of the anterior surface of the pinna is tightly bound to the underlying perichondrium and cartilage, whereas the skin of the posterior surface is thicker and has more soft tissue between the skin and the perichondrium. The lymphatics are in the space between the skin and perichondrium. The relatively high incidence of metastatic spread in external ear cancers might be explained by the short vertical distance between the epidermis and the lymphatics, and this anatomic fact may account for the high incidence of neck metastasis from both SCC and melanoma despite their different cells of origin.[61]

The helix is the most common site of auricular carcinomas, accounting for approximately 50% of tumors.[8,11] This observation is true across the three major histologic types (**Table 23.3**). The concha and scapha account for approximately 17% to 30% of tumors.[8,16,17] The posterior surface is involved in 12% to 28% of tumors (**Fig. 23.3**).[8,62,63] The lobule is involved in 2.7% to 8% of tumors.[8]

Table 23.3 Sites of External Ear Involvement from Squamous Cell Carcinoma (SCC), Basal Cell Carcinoma (BCC), and Melanoma

Anatomic site	Bailin[59] BCC	Afzelius[15] SCC	Byers[8] SCC	Shockley[16] SCC	Silapunt[18] SCC	Byers[54] Melanoma	Cole[65] Melanoma

Figure 23.3. BCC involving the posterior surface of the pinna. (From Gidley PW. Special considerations: periauricular lesions. In: Weber RS, Moore BA, eds. *Cutaneous Malignancy of the Head and Neck: A Multidisciplinary Approach*. San Diego, CA: Plural Publishing, Inc.; 2011:155–172, with permission.)

One study of melanoma of the external ear described that centrally located tumors (concha, tragus, and antitragus) have a worse prognosis than do more peripherally positioned tumors.[64] Interestingly, the triangular fossa and antihelix were not reported as involved by melanoma in two large series.[54,65]

The external auditory meatus has two parts: a lateral cartilaginous part, which has a relatively thick epidermis with hair follicles, and a medial bony part, which has a relatively thin epidermis devoid of hair follicles. The bony–cartilaginous junction marks an important landmark when evaluating external ear canal lesions. Lesions that involve the bony canal will require lateral

temporal bone resection (LTBR) for complete extirpation, whereas lesions that are confined to the membranous canal can often be resected with only soft tissue.

The tympanic membrane (TM) marks another important landmark in evaluating external ear canal tumors. Tumors that are lateral to the TM can usually be completely excised with LTBR, whereas tumors that involve the middle ear, mastoid, facial nerve, and deeper structures will require more extensive surgical resection. Once a tumor fills the ear canal, physical examination becomes less useful, and CT and MRI are necessary to determine the extent of disease.

SIGNS AND SYMPTOMS

The physical examination of these patients demands close scrutiny of the external ear, ear canals, tympanic membranes, parotid gland, periauricular skin, cervical lymph nodes, and cranial nerves. Microscopic examination of the ear canal is important to determine the extent of disease into the ear canal.

External Ear

External ear cancers usually present as a nonhealing ulcer. Itching and occasional bleeding are other common symptoms (**Fig. 23.4A**). Far advanced and neglected tumors can erode away skin and reveal the cartilaginous framework (Fig. 23.4B and C). Facial paralysis and facial numbness are ominous signs of perineural spread.

(Used with permission, University of Texas MD Anderson Cancer Center, Department of Head and Neck Surgery.)

Temporal Bone

The signs and symptoms of these tumors are vague and can be confused with benign disease. Otorrhea, otalgia, and hearing loss are the most common symptoms of temporal bone tumors.[66] However, these symptoms are also seen in benign conditions such as otitis externa, otitis media, or cholesteatoma.[67] The majority of patients with benign disease will respond to aural toilet and eardrops or oral medications. Suspicion should arise when patients with these symptoms do not respond to standard therapy.[67]

The classic triad of otorrhea, otalgia, and hearing loss is found in only 10% of temporal bone cancer patients. If patients with these symptoms do not respond to standard therapy, then any suspicious tissue should be sent for pathologic evaluation.

The differential diagnosis for disease in the ear canal should include skull base osteomyelitis (also called malignant otitis externa), pseudoepitheliomatous hyperplasia, and carcinoma.[68] The diagnosis unfortunately is delayed in many patients, and the duration of symptoms can vary from months to several years. [66,69]

Other symptoms, such as trismus, facial weakness, dysphagia, and hoarseness, are seen much less commonly and are usually associated with advanced-stage disease. The temporal bone and ear canal are a rare location for metastatic lesions, usually from breast, lung, prostate, or kidney primaries.[70–73]

SCC involving the ear canal will have an exophytic or ulcerated appearance (**Fig. 23.5**) and can be heralded by erythematous skin and granulation tissue. BCC usually has an ulcerated appearance with rolled edges. ACC in its early stage is often subcutaneous (**Fig. 23.6**). Occasionally, some tumors will have a subcutaneous spread and a cursory examination of the canal might miss the ear canal involvement (**Fig. 23.7**).

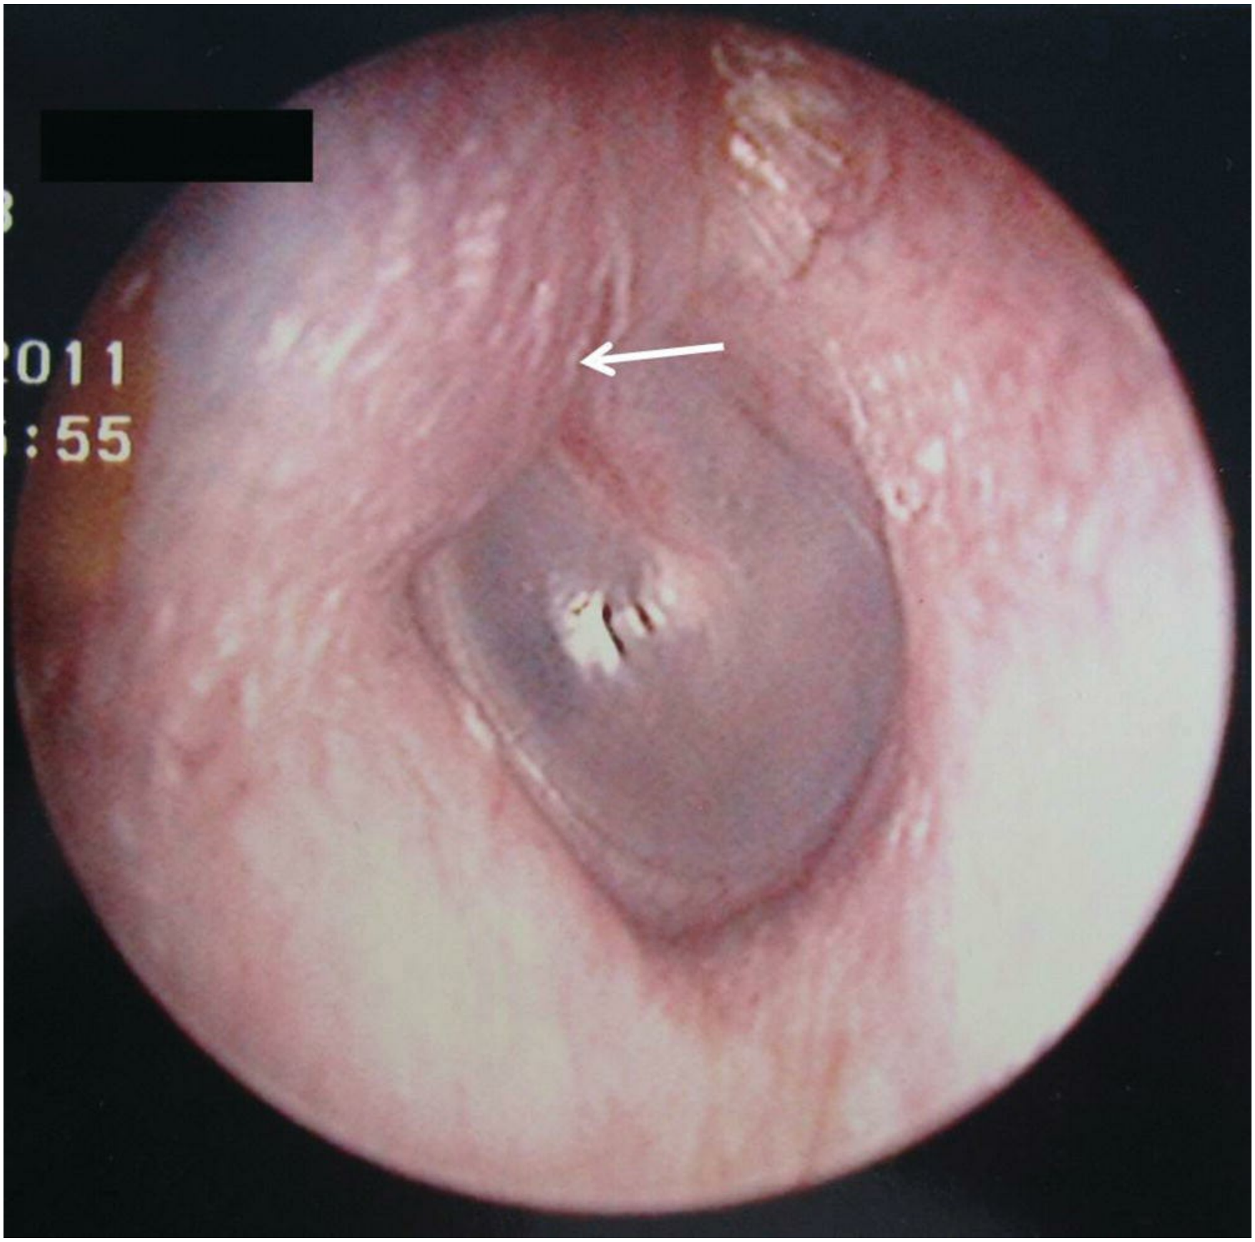

Figure 23.7. Subtle left anterosuperior ear canal swelling (*arrow*) due to infratemporal fossa chondrosarcomas. (Used with permission, Department of Head and Neck Surgery, University of Texas MD Anderson Cancer Center.)

Facial paralysis, when it occurs, is a very ominous finding. It's linked with a poor prognosis.[25,74,75] In a series from MD Anderson, approximately 40% of patients had various degrees of facial weakness or paralysis at presentation.[26] Cervical lymphadenopathy is a particularly poor prognostic sign associated with worse survival.

DIAGNOSTIC IMAGING

Small, early-stage external ear cancers usually do not require any imaging studies; however, late-stage skin cancers, tumors that have spread to parotid gland or lymph nodes, or tumors that involve the ear canal demand radiographic evaluation. Diagnostic imaging is imperative for understanding the three-dimensional anatomy of external canal and temporal bone tumors. CT scan and MRI provide complementary details.[76] CT scan is generally obtained as an initial study because it gives an excellent view of soft tissue and bony anatomy.[77] Given that MRI lacks bony detail, its use is reserved as an adjunct especially in cases where dural involvement or perineural invasion is suspected (**Fig. 23.8**).

Head and Neck Surgery.)

CT and MRI can be reviewed systematically by noting disease involvement at 12 important sites: the 4 quadrants of the ear canal, the infratemporal fossa, middle ear, otic capsule, mastoid, jugular foramen, carotid canal, tegmen or middle fossa and posterior fossa.[78]

Leonetti and colleagues[79] looked at different paths of invasion of temporal bone tumors. They identified that tumors grow superiorly through the tegmen, anteriorly through the glenoid fossa and infratemporal space, inferiorly through the hypotympanum and jugular foramen, posteriorly into the mastoid, and medially through the carotid canal and inner ear. They noted that anterior and inferior spread is accurately assessed by CT scan and MRI; however, they found that there was underestimation of disease when disease involved mastoid and middle ear mucosa, the tegmen tympani, the middle fossa dural, or the carotid canal. Local recurrences were found in these four areas on retrospective review.[79]

STAGING

External Ear

The staging of cutaneous carcinomas (excluding carcinoma of the eyelid and melanomas) has been updated, and this marks a departure from previous staging schemes. Although the external ear does not have a unique staging system, it is considered a high-risk factor in the 2010 AJCC TNM staging for cutaneous malignancy (**Table 23.4**).[51] This staging system takes into account the high-risk features of depth of invasion, perineural invasion, and histologic differentiation. Two centimeters (2 cm) continues to be an important demarcation for staging. An external ear cancer with two or more high-risk features is considered T2 regardless of size. An external ear cancer that invades the temporal bone is considered T3. Perineural invasion of the skull base (e.g., facial or trigeminal nerve) is considered T4.

Table 23.4 TNM Staging for Cutaneous Carcinomas

Primary Tumor (T)	
TX	Primary tumor cannot be assessed.
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤2 cm in greatest dimension with <2 high-risk features[a]
T2	Tumor >2 cm in greatest dimension OR Tumor any size with ≥2 high-risk features[a]
T3	Tumor with invasion of maxilla, mandible, orbit, or temporal bone
T4	Tumor with invasion of skeleton or perineural invasion of skull base
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No regional lymph node metastases
N1	Metastasis in a single ipsilateral lymph node, ≤3 cm in greatest dimension
N2	Metastasis in a single ipsilateral lymph node, >3 cm but ≤6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node, >3 cm but ≤6 cm in greatest dimension
N2b	Metastases in multiple ipsilateral lymph nodes, ≤6 cm in greatest dimension
N2c	Metastases in bilateral or contralateral lymph nodes, ≤6 cm in greatest dimension
N3	Metastasis in a lymph node, >6 cm in greatest dimension
Distant Metastasis (M)	
M0	No distant metastases
M1	Distant metastases

[a]High-risk features for T stage: (1) depth/invasion >2 mm thickness (Breslow thickness), Clark level ≥ IV, or positive perineural invasion, (2) poorly differentiated or undifferentiated, or (3) anatomic location of the ear.Used with the permission of the American Joint Committee on Cancer (AJCC), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Manual, Seventh Edition (2010) published by Springer Science and Business Media LLC, www.springer.com.

Temporal Bone

There is not an AJCC-approved staging system for temporal bone cancers. Several staging systems have been proposed.[22,80–83] The first iteration of the University of Pittsburgh Staging System was proposed by Arriaga and colleagues[81] in 1990 and was modified more recently by Moody and colleagues[19] (**Table 23.5**). This staging system provides a comprehensive means of assessing these tumors, and the Pittsburgh T stage has been shown to predict overall survival.[25,66,75] The presence of facial paralysis is an important change in the current system of staging when compared to the original iteration.[84]

Table 23.5 Modified Pittsburgh Staging System[19] for Squamous Cell Carcinoma of the Temporal Bone

T Classification	Description
T1	Limited to the EAC without bony erosion or evidence of soft tissue involvement
T2	Limited to the EAC with bone erosion (not full thickness) or limited soft tissue involvement (<0.5 cm)
T3	Erosion through the osseous EAC (full thickness) with limited soft tissue involvement (<0.5 cm) or tumor involvement in the middle ear and/or mastoid
T4	Erosion of the cochlea, petrous apex, medial wall of the middle ear, carotid canal, jugular foramen, or dura; with extensive soft tissue involvement (>0.5 cm, such as involvement of the TMJ or styloid process); or evidence of facial paresis
N Classification	
N0	No regional nodes involved
N1	Single metastatic regional node <3 cm in size
N2	
N2a	Single ipsilateral metastatic node 3–6 cm in size
N2b	Multiple ipsilateral metastatic lymph nodes
N2c	Contralateral metastatic lymph node
N3	Metastatic lymph node >6 cm in size
Overall Stage	
I	T1N0
II	T2N0
III	T3N0
IV	T4N0 and T1-4N+

EAC, external auditory canal; TMJ, temporomandibular joint; N+, any positive lymph node.

Given that cervical lymphadenopathy carries a poor prognosis, overall staging for temporal bone tumors is slightly different than staging for other head and neck tumor sites. T1N0 tumors are stage 1, T2N0 tumors are stage 2, and T3N0 tumors are stage 3. However, stage 4 tumors include T4N0 and any T with N+ status.[81]

RISK FACTORS FOR NODAL METASTASIS IN EXTERNAL EAR CANCERS

Many authors have struggled to identify risk factors for nodal metastasis in order to determine which patients will need parotidectomy and/or elective neck dissection:

- Location on or around the external ear as an independent risk factor for metastatic spread.[9,15,85,86] The metastasis rate for the external ear was 11.0% versus 5.2% for sun-exposed skin.[86]
- Horizontal size.[85–88] TNM staging uses 2 cm to separate T1 from T2 lesions. The NCCN guidelines consider any ear tumor ≥6 mm in size to be a high-risk lesion for recurrence and metastasis.[50]
- Tumor thickness, more than 4 mm.[40,85,86,89] In a prospective study of 615 patients with cutaneous SCC, nodal metastasis occurred in 4% of patients with tumors 2.1 to 6.0 mm in thickness and in 6% of patients with tumors thicker than 6.0 mm.[85] Another study of 509 patients found that a tumor thickness of 5 mm is an important determinant of lymph node metastasis. Nodal metastasis was found in 2.9% of patients with lesion thickness ≤5 mm and was 17.5% when tumor thickness was >5 mm. Their mean follow-up was 5.3 years.[90]
- Depth of invasion. Tumors that reach Clark level V had a metastatic rate of 30.6%, whereas tumors that reach Clark level IV had only a 10% rate.[15] A more recent study found that patients with nodal metastasis were significantly more likely to have invasion beyond Clark III.[88] Furthermore, invasion beyond subcutaneous tissues has been found to be an independent indicator of outcome.[87]
- Degree of differentiation.[88,90,91] SCC lesions of poor histologic differentiation have double the local recurrence rate and triple the metastatic rate of those lesion that are well differentiated.[86] Others have also been unable to make a correlation.[15,47,85]
- Immunosuppression. In the setting of organ transplantation, immunosuppression has been linked with development of nonmelanoma skin cancers, especially SCC.[85,92] Although immunosuppressed patients may only account for 5% of the cutaneous SCC population,[40] the overall risk to these patients of developing a malignancy is high. By one estimate, the chance of a patient developing one cutaneous malignancy post renal transplant is 66% within 24 years.[93] In a series of 68 organ transplant patients with metastatic skin cancer (85% SCC), the median primary size was only 12 mm, the median depth of invasion was only 3.2 mm, and the 3-year disease-specific survival was only 56%, thus indicating a lower threshold for metastatic spread and worse prognosis in this clinical setting. [94]

- Perineural invasion.[88,95–97] Perineural invasion is found in 5% to 10% of tumors and is associated with a higher incidence of nodal metastasis.[40,88,95] Goepfert et al.[96] reported a significant increase in both nodal (35% vs. 15%) and distant (15% vs. 3.3%) metastasis for patients with perineural invasion versus those without.
- Lymphovascular invasion. Lymphovascular invasion was found in 40% of patients with nodal metastasis versus 8% of patients without nodal metastasis.[98]
- Other features: cartilage or bone invasion[7,15]

INCIDENCE OF LYMPH NODE METASTASIS

External Ear

The overall incidence of lymph node metastasis from SCC is 2% to 4%.[6,46,85] Lymph node metastasis is a significant prognostic marker for any skin cancer. In the United States, 2,500 patients die annually from advanced skin cancer, usually developing metastatic lymph nodes during their clinical course.[99]

Whereas cutaneous SCC from other body areas has a low rate of metastatic spread to regional lymph nodes (range 0.5% to 2%),[44,45] SCC from the outer ear has a much higher rate, ranging from 10% to 16%.[8,15,47,63] In a meta-analysis, the incidence of lymph node metastasis to the parotid and upper cervical chain for SCC was found to be 11.2%.[61]

The rate of metastatic spread from auricular melanoma is even higher, perhaps as high as 40%.[100] Byers et al.[54] noted an overall incidence of clinically positive nodes in 42 of 102 patients with melanoma of the outer ear.

A systematic data review found that lymph node metastasis occurred in 85% of patients within the first 12 months and in 98% of patients within the first 24 months of diagnosis.[12,61,101]

The lymphatics of the outer ear drain to preauricular, postauricular, parotid, and upper cervical lymph nodes.[8,11,102] The parotid and upper jugular

nodes are the most frequent site of involvement.[47,54,61,102] Turner et al.[12] noted that 70% of their patients had parotid involvement, 30% had cervical node involvement, and 14% had both. The most common site of lymph node involvement is levels II and III.[12] Suboccipital nodes have not been found involved.[8]

Temporal Bone

The incidence of lymph node metastasis has been considered to be low in temporal bone cancers. This perception is probably related to the small numbers of tumors seen and the wide variety of histologic tumor types, some which are known to metastasize and others which usually do not metastasize. In a literature review examining 18 papers and covering nearly 500 patients with SCC of the ear canal and temporal bone, the mean incidence of lymph node metastasis was 17.7%.[103]

The first echelon of lymphatic drainage for SCC of the ear canal and temporal bone is to level II and to intraparotid nodes.[56,66,104]

TREATMENT—SURGERY

Surgical Margins

Consistent with all head and neck tumors, negative surgical margins are consistently associated with superior disease-free and overall survival.[105] Incompletely excised tumors are at high risk for local recurrence and neck metastasis.[86,106] The rate of incomplete excision of SCC from the external ear is higher than all other skin sites (20.5% vs. 4.8%, $p = 0.001$).[107,108] As a result, the recommendation was for an excision margin of 5 mm where feasible.

In a prospective study of BCC, Wolf and Zitelli[109] found that 4-mm margins were needed to eradicate 95% of BCC that are <2 cm in diameter. Thomas et al.,[106] using a Mohs surgical technique, recommend a 4-mm margin for nonmelanoma skin cancers up to 20 mm wide. Similar support is found for both BCC and SCC.[109]

The National Comprehensive Cancer Network of America 2014 guideline

recommends a 4- to 6-mm surgical margin for SCC.[49,50]

Margins for melanomas have also been studied. Narayan and Ariyan[110] did not observe any recurrences for patients with 1-cm negative margins. Pockaj et al.[111] reported that 80% of recurrences occurred in patients with a margin <1 cm. Most authors recommend a 1-cm margin for invasive ear melanoma.[110,112]

SURGICAL TECHNIQUES

External Ear Cancers

- Cryosurgery, curettage, and electrodesiccation[113–115]

This technique has been reported to be useful in previously untreated, nodular lesions. The tumor is electrodesiccated and removed with a curet. The curet allows the surgeon to distinguish between tumor and normal skin.[109] Recurrence rates for favorable BCCs are generally low, but repeated treatments might be required.[115] This treatment is not appropriate for tumors that are large, infiltrating, fibrosing, or recurrent. The ear has been identified as a high-risk area for recurrence when treated by electrodessication.[116]

- Mohs micrographic surgery (MMS)

For SCC, MMS has been shown to be effective in complete excision and superior in local tissue conservation.[117] In a cosmetically prominent area, such as the external ear, conservation of local tissue is important. Multiple studies have shown low recurrence rates with this technique, usually <5%.[5,18,86,118–121] Primary wound closure, split-thickness skin grafts, healing by secondary intention, and local flaps have all been described as useful in reconstructing the resulting defect.[117,122]

- Wide local excision and their reconstructions[8,47,123]

The goal of surgical excision is complete tumor removal with minimal cosmetic deformity. Because most tumors occur on the helix, simple wedge

excision with primary closure can be achieved with good cosmetic results. Tumors of the conchal bowl can be excised and the site reconstructed with a skin graft. Local flaps can be employed in reconstructing helical, scapha, conchal bowl and lobule cancers. Several articles have described these techniques.[117,123–142]

- Total auriculectomy

Total auriculectomy is needed only for tumors that occupy most of the pinna. In this circumstance, the tumor almost always extends into the ear canal, and complete excision will require an LTBR with parotidectomy and neck dissection. Leaving the ear canal intact, while excising all of the external ear cartilage, risks canal stenosis and trapping of debris, precipitating chronic otorrhea. This situation is compounded when postoperative radiotherapy (PORT) is given.

Temporal Bone Cancer

Whereas single-modality radiotherapy has been reported as treatment for temporal bone tumors,[143–145] surgical resection has been considered the standard of care.[75] Surgical management of these tumors is predicated on and tailored to the extent of disease. The goal of surgery is to extirpate disease, achieving a negative margin, while minimizing morbidity or mortality.

- Local canal excision

Small, early-staged tumors that are confined to the cartilaginous outer ear canal can be managed with a wide local excision[56]. This situation occasionally arises in the case of a tragal-based or conchal-based tumor that extends into the membranous ear canal. This procedure is usually performed under general anesthesia using the operative microscope. An endaural incision helps with visualizing tumor extent. Skin and underlying cartilage are excised using frozen section pathology for margin evaluation. Reconstruction is performed with a split-thickness skin graft.

The skin of the bony ear canal is thin and achieving a negative deep margin is difficult once the tumor reaches the bony ear canal. If the medial (or bony canal) extent of the tumor cannot be cleared, then the procedure

should be converted to an LTBR. Anecdotally, surgeons have tried to remove the skin from the bony ear canal, the so-called sleeve resection, reconstructed the defect with a split-thickness skin graft, and used radiotherapy as a salvage therapy. This situation usually develops into a narrow ear canal with exposed bone and chronic drainage and ultimately can lead to osteoradionecrosis of the temporal bone. LTBR provides better tumor control and overall survival for these patients.[58]

- Lateral Temporal Bone Resection

The real workhorse of otologic oncologic surgery is the LTBR. This procedure removes the bony canal en bloc lateral to the facial nerve. The goal of LTBR is en bloc resection of tumors involving the external auditory canal without tumor spillage. The strategy to achieve this goal is bony dissection to free the external canal. Details of this procedure have been previously published.[146] The specimen includes the tympanic membrane, malleus, and incus. The stapes, facial nerve, and inner ear structures are preserved. The amount of cartilaginous ear canal and pinna resected depends on the tumor extent in these structures. LTBR can be combined with parotidectomy, neck dissection, mandibulectomy, and craniotomy. Reconstruction technique will depend on the defect and is influenced by previous irradiation.

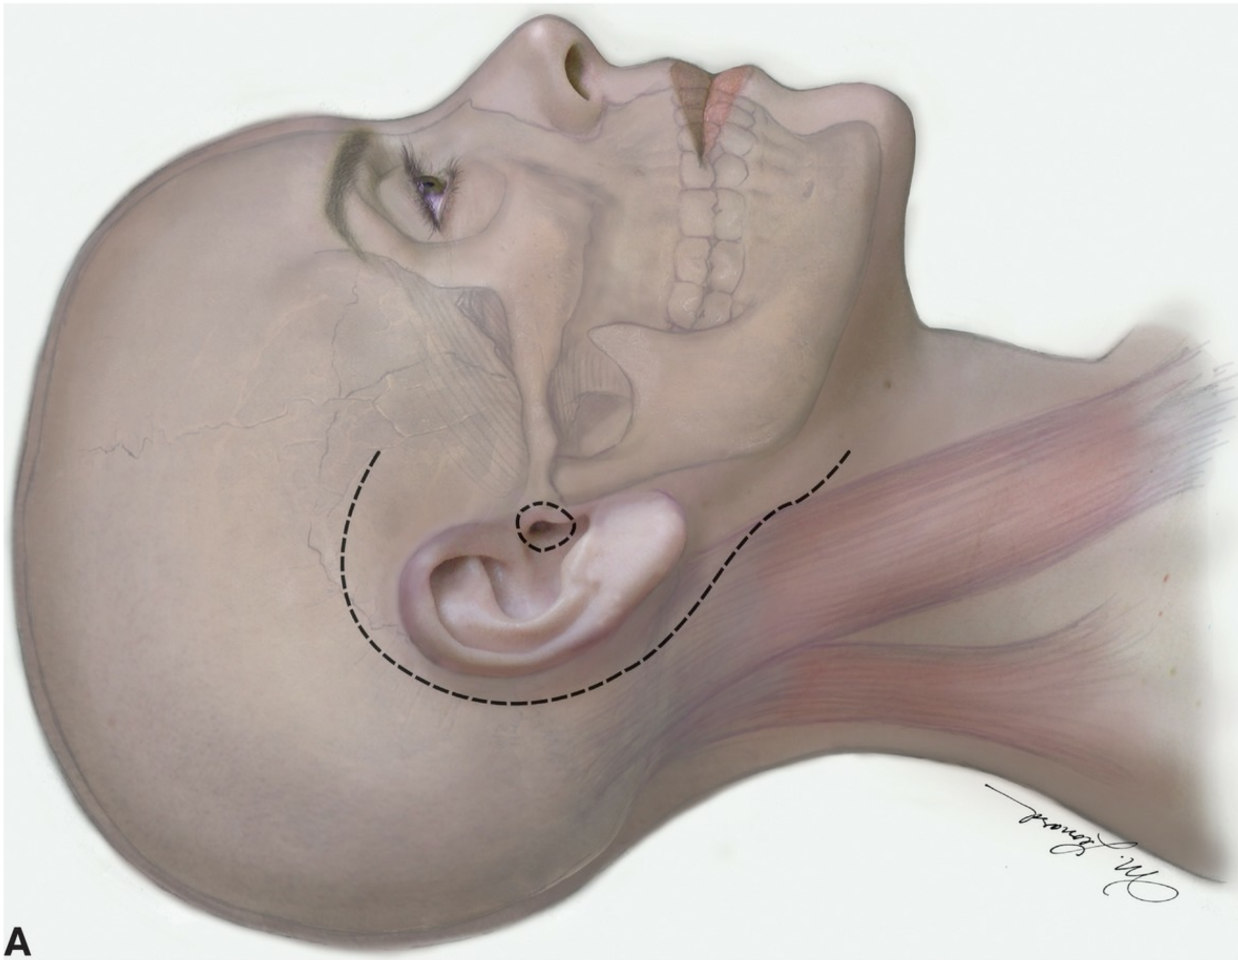
General Considerations

LTBR with parotidectomy, neck dissection, and possible microvascular free flap reconstruction usually requires 8 to 12 hours of general anesthesia. The patient’s general health must allow such a surgical procedure. Intraoperative facial nerve monitoring is always used, and this fact must be communicated to the anesthetist to avoid use of long-term paralytics. Antithromboembolism techniques, TED hose and sequential compression devices, are also used.

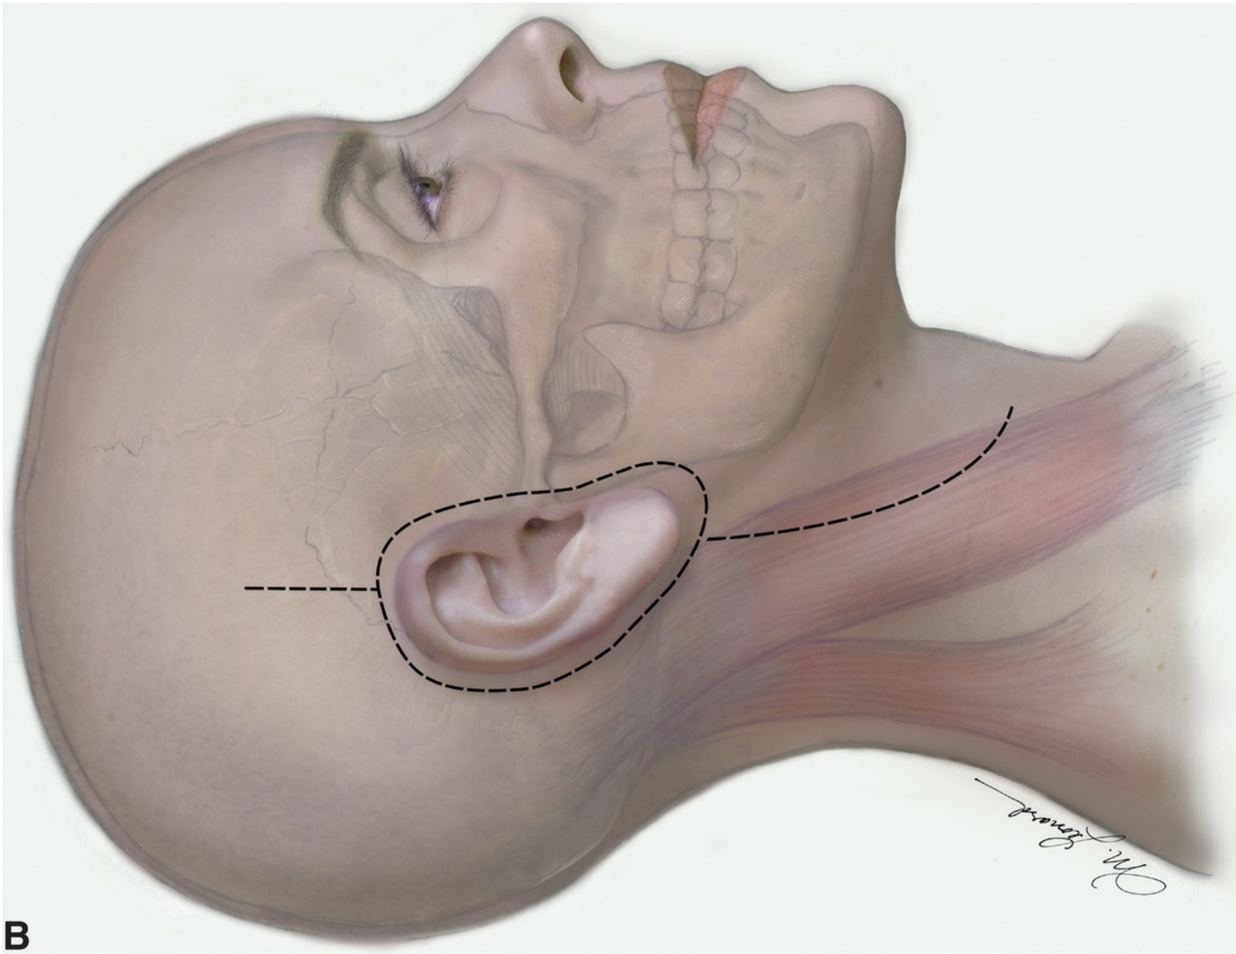
Skin Incision

The surgeon has a choice of incisions for temporal bone resection. This decision is based on location of tumor; the need for auriculectomy, parotidectomy, and/or neck dissection; previous incisions; and the need for craniotomy. A large postauricular C-shaped incision is perhaps the most versatile incision and is utilized when the auricle is normal (**Fig. 23.9A**).[146]

The external auditory meatus is cut lateral to the tumor. The auricle can be elevated with a wide anteriorly based skin flap. This incision gives access for parotidectomy, neck dissection, craniotomy, and temporalis muscle flap.



A



B

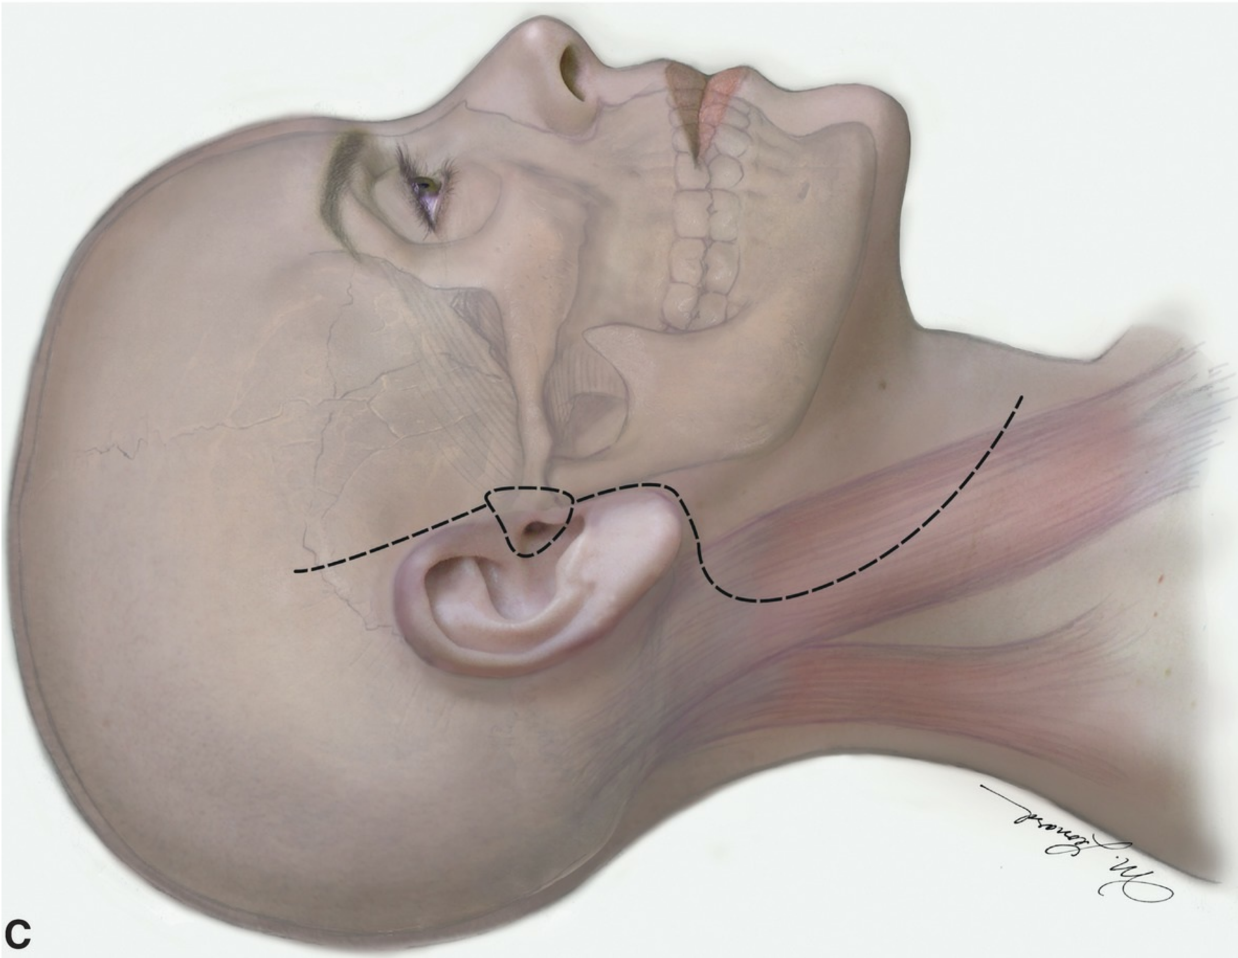


Figure 23.9. Incisions for LTBR. **A:**C-shaped postauricular incision. **B:** Total auriculectomy incision. **C:** Preauricular incision with canal ellipse. (From Gidley PW. Lateral and subtotal temporal bone resection. In: Cohen JI, Clayman GL, eds. *Atlas of Head and Neck Surgery*. Philadelphia, PA: Elsevier Saunders; 2011:438–449, with permission.)

When auriculectomy is required, an incision that circumscribes the tumor and auricle is used (Fig. 23.9B). Surrounding skin can be undermined giving enough exposure for LTBR, parotidectomy, and neck dissection. Limited middle fossa craniectomy can be performed through this approach. This situation produces the largest soft tissue defect and generally requires microvascular free flap for closure.

When the tumor is confined to the ear canal, a modified parotidectomy incision can be combined with an elliptical incision around the external meatus (Fig. 23.9C). This incision is especially advantageous in the circumstance of recurrent disease following previous parotidectomy or

radiotherapy. The incision can be extended anterior to the helix and superiorly into the temporal scalp. The remaining pinna is elevated with a broad posteriorly based skin flap. This incision is probably best for T1 and T2 ear canal cancers and parotid-based tumors that involve the ear canal. Parotidectomy and neck dissection are performed, and reconstruction can be with either a temporalis muscle flap or microvascular free flap. The posteriorly based skin flap containing the pinna has some disadvantages: (1) the pinna is folded or retracted, which could compromise its blood supply and (2) the temporal bone surgeon has to work over the flap containing the pinna.

Bony Dissection

Following skin incisions, a complete mastoidectomy is performed. The tegmen is thinned and used as a guide to judge the level of the middle fossa dura. The antrum is opened, the attic is widened, and the incus and malleus head are identified. The horizontal semicircular canal is preserved throughout this dissection.

Bone at the root of the zygoma is removed, and the temporomandibular joint is identified at its lateral bony margin. Drilling continues through zygomatic air cells, working between the bony ear canal and tegmen and staying lateral to the ossicular chain. Care is taken to avoid a dural tear and to avoid violating the external ear canal bone and spilling tumor into the operative field. The entire TMJ capsule is exposed from medial to lateral.

The facial recess is opened, and the middle ear is checked for disease. (If disease is found in the middle ear, the surgical procedure will need to expand beyond an LTBR.) The facial nerve is identified at its tympanic segment and followed through its mastoid course to the stylomastoid foramen. The digastric ridge is drilled away to identify the underlying digastric muscle. A cut is made in the anterior wall of the mastoid tip, lateral to the facial nerve and inferior to the tympanic ring. This maneuver liberates the mastoid tip, and its soft tissue attachments are cut with electrocautery. Removal of the mastoid tip unifies the mastoid with the neck, and it allows the facial nerve to be traced from the mastoid into the parotid gland.

The facial recess is then extended and the chorda tympani nerve is divided. The annulus is identified, and drilling continues between the annulus and the facial nerve until the hypotympanum is reached. The inferior

tympanic bone is removed, and the soft tissue anterior to the tympanic ring is identified. In making the inferior final cut, care must be exercised to avoid having the shaft of the drill rest on the facial nerve. Only prudent surgical technique can avoid injury to the facial nerve here, because the facial nerve monitor will not alarm from thermal injury to the nerve.

The final bony cuts are made to free the anterior-inferior extent of the tympanic ring. Occasionally, the carotid artery is in contact with the annulus here. Vigilance is required to avoid injury to a laterally placed carotid artery.

The incus is disarticulated. Thumb pressure on the canal causes it to fracture anteriorly. A Freer elevator can be used to assure that the canal is entirely mobilized, but care must be taken to avoid using the facial canal or middle fossa dura as a fulcrum.

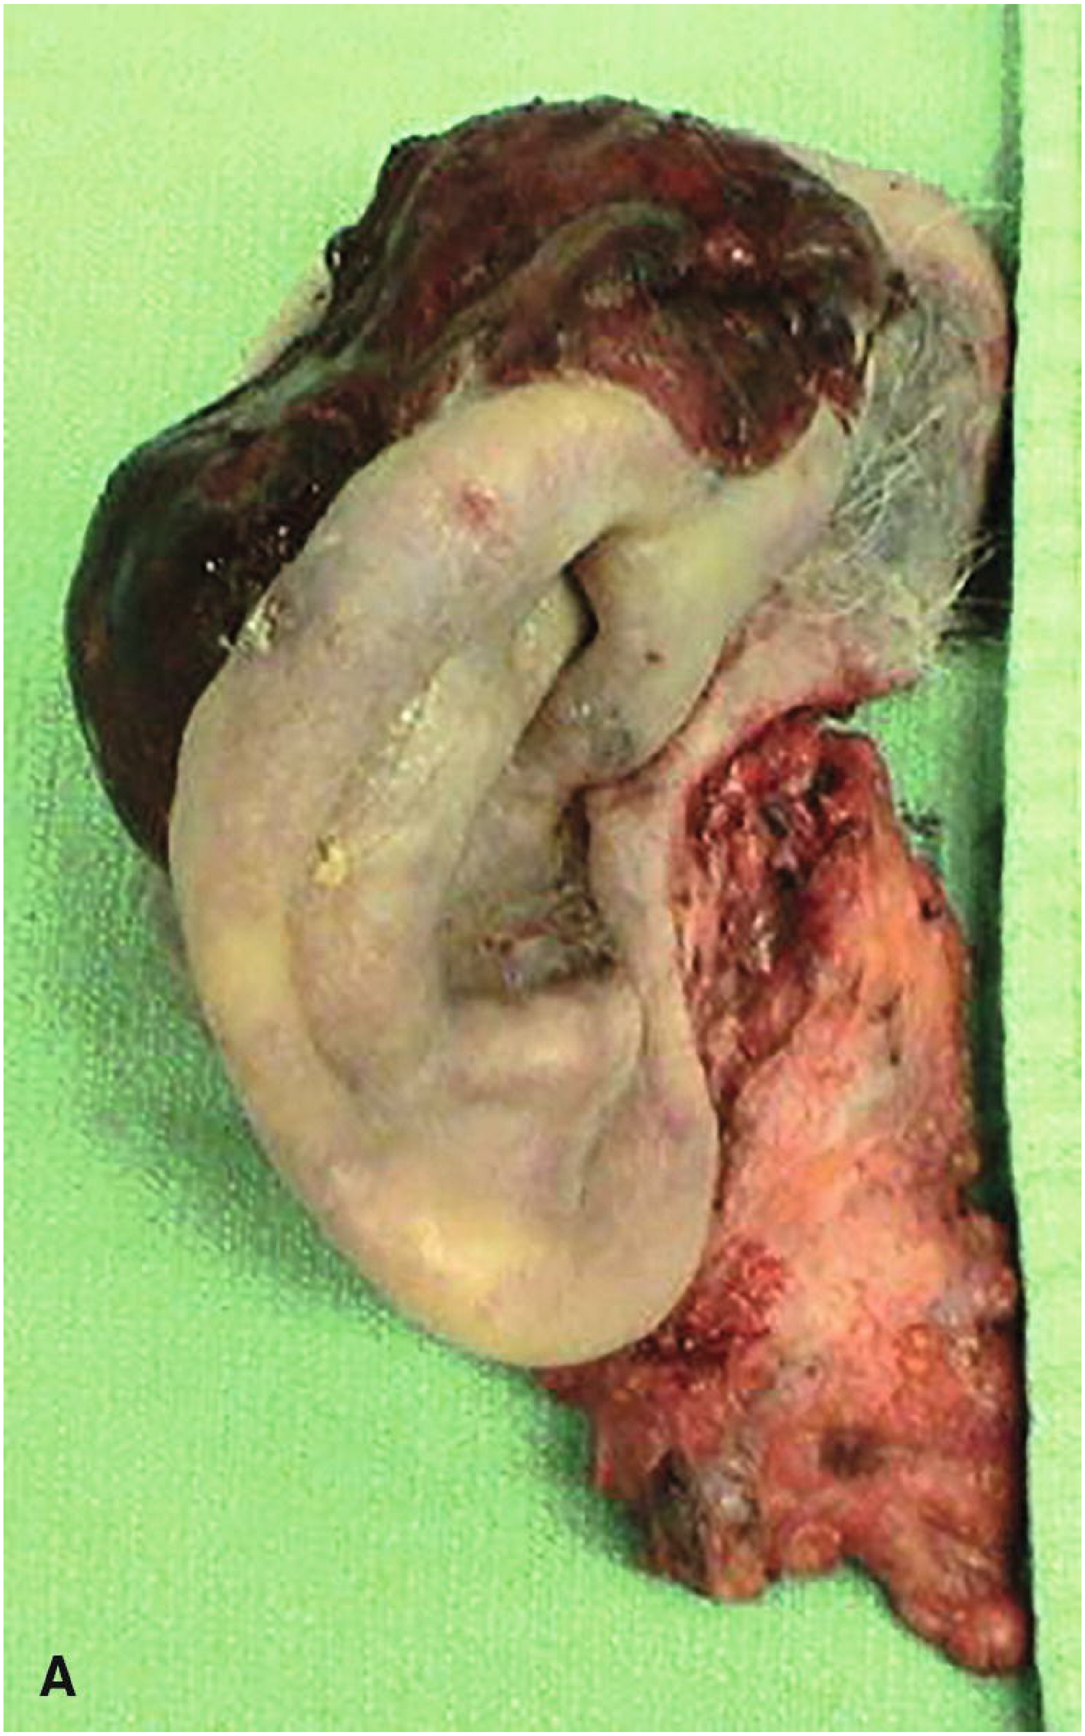
Facial Nerve Management

The mastoid segment of the facial nerve can be decompressed, and the nerve traced into the parotid gland to aid in parotidectomy. The facial nerve can be assessed for perineural disease. Perineural disease can produce a nerve that is thicker and redder than usual. If the patient has normal facial function preoperatively, then efforts should be made to preserve this function. If the patient has pre-existing facial paralysis and facial nerve sacrifice is planned, then the nerve can be divided and the proximal end sent for frozen section evaluation. A tumor-free margin should be sought; however, a labyrinthectomy is not performed for the sole reason of trying to achieve a negative facial nerve margin. Our philosophy has been to treat this remaining microscopic disease with PORT. Successful facial nerve grafting and reasonable survival can be achieved even when microscopic disease remains in the proximal segment of the facial nerve.[147]

If nerve sacrifice is required and if usable proximal and distal segments are available, then an attempt should be made at facial nerve grafting.[148,149] The great auricular nerve is a reasonable choice for short defects; however, the facial nerve defects that result from LTBR and parotidectomy are usually too long to be grafted with the great auricular nerve. The cutaneous branch of the anterior femoral nerve, which is in the field of the anterior lateral thigh flap, and the sural nerve are better options.[148]

Some tumors can be adequately treated with LTBR alone; however, the

majority of cases will require concomitant parotidectomy and upper neck dissection (levels II and III). These procedures commence following LTBR. Large auricular cancers and large parotid tumors can be resected en bloc along with the ear canal. This surgery creates a “composite resection” that includes the external ear, ear canal, parotid, and neck dissection and occasionally the upper mandible as one single specimen (**Fig. 23.10**).



A

B

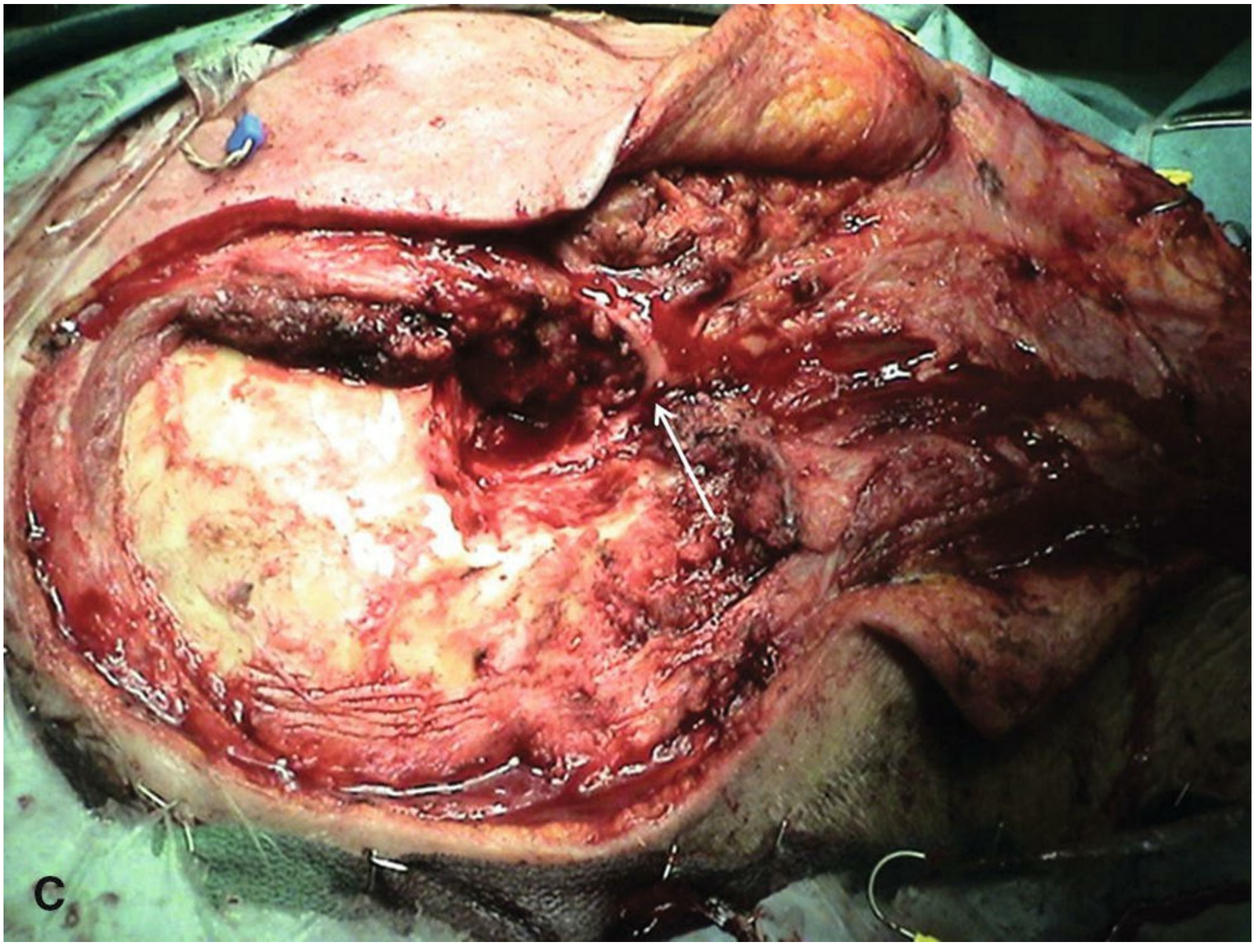


Figure 23.10. A: Large auricular cancer removed as a composite resection including auricle, ear canal, parotid, and neck dissection. **B:** Undersurface of defect shows intact ear canal and TM. **C:** Defect shows intact facial nerve (*white arrow*) and was reconstructed with an anterior lateral thigh microvascular flap. (Used with permission, University of Texas MD Anderson Cancer Center, Department of Head and Neck Surgery.)

Reconstruction

Historically, surgeons reconstructed the lateral temporal bone defect by covering the cavity with a split-thickness skin graft.[150] This technique offered patients an option for hearing reconstruction. However, these cavities can develop serious, bothersome drainage and infection especially after radiotherapy. Furthermore, these patients tended to have poor hearing outcomes given the possible chronic infection and sensorineural hearing loss from radiotherapy.

More modern techniques of reconstruction emphasize closing off the cavity from the outside world. The type of reconstruction depends on several factors: size of defect, history of preoperative radiotherapy, vascular and dural coverage, and cosmesis. Small, uncomplicated defects can be reconstructed with temporalis muscle flap.[151] A split-thickness skin graft can be used to cover the flap and to close a small cutaneous defect. However, microvascular free flap reconstruction will be required in most circumstances especially in patients with large skin defects, previous radiotherapy, or when the dura or vascular structures need coverage.[149,152–154]

When facial nerve sacrifice has occurred, nerve grafting should be attempted.[154] Additionally, techniques for facial rehabilitation and eye protection should be considered at the time of the primary surgery. Gold weights, tarsorrhaphy, canthoplasty, brow lifts, and static slings each have a role to play. Oculoplastic surgeons are invaluable members of the team to help prevent or manage eye complications related to facial paralysis.

Osseointegrated implants offer patients an option for hearing restoration and for prosthesis fixation. Implants can be placed either at the time of primary surgery or at a time following completion of therapy. Loading can begin in 3 months in patients not treated with radiotherapy. However, 6 months are allowed to pass before using an implant in an irradiated field.

- Subtotal Temporal Bone Resection (STBR)

Tumors that extend into the middle ear will need surgery beyond the LTBR.[75,82] STBR extends the dissection into the labyrinth, the cochlea, or both. Oftentimes, LTBR is required as an initial first step to permit access to deeper structures.

Skin Incisions

These tumors tend to have their epicenter in the middle ear or mastoid and thus have limited ear canal involvement. A large C-shaped postauricular incision works well. Frozen section is used to confirm a negative ear canal margin, and the ear canal is oversewn.

Bony Dissection

LTBR is performed to remove the disease contained within the ear canal. This gives an unimpeded view of the middle ear, inner ear, and carotid–jugular triangle. Labyrinthectomy, jugular foramen dissection, and cochlectomy are performed as needed depending on disease extent. The eustachian tube mucosa can be involved, and the carotid artery often must be dissected and decompressed. Tumor dissection is performed in a piecemeal fashion. Tissue sampling for frozen section is used liberally to determine the full extent of disease.

The dura of either the posterior or middle fossa is often involved in these tumors. Dural resection is again directed by extent of disease, and frozen section is used to control the margin.

Facial Nerve Management

These patients generally present with facial nerve dysfunction, and these tumors generally involve the facial nerve in its mastoid or tympanic segments. Facial nerve sacrifice is required in this circumstance. Because labyrinthectomy is being performed, the facial nerve can be traced proximally and a tumor-free margin can be obtained. Occasionally, a low-grade tumor, such as an endolymphatic sac tumor or middle ear neuroendocrine tumor, can be adequately dissected away from the nerve and facial function preserved.

Reconstruction Techniques

These procedures generally do not produce large cutaneous defects, but reconstruction is complicated by the presence of a dural defect and the potential for cerebrospinal fluid (CSF) leak. A watertight dural repair should be attempted using allograft duraplasty, but this can be impossible for some defects. Overlay temporalis fascia and abdominal fat graft, as is used in acoustic neuroma surgery, is another option for a small dural defect. Microvascular free flaps can be used, especially in the setting of prior radiotherapy.

- Total Temporal Bone Resection (TTBR)

Although en bloc TTBR has been reported,[155–158] our team does not use this technique. Carotid resection is common to en bloc TTBR, and this carries with it a high morbidity. Our philosophy has been to avoid carotid artery

resection for malignant disease because it produces significant morbidity and does not carry an improvement in overall disease-free survival.

TTBR extends the dissection as described above for STBR and includes removal of the internal auditory canal and petrous apex. Disease removal is piecemeal and directed by frozen section pathology.[75] Reconstruction considerations are similar to those described for STBR.

THE ROLE OF PAROTIDECTOMY AND NECK DISSECTION

External Ear

A persistent controversy in the discussion of SCC of the external ear is the role of parotidectomy and neck dissection. The parotid gland contains lymph nodes that can be the first echelon in metastatic spread from an external ear site. "Currently there is no evidence-based data that supports a mandatory elective parotidectomy in the context of a clinically N0 parotid gland."[11] In the past, authors have surmised that the parotid involvement is low, and therefore, parotidectomy was unwarranted unless clinically involved.[62] Clearly, this discussion revolves around the risk–benefit analysis. The benefits are adequate staging of disease and the potential for durable, recurrence-free survival, whereas the alternative of recurrence following multimodality therapy has a dismal prognosis.

The risks of parotidectomy are well known: facial nerve injury, cosmetic deformity, and Frey syndrome.[159] The incidence of temporary facial paralysis in this setting ranges from 5% to 43%, whereas permanent paralysis is usually <3%.[11,98,160–168]

Osborne et al. studied clinically advanced nonmelanomatous auricular carcinomas. Eleven of these patients had large SCC of the auricle requiring total auriculectomy for excision; 53% of these were recurrent tumors. Clinically and radiographically, these patients all had N0 necks. All underwent elective parotidectomy. Pathologically, none of these patients had metastatic disease. Therefore, the authors concluded that parotidectomy may not be necessary for advanced outer ear cancer when the parotid or external

ear canal is not clinically involved.[11] However, parotid involvement has been found in up to 70% of external ear SCC patients when cervical lymphadenopathy is present.[12]

For the patient with clinically involved parotid gland, cervical lymphadenectomy should be performed because a significant proportion of these clinically N0 necks will harbor occult metastatic disease (30% to 42%).[12,98,169] Selective node dissection, levels II and III, will usually encompass these nodes.[98] In patients with far advanced disease (stages III and IV), a more comprehensive neck dissection is recommended to include even level V lymph nodes.[170]

As a principle, a working facial nerve should be spared unless overtly, macroscopically involved with tumor.[12] Progressive facial palsy, especially isolated branch deficits, in the setting of past skin cancer excision should be viewed with suspicion. This patient will most likely have perineural spread along the facial nerve, producing this deficit. Occasionally, cancer from the sideburn area can travel along the auriculotemporal nerve and can involve both the facial and the trigeminal nerve (see Fig. 23.8).[171]

Rates of facial nerve sacrifice are difficult to compare. Byers et al.[8] noted that 46 out of 486 patients required facial nerve sacrifice. In patients with aggressive cutaneous SCC, facial nerve preservation might be possible in approximately 70% of patients, leaving 30% of patient requiring nerve sacrifice.[98] For the majority of patients, superficial parotidectomy with preservation of the facial nerve will be sufficient to manage suspected metastatic disease within the parotid.[98] Radical parotidectomy with facial nerve sacrifice is indicated for macroscopic nerve involvement or preoperative facial nerve dysfunction.

The role of neck dissection in the clinical N0 neck is a topic of discussion affecting a broad range of tumor types and locations found in the head and neck. Previously, a 20% rate of occult neck metastasis was used as a justification for neck dissection.[172] More recently, the rate to justify neck dissection has been lowered to 15%.[173] Using selective neck dissection rather than radical neck dissection avoids many of complications of radical neck dissection and allows for a lowering of the necessary metastatic rate threshold. Furthermore, neck dissection in the setting of the N0 neck allows for proper staging and for defining the role of adjuvant therapy.[174,175] For

external ear cancers with clinically positive parotid disease, a modified neck dissection including levels II and III is recommended for staging followed by radiation depending on pathologic findings.[175,176]

In the report by Byers et al.,[8] the indication for elective neck dissection required the constellation of initial ear cancer, histologically poorly differentiated tumor, and lesion over 3 cm. His recommendation was for a comprehensive supraomohyoid neck dissection, sparing the spinal accessory nerve, jugular vein, and sternocleidomastoid muscle.

Rowe et al.[86] reported a 45% incidence of nodal metastasis in patients with recurrent skin SCC. In a meta-analysis of 11 articles covering 526 patients with SCC of the ear, an overall rate of metastatic spread to the parotid and upper cervical chain was found in 11.2% of patients.[61]

Regardless, cervical lymphadenectomy is indicated for palpable neck disease and should be considered for patients with recurrent tumors. In this setting, parotidectomy should also be performed. The dictum first promulgated by Byers et al.[8] is that neck dissection should never be performed without parotidectomy in the setting of SCC of the outer ear, and this dictum has been reiterated by others.[9] Other proponents of neck dissection for the N0 neck are found in the literature.[7,9,15,90,97,98,162,169,177]

The role of elective neck dissection for melanoma is perhaps even more controversial. Four large prospective, randomized trials have been performed for cutaneous melanoma and have failed to demonstrate a survival benefit for elective lymphadenectomy.[178–181] In a retrospective review, Byers et al.[54] did not observe a survival difference between elective and salvage neck dissection in melanoma.

Role of Sentinel Lymph Node Biopsy for External Ear Cancers

The role of sentinel lymph node biopsy (SLNB) has yet to be defined for auricular cancers. The rationale for SLNB is to identify potential lymph nodes for sampling in the clinically N0 neck. SLNB has been shown to be effective at determining the rate of occult malignancies in melanoma and some head and neck SCCs.[65,88,92,101,111,182–193]

Cole et al. used SLNB in 9 of 19 patients with auricular melanoma. The

criteria for SLNB in their patient population are not stated, though patients who did have SNLB had thicker lesions (2.30 mm vs. 0.81 mm).[65]

Pockaj et al. reported that 10 of their 78 patients underwent SLNB. All 10 had negative lymph node biopsies, and all 10 remain free of recurrence with a median follow-up of 38 months.[111] They consider SLNB as a highly successful and low-morbidity alternative to elective neck dissection.

Pathak et al.[184] studied lymphatic metastasis from head and neck melanomas. Their study of 169 patients included 20 patients with melanoma of the ear. They found a 100% correlation between the predicted site of involvement and the clinical site of metastatic disease for the primary site, namely, the parotid and cervical lymph node levels 1 through 5. This finding countered a reported 34% discordancy of lymphoscintigraphic positive nodes versus clinically suspected lymph nodes. They further point out that no ear or periauricular melanomas involved postauricular lymph nodes, although lymphoscintigraphic studies showed that postauricular nodes were involved 12% of the time.[194]

Carlson et al. studied SLNB in 58 cases of head and neck melanoma, of which 8 arose from an external ear primary site. Their study demonstrated that lymphatic drainage in these cases was to either parotid or anterior neck nodes and not to posterior neck nodes.[187]

Shpitzer et al.[191] studied SLNB in 15 patients with melanoma of the helix of the ear. Tumor thickness varied from 0.70 to 10 mm (mean 1.2 mm and median 2.13 mm). Sentinel lymph nodes were found in level IIA in 13 of the 15 patients (87%). Four patients (27%) had a sentinel lymph node in the parotid gland. No lymph nodes were found in the retroauricular region. All lymph nodes examined were tumor negative. All patients remained tumor free during a short follow-up (median 39 months, range 12 to 73 months).[191]

Temporal Bone

The parotid gland can be involved either by direct extension through the fissures of Santorini or by metastatic spread to intraparotid lymph nodes.[56,58,195] Morris et al.[56] described a series of 72 patients with temporal bone cancer in whom 36% of patients had direct tumor invasion into the parotid and 25% had metastatic intraparotid lymph nodes. Gidley et al.[26]

found that about 11% of their series of 157 temporal bone cancer patients had salivary gland invasion. For these reasons, superficial parotidectomy, at a minimum, should be performed with LTBR.

Primary tumors of the ear canal, middle ear, and mastoid rarely (around 10%) present with cervical lymphadenopathy.[56,103,196,197] Levels II and III are most commonly involved.[26] Although overall nodal involvement is low, neck dissection and parotidectomy permit accurate tumor staging.[66,198] Neck dissection also facilitates vessel exposure when microvascular free flap reconstruction is needed.

Because the ear canal is more commonly involved by parotid primaries or periauricular skin cancers, parotidectomy and neck dissection are required to address the primary tumor.[199]

COMPLICATIONS OF SURGERY

Temporal bone resection can be associated with high complication rates. All patients are counseled about the risks of surgery: hearing loss, tinnitus, dizziness, facial weakness or paralysis, loss of taste on the tongue, loss of the outer ear, CSF leak, and meningitis. Major complications, defined as requiring additional surgery or additional intensive medical therapy, have remained below 10%. CSF leak and meningitis occur at rates consistent with transtemporal skull base surgery. Pulmonary embolism, myocardial infarction, and death have been reported following temporal bone resection.[26,200] For these reasons, patients must be in good general health to be able to tolerate such surgery.

A maximal conductive hearing loss is the expected outcome of LTBR. This hearing loss can be overcome with an osseointegrated bone-conducting hearing aid. Single-sided deafness (SSD) will occur from STBR and TTBR. Osseointegrated bone-conducting hearing aid or a contralateral routing of sound (CROS) hearing aid is an option for hearing rehabilitation for these SSD patients.

Facial paralysis is a disappointing, but often unavoidable, outcome of temporal bone surgery. Rates of facial nerve sacrifice might be nearly 50% in the setting of advanced disease.[26] Plastic reconstructive surgeons and oculoplastic surgeons are invaluable in helping to manage facial paralysis, to

protect vision, and to restore cosmesis.

CONTRAINDICATIONS TO SURGERY

Surgery is not indicated for patients with unresectable disease, distant metastasis, or poor general health status. Tumors that encase the carotid or vertebral artery, that erode into the cervical spine, or that have significant brain invasion are not considered for surgical treatment. Although the use of carotid artery bypass has been reported for skull base cancers,[201] the long-term results for this technique are disappointing, yielding only a 20% 2-year survival and the attendant risks of postoperative stroke or death[202]. Our team has avoided such surgery and relied on palliative chemotherapy and radiotherapy for these patients.

Isolated and limited temporal lobe involvement can be resected.[157,203] Moffat et al.[204,205] have reported reasonable results following resection of temporal bone tumors with brain invasion. However, in our patient population, we have rarely found isolated brain invasion from temporal bone tumors that did not have concomitant carotid artery involvement or metastatic disease.[26]

TREATMENT—RADIOTHERAPY

Primary Radiotherapy

Radiotherapy has been used either as single-modality therapy or as adjuvant therapy in the postoperative setting. Most surgeons have elected to treat these external ear cancers surgically and to reserve radiotherapy for recurrences or locoregional failures.[8] Elective radiotherapy for external ear cancers lacks high-level supportive evidence.[40] Kwan et al.[206] reported higher rates of locoregional failure in patients with SCC not receiving radiotherapy than in those patients who did.

Primary radiotherapy was used to treat temporal bone cancers up to the 1970s[57,207,208]; however, this technique had a relatively low overall cure rate. Only a few papers have recently reviewed the role of radiotherapy as single-modality therapy.[144,197,209,210] Kang et al.[211] concluded that radiotherapy

alone was not inferior to combined surgery and radiotherapy for disease-specific survival, but they found that local control was worse when radiotherapy alone was used.

Adjuvant Radiotherapy for External Ear Cancers

The majority of patients will be successfully managed with wide local excision achieving negative margins. PORT should be considered for the patient with pathologic indicators: multiple positive lymph nodes (especially if extracapsular spread [ECS] is seen), perineural spread, involvement of named nerve, lymphovascular invasion, or positive or "close margins."[175,176] Byers et al.[8] employed PORT for only five patients and recommend its use when extensive local disease requiring resection of the temporomandibular joint, ascending ramus of the mandible, or temporal bone or total parotidectomy are required.

The role of radiotherapy for external ear cancer and the clinical N0 neck has not been suggested or reported, although there has been proven benefit for other diseases with suspected micrometastasis.[212,213]

However, there is ample evidence of improved locoregional control using PORT for external ear cancers when the indications listed above are present.[214–219] For a dissenting view for PORT, the reader is referred to Gal et al.[39]

Most recent publications suggest 60 Gy in 2 Gy daily fractions as an acceptable dose for PORT[98] and 50 Gy to the undissected neck.[92]

Adjuvant Radiotherapy for Temporal Bone Tumors

Radiotherapy plays a significant role as adjuvant therapy for temporal bone cancers or as treatment for patients who are not candidates for surgery. Advances in skull base techniques vaulted surgery into its current role as primary therapy, using radiotherapy as a postoperative adjuvant.[56,75,220] The combination of these two modalities has improved overall survival for temporal bone cancer patients.[35,153]

Currently, radiotherapy is recommended for T2 and higher-staged tumors.[66,205,209,221] Other indications for PORT include recurrent tumors, positive margins, perineural spread, positive lymph nodes, or extracapsular

spread.[153]

Intensity-modulated radiotherapy (IMRT) allows the radiation oncologist the ability to adequately treat the tumor site while minimizing dose to surrounding structures, especially the temporal lobe and brainstem. Dosages vary widely in the literature. Pfreundner et al.[222] recommended 54 to 60 Gy in patients with negative margins and a minimum of 66 Gy with positive margins. Prabhu et al.[223] gave doses between 60 and 66 Gy for patients with negative margins and doses between 68 and 72 Gy for patients with positive or close margins.

TREATMENT—CHEMOTHERAPY

Advancements in chemotherapeutic agents have ushered in a new era of treatment for head and neck tumors.[224–229] Data from these studies have been extrapolated from mucosal epithelial tumors of the head and neck to other sites. Only a few, isolated studies have examined the role of chemotherapy for temporal bone cancers.[230–232]

Nakagawa et al.[230] described a series of 25 patients with primary SCC of the ear canal and middle ear. Six patients (one patient—T2; three patients—T3; two patients—T4) received preoperative chemotherapy followed by surgery and radiotherapy. Five of these six patients achieved mean survival of 60 months. Chemotherapy and radiotherapy alone were used in seven patients with T4 disease; three of these seven patients had no evidence of disease at mean of 31.6 months.

In a pilot study, Shiga et al.[231] described a series of 14 patients with SCC of the temporal bone of whom 9 had stage IV disease and were treated with concomitant chemoradiotherapy. Their chemotherapy regimen included docetaxel, cisplatin, and 5-fluorouracil (so-called TPF). Eight of nine patients achieved complete response. The authors concluded that the use of concomitant chemotherapy with TPF was safe and effective as treatment for patients with cancer of the temporal bone.[231]

Intra-arterial chemotherapy has been proposed and tested in a very small number of patients. Sugimoto et al.[232] published a small series of five patients with T3 and T4 SCC of the temporal bone who were treated with radiotherapy and intra-arterial chemotherapy consisting of cisplatin and

thiosulfate. Three patients obtained a complete response and had mean survival of 28 months.

SURVIVAL AND RECURRENCE RATES

External Ear

The ear, anterior scalp, forehead, and temple are the most frequent sites of primary SCC in the head and neck.[92] Survival is dependent on locoregional control. Most patients with SCC who experience a relapse will have that relapse in the neck. Therefore, any treatment that improves locoregional control is likely to increase survival.

Neck recurrences develop in a delayed fashion. The median time to develop a nodal metastasis is approximately 12 months,[12] although some late recurrences (between 24 and 36 months) have been reported.[233,234] Recurrence rates for SCC of the ear are higher than are those for other sun-exposed skin sites. Rowe et al.[86] analyzed more than 220 articles and determined a local recurrence rate for ear SCC of 18.7% compared to 7.9% for other body areas. Neck recurrence rates are also higher for external ear (11.0%) than for other body sites (5.2%).[86]

Neck metastasis has a significant impact on overall survival. Byers et al.[8] noted that the 2- and 5-year survival of patients with SCC of the external ear and neck disease was 65% and 46%, respectively. If two or more nodes were found, then survival rates dropped to 57% and 14%, respectively.[8] Interestingly, they found high rates of ECS (93% of patients), although as a single variable for survival, ECS was not as significant as multiple node involvement.[8]

Recurrence following multimodality therapy is often regional (70% to 80%) and often incurable.[235] Recurrence rates in patients treated with multimodality therapy range from 10% to 38% in this setting.[12,92,98,235]

Survival for the patient with recurrent squamous cell cancer following multimodality therapy is poor. Overall survival is 65% at 2 years and 46% at 5 years.[7]

For patients with SCC, Byers et al.[8] could not correlate local or regional

failure or survival to patient age, gender, type of neck dissection, site of primary cancer, site of nodal metastases, or histologic findings. In his study, 6% of patients presented with N1 neck and another 6% of patients developed neck metastases within 24 months of treatment.[8]

Lymph node metastasis is associated with lower 3-year disease-free survival, disease-specific survival, and overall survival.[98] Published studies of external ear SCC is presented in **Table 23.6**.

Table 23.6 Compilation of Published Reports of SCC of the External Ear

Authors	Year	Total No. Patients	Median Age, Years (Range)	Parotid Metastasis Rate at Presentation	Neck Metastasis Rate at Presentation	Local Recurrence Rate	Regional Recurrence Rate	Distant Metastasis Rate	Overall Survival	Mean F/U, Months

Temporal Bone Cancer

Historically, temporal bone tumors were associated with dismal results and a poor prognosis.[236,237] However, advancements in multiplanar imaging, skull base surgical techniques, IMRT, and chemotherapy have combined to improve overall survival. A cogent staging system, as proposed initially by Arriaga et al.[81] and later modified by Moody et al.,[19] has allowed comparison of results across time and institutions. This later iteration of the Pittsburgh staging has demonstrated that survival is progressively worse with increasing T stage,[74] and this finding is supported by other papers.[66,197,238] The

Pittsburgh tumor staging is an important, independent factor for prognosis and a reliable predictor for outcomes for SCC.[66]

Small tumors that are limited to the ear canal with minimal soft tissue involvement or bone erosion (i.e., T1 and T2 tumors) can be completely excised with LTBR. Whereas T1 tumors can be treated with surgery alone, T2 tumors have improved outcomes when PORT is added.[66,209] These patients with early-stage disease enjoy 80% to 100% 5-year survival rates.[33,75,239,240]

Larger tumors (T3 and T4) involve significantly more anatomic structures and present a significantly more difficult tumor to treat. These tumors can be conceptualized in two varieties: external ear canal tumors that erode past the eardrum into the middle ear and tumors that arise primarily within the middle ear, inner ear, or mastoid. When tumors involve the middle ear, the LTBR is no longer an adequate or sufficient surgical treatment.[241] Multidisciplinary team management is required for these larger, advanced-staged tumors. These patients might require a combination of surgery, radiotherapy, and chemotherapy for treatment of their tumors. Treatment goals remain consistent despite the large size of the tumor: adequate disease resection to achieve negative margin while minimizing damage to surrounding normal structures. Despite adequate treatment, overall 5-year survival rates do not exceed 50% for this group of late-stage tumors (**Table 23.7**).

Table 23.7 Comparison of Recently Published Survival Results for Squamous Cell Carcinoma (SCC) of the Ear Canal and Temporal Bone

Authors (Year)	Total Patients (n)	T Stage* (n)	Mean FU (Months)	Overall 5-Year Survival (%)	Disease-specific Survival (%)	Disease-Free Survival (%)
Yin et al. (2006)[197]	95	NS	NS	66.8% (cohort) Stage I = 100% Stage II = 100% Stage III = 67.2% Stage IV = 29.5%	NS	NS

Only studies with 30 or more patients are included.

*Pittsburgh 2000 staging system[19] is used except where noted by † for Stell and McCormack staging system.[80]

Facial nerve involvement, positive lymph nodes, extratemporal disease extension, and positive surgical margins are all factors linked with poor overall survival.[26,30,33,56,197,238] A systematic review of SCC of the temporal bone showed that 5-year overall survival dropped to 19.1% in patients with facial paralysis versus 59.4% in patients without facial paralysis, regardless of tumor stage.[74]

Although lymph node metastases are uncommon, their presence is a significant risk factor for poor survival.[26] For patients with SCC, Morris et al.[56] reported that 5-year disease-specific survival (DSS) was 81% in node-negative patients and 19% in node-positive patients ($p < 0.0001$).

Margin status is a strong predictor for recurrence, and rates of positive margins vary between 20% and 33%.[26,33,56,66,197,238] Morris et al.[56] describe 5-year DSS of 81.7% for patients with negative margins versus 50.0% for patients with positive margins ($p = 0.03$, log rank).

Other factors that are linked to high recurrence rates and poor survival include such factors as middle ear invasion,[238] need for mandibulectomy,[26,56] performance of craniotomy, dural involvement,[75] facial nerve sacrifice, and parapharyngeal space or infratemporal fossa dissection.[242] Middle ear invasion is an important factor, because tumors that are confined to the ear canal can be resected en bloc with LTBR. Survival rates decrease to about 20% when the middle ear is involved with tumor compared to 60% or higher when the middle ear is not involved.[57,75,238]

Intracranial disease extension can be successfully treated.[200,205] Dural involvement was seen in about 5% of patients from a series of 157 temporal bone cancer patients.[26] Dean et al.[153] found intracranial disease in 16 out of 65 patients, and they found that it did not have an effect on disease-free survival. The local control rates were similar with or without intracranial extension (76.9% vs. 71.7%, respectively).[153]

Recurrences tend to occur within the first 2 years following completion of therapy and are a major cause of mortality.[26,56,75] A large study of 157 patients with temporal bone tumors showed a mean time to recurrence of 13 months.[26] In this study, recurrences were 12.7% local, 6.4% regional, and 13.4% distant. The most common sites for distant spread are lung, brain, and dermal metastases.[26] Morris et al.[56] showed recurrence rates of 20.5% for local disease, 5.5% for regional disease, and 22.9% for distant disease. Recurrence rates tended to be higher with salivary gland origin tumors.

Because temporal bone tumors are rare, many authors have lumped several different tumor histologies into analysis.[26,56] This lumping can make analysis difficult because tumor biology and behavior vary widely among these histologies. A clear distinction in tumor behavior exists between SCC and ACC. Although SCC is the most common tumor type, it has a lower overall 5-year survival rate than is reported for ACCa of the ear canal.[66,69,243,244] Whereas mean time to recurrence with SCC is around 2 years, the mean time to recurrence for ACCa is reported to be nearly 8 years.[66,69]

CONCLUSIONS

The external ear is a frequent site of skin cancer, and it carries a relatively

high risk compared to other sites for cutaneous malignancy. SCC and BCC occur at nearly equal frequency. Early-stage cancers can generally be cured with surgery that achieves negative margins. A variety of surgical approaches and reconstructive options are available for these early-stage tumors. Advanced-stage tumors require more aggressive status perhaps including total auriculectomy, LTBR, parotidectomy, and neck dissection. The roles of elective parotidectomy and neck dissection are controversial when these areas are not clinically involved. Radiotherapy is useful as a postoperative adjuvant for advanced tumors and as an alternative to surgery in sickly patients.

Ear canal and primary temporal bone tumors are rare. The temporal bone is more likely to be involved secondarily by tumors from the parotid gland or periauricular skin. Suspicious lesions of the ear canal should be biopsied for proper diagnosis. The most common tumor type is squamous cell cancer; however, a long list of tumor types has been described involving the temporal bone.

Surgical resection to achieve negative margins is the mainstay of treatment. Small tumors (T1 and T2) can oftentimes be treated with LTBR. Parotidectomy and neck dissection are added for disease extension and proper staging. Higher-staged tumors, T3 and T4, will generally require STBR or TTBR along with possible craniotomy, mandibulectomy, resection of the zygoma, and dissection of the infratemporal fossa.

Small defects can be adequately reconstructed with a temporalis muscle flap. Microvascular free flaps are used for large defects and for patients with a history of prior radiotherapy. Adjuvant PORT has demonstrated improved survival for patients with temporal bone tumors staged T2 or higher. Chemotherapy has an emerging role for advanced-stage disease. Evaluation and management of patients with temporal bone tumors by a multidisciplinary team are critical in order to optimize outcomes in this group of patients

24 Cancer of the Head and Neck in the Pediatric Population

Catherine G. Lam Atmaram Pai Panandiker Jon P. Ver Halen Noah D. Sabin, Sandeep Samant

Introduction

Epidemiology

It is estimated that 15,780 new cases of cancer and 1,960 cancer-related deaths occurred among children and adolescents below age 20 in the United States in 2014.[1] Tumors of the head and neck region account for 5% to 10% of all childhood malignancies.[2,3] Similar to other childhood cancers, the incidence of head and neck malignancies in the pediatric age group has demonstrated apparent increases in the United States in recent decades.[2] Given the potential for pediatric head and neck tumors or their treatment to adversely affect critical structures, functional outcomes, and quality of life, coupled with the rarity and diversity of many such tumors, multidisciplinary team management with expertise specializing in pediatric cancer is obligatory.

In an analysis using the National Cancer Institute's population-based tumor registry, Surveillance, Epidemiology, and End Results (SEER), 3,050 children younger than age 19 years with head and neck tumors were identified from 1973 through 1996. Dominant histologic categorizations included lymphoma (27%), neural tumors (including neuroblastoma and retinoblastoma, 23%), thyroid cancers (21%), and soft tissue sarcomas (12%). The most common individual diagnoses were papillary thyroid carcinoma (*n* = 537), Hodgkin lymphoma (HL) (*n* = 515), retinoblastoma (*n* = 497), non-

Hodgkin lymphoma (NHL) (*n* = 301), and rhabdomyosarcoma (*n* = 239). Unlike cancers of the head and neck among adults, squamous cell carcinomas in pediatric patients are rare, accounting for fewer than 2% of cases.[2] Another recent analysis, looking only at sarcomas of the head and neck in the SEER database from 1973 through to 2010, identified 1,244 pediatric cases (including up to age 19 years) and 11,481 adult cases, with 10-year survival of 71% in pediatric patients compared to 61% in adult patients.[4] In this analysis of head and neck sarcomas, the most commonly reported histologies were rhabdomyosarcoma (48%), malignant fibrous histiocytoma (MFH, 11%), osteosarcoma (8%), and Ewing sarcoma (6%).[4]

The age of presentation can provide important initial guidance for conditions likely to be malignant arising in the head and neck. From the SEER database, retinoblastoma, neuroblastoma, germ cell tumors, and rhabdomyosarcoma are among the most common conditions among neonates and infants.[2] Among children below age 10 years, one can see various conditions, including NHL and HL. Among children and adolescents above age 10 years, dominant malignancies of the head and neck include thyroid cancer, Hodgkin and non-Hodgkin lymphoma, and melanoma.[2] Certain tumors are rarely seen outside of their typical age of presentation, including malignant germ cell tumors involving the head and neck, which are mainly seen only in neonates or infants,[5] and retinoblastomas, which are rarely seen in children older than 5 years.

Of note, clinical reviews of malignancies of the head and neck do not consistently include important differential diagnoses such as retinoblastoma in the pediatric age group, and leukemia presenting with chloromas. In addition to primary cancers arising in the head and neck, conditions such as malignant germ cell tumor, lymphoma, and neuroblastoma may also metastasize to the nodes, soft tissue, or bones of the head and neck.

Secondary malignant tumors of the head and neck, that is, those resulting from prior therapy including radiation therapy and alkylating chemotherapy agents, account for about 0.8% of tumors of the head and neck in the pediatric age group[2] and may include thyroid carcinoma, osteosarcoma, MFH, and salivary gland tumors.[6,7]

Diagnostic Evaluation: An Overview

As most masses in the head and neck in pediatric age group are benign, careful clinical history and physical examination with additional workup when appropriate are warranted to diagnose patients with malignant lesions. Conditions to be considered include lesions primarily arising in the head and neck, those that are metastatic to the head and neck, and secondary malignancies. Primary head and neck lesions can include congenital or developmental lesions, inflammatory or infectious masses, benign tumors, or malignant tumors (**Table 24.1**).

Table 24.1 Sample Differential Diagnoses for Head and Neck Masses

Common Presenting Site	Differential Diagnoses[a]			
	Congenita	**Inflammatory/Infectious**	**Benign Tumors**	**Malignant Tumors**
Lateral neck mass	■ Cervical rib ■ Branchial cleft cyst	■ Reactive lymphadenopathy (e.g., viral, bacterial, mycobacterial, granulomatous) ■ Sialadenitis	■ Focal myositis ■ Torticollis ■ See nonlocalized	■ Hodgkin lymphoma ■ Non-Hodgkin lymphoma ■ Retinoblastoma
Midline neck mass	■ Thyroglossal duct cyst ■ Dermoid cyst ■ Thymic cyst ■ Lymphatic Malformation	■ Thyroid disease	■ Thyroid nodule ■ Tracheal and endobronchial tumors ■ Parathyroid adenoma ■ Paraganglioma	■ Thyroid carcinoma ■ Tracheal and endobronchial malignancies ■ Parathyroid carcinoma ■ Malignant paraganglioma
Nonlocalized or various	■ Vascular malformation	■ Ludwig angina ■ Abscesses	■ Hemangioma ■ Lipoma ■ Fibroma ■ Neurofibroma ■ Lymphangioma ■ Salivary gland tumors	■ Hodgkin lymphoma ■ Non-Hodgkin lymphoma ■ Thyroid carcinoma ■ Rhabdomyosarcoma ■ Neuroblastoma ■ Nasopharyngeal carcinoma ■ Germ cell tumor ■ Desmoid tumor ■ Salivary gland malignancies ■ Skin malignancies ■ NUT midline carcinoma ■ Metastatic cancer

[a]Note that variants of some conditions may appear in more than one category.

Assessment of a child with a mass in the head and neck should start with a detailed clinical, past medical, and family history, immunization history, and recent and current medications. History should detail the onset, nature, and timing of any changes associated with the mass, along with potential exposures and risk factors for infection (e.g., tuberculosis), travel, and exposure to animals (e.g., zoonoses).

Congenital or developmental lesions may first be evident in the early postnatal period, but in some cases they can manifest later in life, with gradual growth over time or with concomitant secondary infection. Benign

tumors can similarly sometimes be brought to medical attention in the setting of concurrent infection. Whereas inflammatory/infectious etiologies are typically first considered for masses that acutely enlarge and are associated with acute fever, tenderness, or skin changes such as erythema or warmth, red flags should prompt consideration of an underlying malignancy. Potential red flags include firm, fixed/immobile or large (>1.5 to 2 cm) masses; lymph nodes in atypical locations (e.g., supraclavicular) or multiple locations; masses initially queried to be inflammatory or infectious in nature that do not respond to initial empiric management or persist beyond 4 to 6 weeks; or constitutional symptoms such as malaise, weight loss, anorexia, and unexplained fevers or night sweats.

Relevant clinical and functional impairments to assess on history and to observe on examination may include abnormal eye movements; distorted vision; proptosis; Horner syndrome; cranial nerve palsies; paresthesias; recurrent epistaxis; increasing nasal congestion; evidence of recent suspected/confirmed infections; loss of smell; stridor; dysphagia and odynophagia; impaired gag; trismus; deviated tongue; dental health; change in tooth position; change in voice or hoarseness; otorrhea; progressive tinnitus or hearing loss; otalgia; vertigo; neck tilt or torticollis; facial and/or neck swelling; deviated trachea; increased vascular markings, pulsatility, or overlying skin changes; or features of hypothyroidism or hyperthyroidism.

Physical examination should also include evaluation for movement of the mass with tongue protrusion (e.g., thyroglossal duct cysts, which typically move upward with tongue protrusion) and include a full systemic examination for systemic lymphadenopathy, with particular vigilance for lymph nodes in atypical sites such as the supraclavicular area or that are firm, fixed, and significantly enlarged; ophthalmologic examination; assessment of tonsillar tissue; oral mucosal examination; thyroid examination; cardiorespiratory examination; abdominal examination for masses or hepatosplenomegaly; genitourinary examination; skin examination for evidence of petechiae or purpura or neurocutaneous markings; dysmorphic features; detailed neurologic examination; and note of any current or impending functional impairment from mass effect.

Any concern for potential airway compromise must be immediately evaluated and managed as an oncologic emergency. As tumors in the head and neck may expand into cavities such as the maxillary sinus with relatively

limited innervation, pain is not necessarily a dominant symptom and more likely becomes prominent with nerve compression or periosteal impingement.[8] Potential intracranial extension, with intraparenchymal brain metastasis or leptomeningeal disease, can also be seen in children and may also be associated with varied acute neurologic symptoms, warranting careful evaluation and management.[8,9] Careful clinical and radiologic assessment as appropriate for a potential mediastinal mass should also be pursued, and managed as a medical emergency, given the risk of acute cardiorespiratory decompensation with sedation or suboptimal body positioning. Once oncologic emergencies have been ruled out or definitively managed, a broad differential diagnosis should be considered.

Targeted laboratory studies should be considered to further evaluate suspected conditions based on initial history and physical examination. Evaluations for persistent adenopathy not responsive to empiric antibiotics may include considerations for *bartonella henselae* (catscratch), Epstein-Barr virus (EBV), cytomegalovirus, toxoplasmosis, histoplasmosis, tuberculosis, and human immunodeficiency virus as appropriate.

Targeted imaging should also be considered to help with diagnosis and further management planning, with sample modalities outlined in **Table 24.2**. For children (up to age 14) with a mass in the neck or adenopathy, the American College of Radiology (ACR) Appropriateness Criteria recommends the use of neck ultrasound as the most appropriate modality, followed by computed tomography (CT) of the neck (with contrast) and magnetic resonance imaging (MRI) of the neck (without and with contrast).[10] Although intravenous contrast is typically recommended with cross-sectional imaging to help characterize the margins of the lesions and abnormally enhancing lesions that may not be pathologically enlarged, this should be considered in conjunction with a specialist team that includes a radiologist. For instance, noncontrast CT is recommended in the setting of suspected salivary gland enlargement due to a sialolith,[10] whereas for a suspected mass in the thyroid, use of iodinated contrast agents is typically avoided or used judiciously only after discussion as a specialist team, as iodine uptake in the thyroid may affect timing of subsequent diagnostic or therapeutic steps.

Table 24.2 Sample Role of Imaging Modalities for Head and Neck Masses

Imaging Modality	Considerations for Use	Typical Uses
Neck ultrasound (US)	■ Helpful to assess solid vs. cystic palpable lesions ■ Can help define location, shape, size ■ No ionizing radiation	■ Initial evaluation of most pediatric neck masses, including suspected thyroid nodule[10] ■ May be performed as a guidance study to facilitate biopsy
Neck ultrasound with Doppler	■ Helpful with characterizing vascularity, and blood flow in solid lesions ■ No ionizing radiation	■ Queried vascular lesion or malformation ■ Initial evaluation for queried vascular occlusion
Computed tomography (CT), neck	■ Typically requested in discussion with specialist team ■ For suspected thyroid mass, consult specialist team prior to using iodinated contrast media ■ Noncontrast CT recommended for suspected sialolith[10] ■ May require sedation	■ Preferred evaluation for retropharyngeal mass[10] ■ May be performed as a guidance study to facilitate biopsy of potential malignant or nondefinitive lesion in deep or challenging locations
Magnetic resonance imaging (MRI), neck	■ Typically requested in discussion with specialist team ■ No ionizing radiation ■ May require sedation with typically longer examination time than other modalities	■ Can be helpful for further evaluation of certain lesions, including vascular malformation, after initial ultrasound, or for further soft tissue and perineural delineation

A chest radiograph, which is readily available, can be useful for particular circumstances. These can include situations when one suspects a mediastinal mass, an oncologic emergency that requires care in patient positioning during the evaluation, as well as for suspected lesions extending into the chest or for gross metastatic disease.

Specialized imaging such as 18F-fluorodeoxyglucose positron emission tomography (FDG-PET), CT or magnetic resonance angiography, or other body imaging is typically reserved for confirmed malignancies in the setting of staging or follow-up evaluation. Key considerations for imaging in children with head and neck malignancies are outlined in **Table 24.3**, with more detailed depictions in the sections and references below.[11–17] In all cases, the concept to "image gently" and expose children to "as low as reasonably achievable" (ALARA) levels of ionizing radiation in imaging should guide practices.[16,18]

Table 24.3 Common Imaging Modalities for Selected Primary Malignancies in the Head and Neck

Head and Neck Diagnosis	US	CT	MRI	PET-CT	mIBG	Bone Scan	Other Considerations
Rhabdomyosarcoma		•	•	•		•	
Desmoid tumor			•				
Bone sarcomas		•	•	+/–		•	
Hodgkin lymphoma		•		•

Paraganglioma			•	•	•		Octreoscan

Note: These are potential options for staging and/or monitoring of primary malignancies in the head and neck that have been described in the literature, by consensus groups or in conventional protocols for children; other modalities may be needed as clinically indicated, including modalities and specification of anatomic sites for full metastatic evaluation. Not all options may need to be used for a single patient. Primary presentations of the same diagnosis outside of the head and neck may also preferentially warrant other modalities.

[a]For select differentiated thyroid carcinoma patients only.

Early consultation with a multidisciplinary specialist team, including providers in pediatric surgery and pediatric hematology/oncology, is warranted for any concerns of potential malignancy.

Fine-needle aspiration (FNA) may be considered for initial tissue evaluation of selected neck lesions of children, with sensitivity ~90% or higher, and specificity ~85%, where the most likely diagnosis is reactive lymphadenopathy.[19,20] Advantages include its minimally invasive nature compared to an open biopsy, relatively low cost, and potential avoidance of general anesthesia in some children.[3,19,20] Anticipatory multidisciplinary planning prior to any potential biopsy is recommended, including at least the surgical, radiology, and pathology teams, as image guidance and rapid on-site processing could critically impact diagnostic yield. With the aid of experienced pediatric cytopathology team members, FNA or core needle/open biopsy specimens can be processed for rapid interpretation with direct smears and cell block preparation for routine hematoxylin and eosin-stained slides, as well as ancillary studies, which can include cultures, special stains for acid-fast bacilli or fungi, flow cytometry, or fluorescent in situ

hybridization.[20] Core needle or open biopsies are recommended when malignant disease is likely, bony lesions are suspected, or preserved tissue architecture or more complete evaluation of suspected heterogeneous tissue (which may be missed by selective FNA sampling) are required for diagnostic confirmation or where FNA sampling was insufficient, indeterminate, or inconsistent with the clinical impression.[8,20]

Clinical Management: An Overview

Optimal management of malignant tumors in the head and neck conditions requires a coordinated multidisciplinary team with familiarity and dedicated expertise in working with children with these rare and complex cancers. Inherent in the very location of tumors of the head and neck and their proximity to multiple vital structures, this group of tumors warrants anticipatory evaluation and management of potential airway compromise and special anesthesia needs and potential functional implications of the mass in its natural course, as well as implications secondary to diagnostic and therapeutic procedures, while considering the child's developmental growth and function.

Functional sequelae to be considered and optimally prevented may include more immediate concerns involving compromised swallowing and the risk of aspiration or ophthalmologic complications,[21] as well as longer-term implications of the cancer or therapy on orofacial development and dentition,[22,23] jaw function,[24] cosmesis, and cognitive function. For instance, patients with a history of dysphagia would benefit from clinical bedside swallowing evaluation by speech language pathologist, as well as barium swallow examination if clinically indicated.

Vigilant supportive care is also required to evaluate and address the known toxicities of cancer therapy that may be exacerbated by the location of the tumor of the head and neck, including oral mucositis. Young patients require nutritional and growth monitoring and may benefit from feeding tubes for enteral nutrition as well as for selected administration of medication. As many effects of the cancer therapy may initially become manifest or progress months or years beyond the treatment period, long-term follow-up for potential late effects is warranted.

Updated general guidance for the core personnel and resources essential

to provide care for children and adolescents with cancer has been recently articulated by the American Academy of Pediatrics. Outcomes for children with malignancy have been demonstrated to be better when core management is at least initiated by specialist pediatric cancer centers.

Typical specialist multidisciplinary team members engaged closely with families of children with malignant masses in the head and neck should include pediatric physicians, nurses, pharmacists, social workers, and other allied health team members working in hematology/oncology; surgery, otolaryngology, and neurosurgery; ophthalmology; dental oncology and orthodontics; radiation oncology; plastic and reconstructive surgery; radiology and diagnostic imaging; pathology; nutrition; speech/language pathology; and child life. In many cases, the expert consultative input of other pediatric team members in anesthesiology, critical care, endocrinology, genetics, infectious diseases, neurology, ocular prosthesis, palliative care, psychology, rehabilitation specialists including occupational and physical therapy, and team members experienced in late effects of therapy is also invaluable. In all cases, the pediatric patient, the family, and the community-based or primary care team members engaged by the family remain central partners with the multidisciplinary specialist team in decision-making and family-centered care delivery.

Surgical Considerations: An Overview

Surgical management of pediatric age group cancer of the head and neck has undergone many significant changes during the past two decades. Most of these changes have occurred as a result of technologic advances, including better imaging, more precise delivery of radiation, advances in surgical technique, and a better understanding of anatomy. The improved understanding of anatomy has had its greatest impact on the development of better and more reliable reconstructive techniques that allow us to perform surgery that, in the past, would have been impossible. We can now be more certain that the defects that we create surgically can, for the most part, be reliably reconstructed. However, in the pediatric age group, cancer of the head and neck is uniquely affected by the need to account for the growing and developing facial skeleton and associated structures. This has a particular impact in children’s dentition, which owing to its continued growth until skeletal maturity often requires a staged approach to reconstruction.

Evaluation for surgery is first dependent on accurate tissue diagnosis, requiring incisional or excisional biopsies for the vast majority of solid tumors. Exceptions include salivary or thyroid masses, for which fine needle aspiration is an option. Subsequent staging evaluation includes routine laboratory studies (complete blood count, basic metabolic panel, liver function tests, lactate dehydrogenase [LDH]), CT scan of the chest, and in many cases positron emission tomography (PET) scan. Unlike in cancer in adults, pediatric resections must balance the extent of surgical resection with functional and aesthetic concerns, and thus, radical resection with negative margins (R0) resections is not always possible. Some pediatric tumors, in fact, are so responsive to nonsurgical therapies or are so indolent in nature (e.g., desmoid tumors) as to make resections unnecessary. As with adult malignancies, patients are frequently candidates for either chemotherapy and/or radiation therapy in either a neoadjuvant or an adjuvant setting. Depending on the pathology of the disease, timing of such treatment may vary. Finally, reconstructive concerns share many similarities with cancers in adults, but have specific differences with regard to the developing pediatric facial skeleton and associated structures.

Role of Radiation Therapy: An Overview

Radiotherapy is a critical component of the multimodality management in the pediatric age group of cancer of the head and neck. Although some tumors involving the head and neck are surgically accessible, complete extirpation of lesions occupying anterior craniofacial spaces or the base of the skull is often impossible without significant morbidity necessitating a management plan that relies on nonsurgical modalities either as surgical adjuncts or for definitive tumor control. Microscopic residual disease is a source of local failure that can be addressed via the use of adjuvant radiotherapy or chemoradiotherapy. Clinical studies of pediatric head and neck cancer seek optimal combinations of multimodality therapy in order to reduce late effects while simultaneously increasing rates of long-term disease control.

Conformal radiotherapy with or without intensity-modulated radiation therapy has been the primary mechanism of radiation dose delivery during the past two decades.[25,26] Advances in software now routinely employ computation-heavy, cost–benefit function analyses of beam modulation to address irregular structures within the body, particularly when they are

concentrically contained within or encapsulated by normal organs with dose-limiting sensitivity to radiation effect.[27,28] Furthermore, physiologic motion is minimal within the head and neck region, allowing greater confidence in patient setup and targeting the tumor bed. Although some advances, like respiratory gating and breathing management (deep inspiration breath hold), have been developed to address organ and target volume motion, most treatment of the head and neck in the pediatric age group can be accomplished without resorting to these specialized measures.[29] Prosthetics in the form of intraoral molds and the use of thermoplastic head and neck immobilization devices frequently serve as positioning aids, both internally and externally for the pediatric oropharynx and head/neck, respectively.[30,31] Fiducial markers can also be implanted to further aid in targeting when extraordinarily high precision is required to spare critical structures skirting radiation dose thresholds.

Frequently, these tumors afflict young children and infants requiring sedation to achieve adequate immobilization suitable for treatment. Most institutions choose to sedate with propofol and avoid airway management when possible, although occasional management of the airway is required to ensure patient safety through a full course of radiation, as determined by the anesthesiologist.[32]

Proton therapy has recently become central to the discussion of pediatric radiotherapy due to the promise of reduced toxicity; larger-scale clinical trials designed to demonstrate the potential advantages are ongoing. Although a major objective of proton therapy is reduction of toxicity, protons do not inherently promise a more efficacious means of disease control (unless normal tissue sparing through improved tumor targeting is enhanced such that dose escalation of residual tumor can result in improved disease control).[33] At this time, precision targeting with proton beam is still developing as a routine component of clinical practice due to various factors, including cost and accessibility. Proton therapy requires prospective study design to provide evidence for the appropriate indications and degree of benefit that may be obtainable.

DISEASE-SPECIFIC OVERVIEW:

DIAGNOSIS, STAGING, TREATMENT, AND PROGNOSIS

Rhabdomyosarcoma

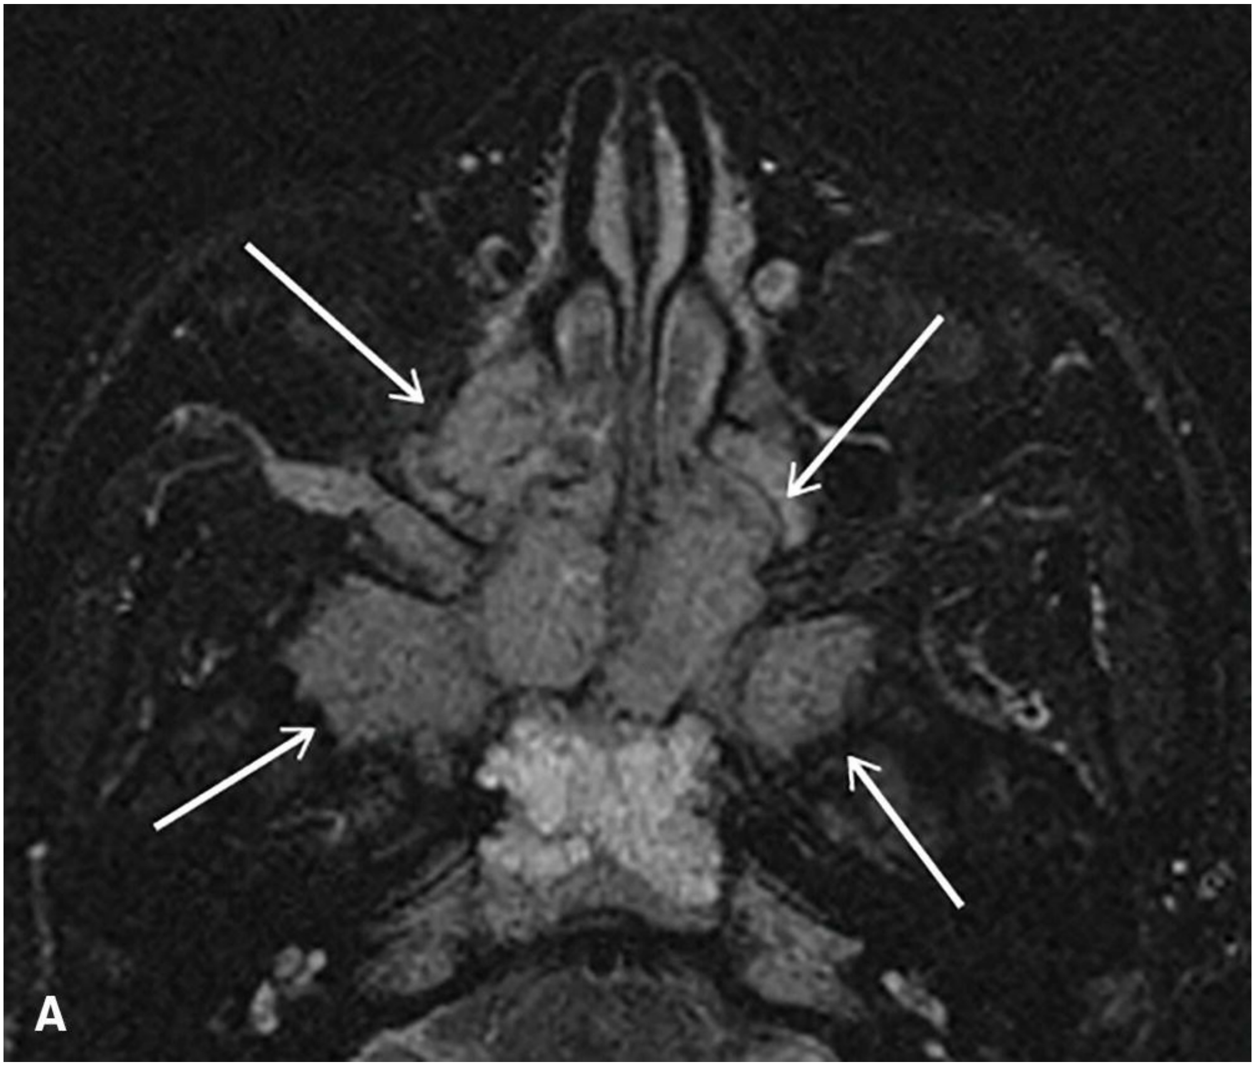
Rhabdomyosarcoma is the most common pediatric soft tissue sarcoma, with an overall annual incidence in the United States of 4.5 cases per million children and adolescents, with the majority occurring in children younger than 10 years.[34] It arises as a primary malignancy in the head and neck in ~35% to 40% of cases, most commonly in the orbit.[3,4,8,21] Cooperative group efforts, including the Intergroup Rhabdomyosarcoma Studies (IRS), have contributed to the advances in management. The mainstay of therapy is multimodal, including multiagent systemic chemotherapy for all patients and either radiation therapy, surgery, or both, as local control for most patients. Across the pediatric age spectrum, outcomes for patients who have rhabdomyosarcoma have improved since 1975, with 5-year survival rates increasing by more than 10% to ~65% or higher for patients younger than 15 years old and to ~50% for patients 15 to 19 years old.[35]

Rhabdomyosarcoma encompasses two main histologic subtypes: embryonal and alveolar. The embryonal subtype is the most common among children, noted in approximately two-thirds of the patients, with common locations including the head and neck and the genitourinary tract. Botryoid and spindle cell variants of embryonal rhabdomyosarcoma have a particularly favorable prognosis.

Within the head and neck, rhabdomyosarcomas are further classified as originating from the orbit (including eyelid), parameningeal (including middle ear/mastoid, nasopharyngeal/nasal cavity, paranasal sinus, parapharyngeal region, and pterygopalatine/infratemporal fossa), or nonparameningeal sites (including the scalp, ear lobe, parotid, oropharynx, and hypopharyngeal region).[8,36] Key prognostic factors for pediatric patients with rhabdomyosarcoma are used by the Children’s Oncology Group (COG) to categorize patients into three risk groups (low, intermediate, and high) based on risk of disease recurrence. Standard prognostic factors include age (best age 1 to 9 years), primary site (favorable sites including orbit, nonparameningeal head and neck, genitourinary sites excluding bladder and

prostate, and biliary tract), tumor size (smaller, ≤5 cm better), tumor resectability, disease spread (better prognosis with localized disease without regional lymph node involvement or distant metastases), and tumor histopathology (embryonal more favorable than alveolar subtype).[36] In recent years, ~80% of alveolar rhabdomyosarcomas have been found to harbor a fusion of the FOXO1 gene (on chromosome 13) with either the PAX3 or PAX7 genes (on chromosome 2). As the presence of FOXO1 gene fusion status is more closely associated with adverse outcomes, in upcoming COG trials, FOXO1 fusion status is anticipated to replace histopathology classification in risk stratification criteria.[37]

Presentation of rhabdomyosarcomas can vary greatly depending on the primary site and typically require an open or core needle biopsy to confirm histopathologic and molecular diagnosis. Radiologic staging has typically included a baseline chest radiograph, chest CT, bilateral bone marrow aspirates and biopsies, and bone scan (with some centers opting for PET–CT in lieu of bone scan). For patients with parameningeal primary tumors, in particular, an MRI of the brain and skull base is required, and baseline lumbar puncture for malignant cells in the cerebrospinal fluid should also be obtained. MRI with MRA/MRV may be used to evaluate the relationship of the tumor to nearby vascular structures. Suspected spinal cord involvement can be investigated with MRI including contrast. Rhabdomyosarcomas of the head and neck have a variable imaging appearance but are often heterogeneous and may contain areas of necrosis and/or hemorrhage. They often erode adjacent bone and may extend intracranially. There are no pathognomonic imaging findings (**Figs. 24.1** and **24.2**).[38]



A

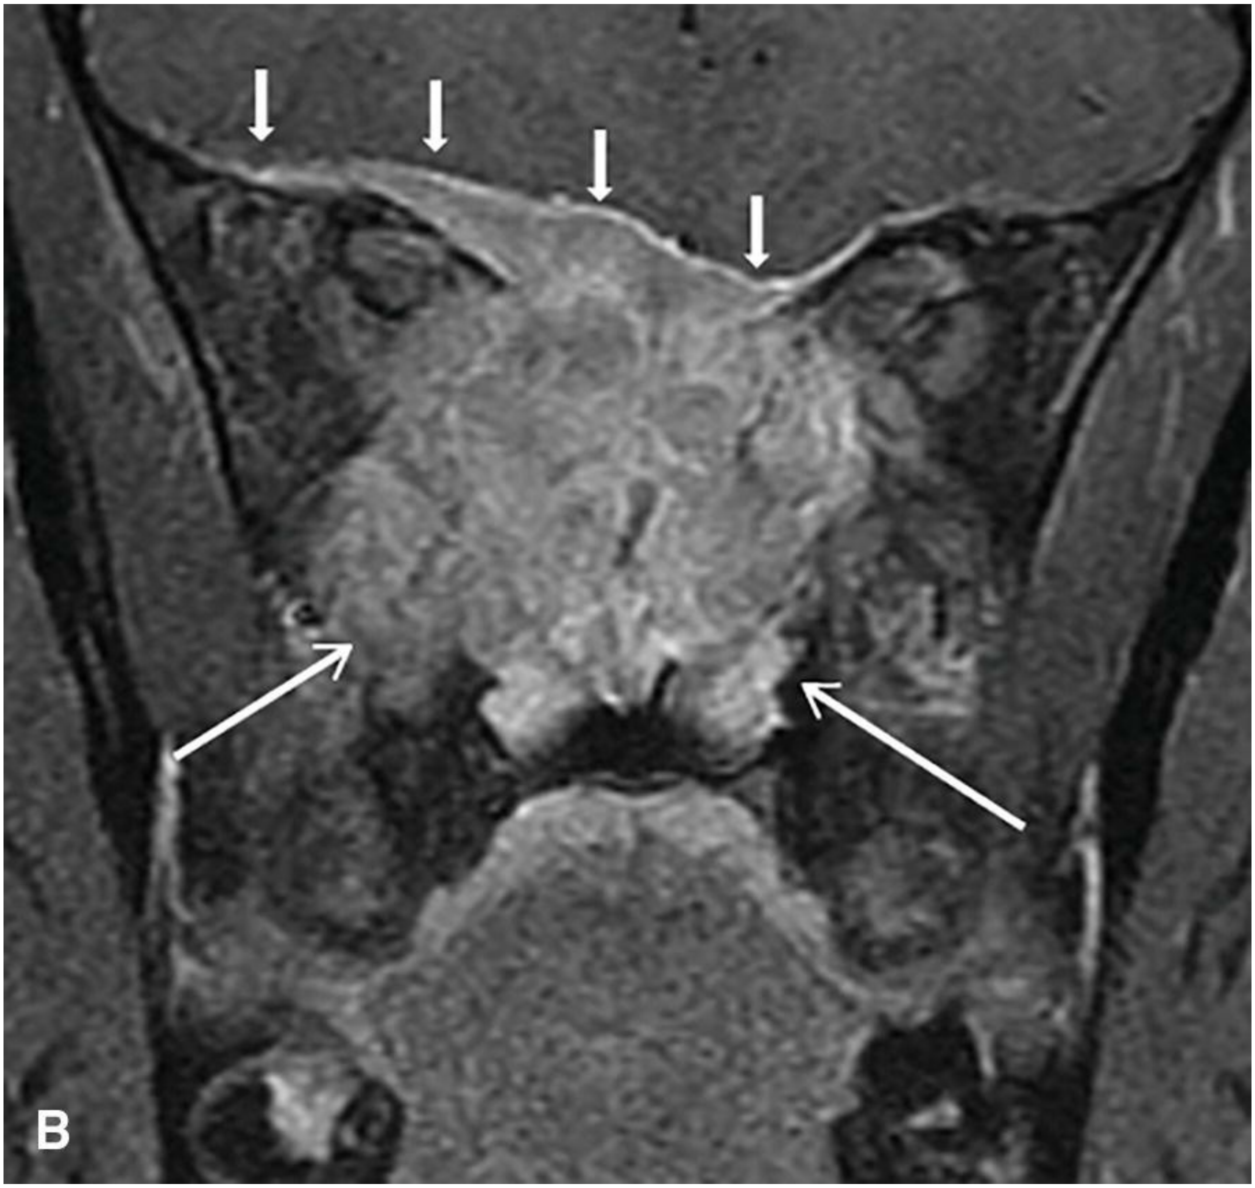


Figure 24.1. Axial short T1 inversion recovery (STIR) (A) and coronal postgadolinium fat-saturated T1-weighted (B) images through the face of a 17-year-old patient demonstrate an irregularly shaped mass (*large arrows*) that involves the central skull base, ethmoid region, and portions of the orbits with intracranial epidural extension (*small arrows*). A biopsy confirmed the diagnosis of alveolar rhabdomyosarcoma.

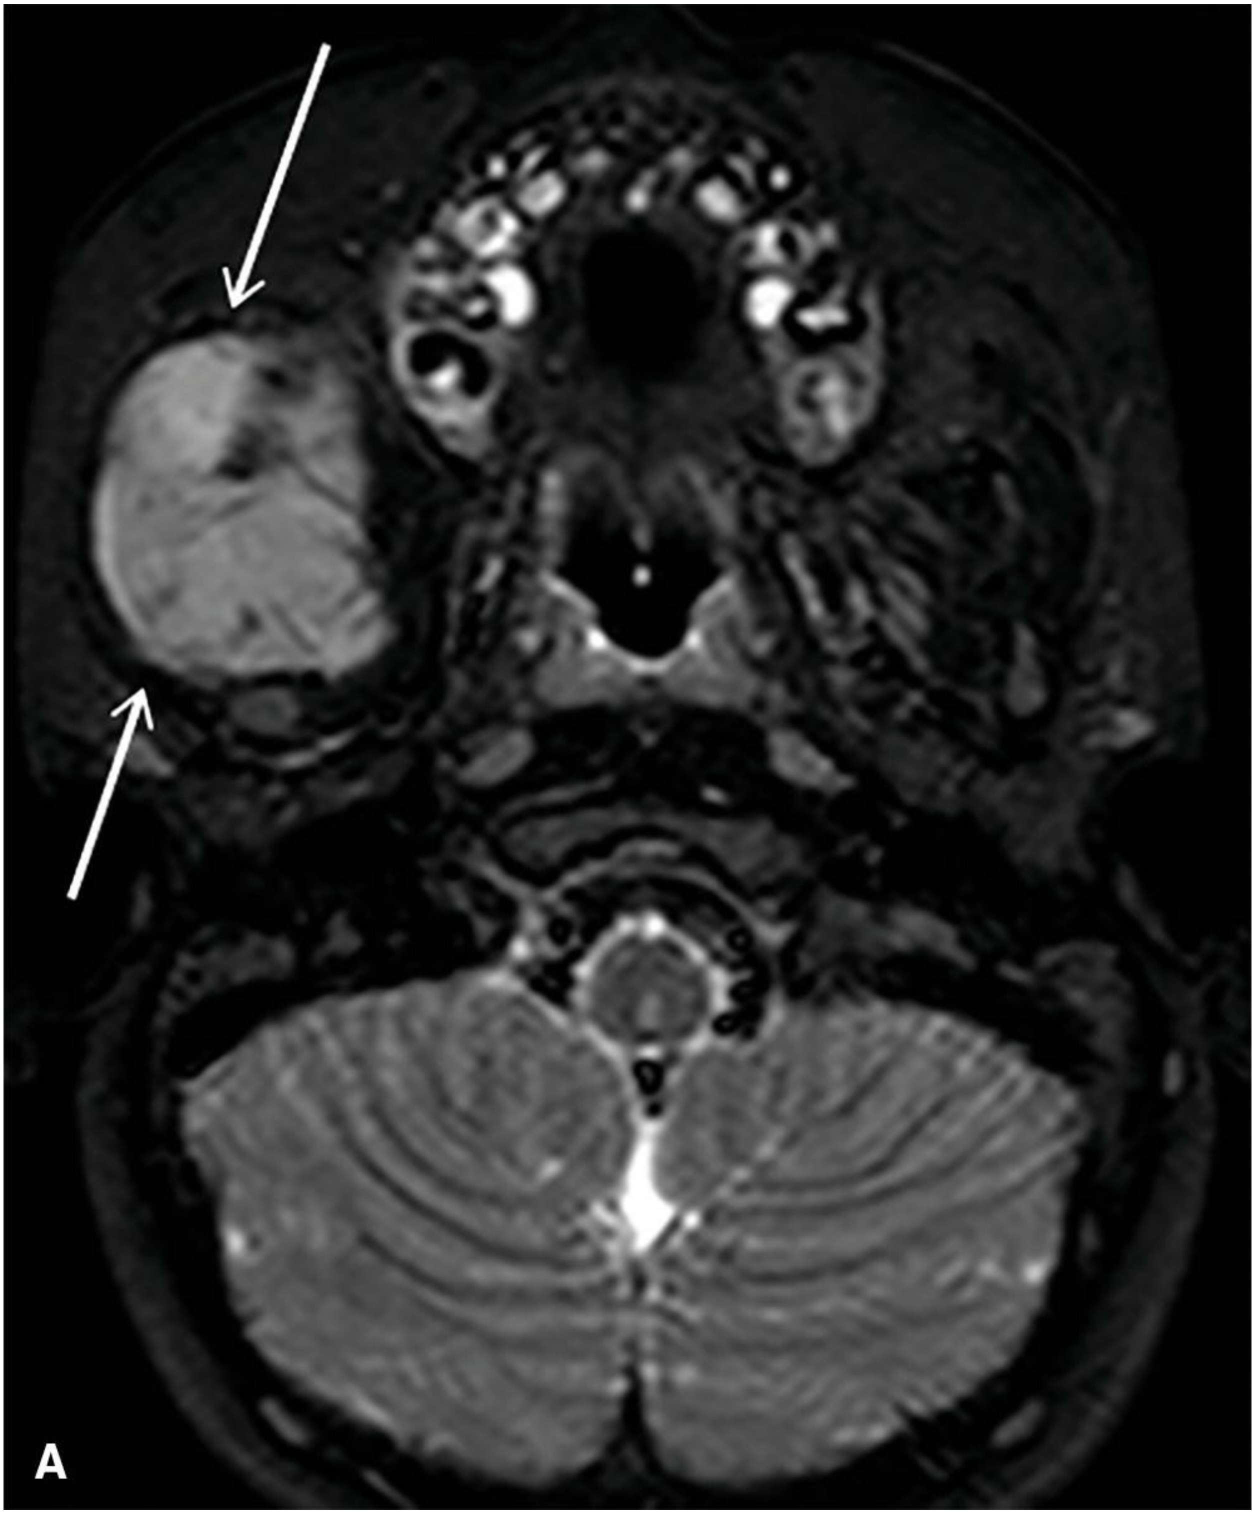


A

B

Figure 24.2. Axial STIR (A) and axial (B) and coronal (C) postgadolinium fat-saturated T1-weighted images through the face of a 2-year-old child reveal a heterogeneous mass (*arrows*) involving the right masticator space. Biopsies of the mass demonstrated embryonal rhabdomyosarcoma.

A recent review of more than 1,600 children with rhabdomyosarcoma from 1991 to 2004 on intergroup studies suggested that staging procedures can be adapted in an algorithmic fashion based on presenting clinical factors, such that patients at low risk of distant metastatic disease—approximately one-third of patients—may be spared bone marrow studies and bone scans.[39]

In addition to standard cross-sectional imaging, PET-CT may also be a helpful adjunct to detect regional or distant metastatic disease, help evaluate therapeutic response, and identify patients who may benefit from therapy intensification for regional control.[40–42] Assessment of regional lymph nodes and potential biopsy where feasible may also guide management,[43] although neither PET scans or lymph node assessments are currently included as requirements in COG treatment protocols.

Comprehensive staging of rhabdomyosarcoma in children typically involves designating a stage (**Table 24.4**), a surgical–pathologic diagnosis, local tumor group (**Table 24.5**), and finally a risk group (**Table 24.6**).

Table 24.4 Children's Oncology Group: Pretreatment Staging System for Rhabdomyosarcoma

Stage	Sites of Primary Tumor	T Stage	Tumor Size	Regional Lymph Nodes	Distant Metastasis
1	Favorable site (Orbit; nonparameningeal head and neck; genitourinary tract other than kidney, bladder, and prostate; biliary tract)	T1 or T2	Any size	N0 or N1 or NX	M0
2	Unfavorable sites (any site other than favorable)	T1 or T2	a, ≤ 5 cm	N0 or NX	M0
3	Unfavorable sites (any site other than favorable)	T1 or T2	a, ≤ 5 cm b, > 5 cm	N1 N0 or N1 or NX	M0
4	Any site	T1 or T2	Any size	N0 or N1 or NX	M1

N0, absence of nodal spread; N1, presence of regional nodal spread beyond the primary site; X, unknown N status; M0, absence of metastatic spread; M1, presence of metastatic spread beyond the primary site and regional lymph nodes; T1, tumor confined to anatomic site of origin (noninvasive); T2a, tumor extension and/or fixation to surrounding tissue (invasive), tumor ≤5 cm in maximum diameter; T2b, tumor extension and/or fixation to surrounding tissue (invasive), tumor >5 cm in maximum diameter.From National Cancer Institute: PDQ® Childhood Rhabdomyosarcoma Treatment. 2014.

Table 24.5 Children's Oncology Group: Surgical–Pathologic Group Assignment System for Rhabdomyosarcoma

Group	Incidence	Definition
I	~13%	Localized tumor, completely removed with microscopically clear margins, and no regional lymph node involvement. Lymph node biopsy or sampling is encouraged if lymph nodes are clinically or radiographically suspicious.
II	~20%	Localized tumor, completely removed with (a) microscopic disease at the margin; (b) regional disease with involved, grossly removed regional lymph nodes without microresidual disease; **or** (c) regional disease with involved nodes, grossly removed but with microscopic residual and/or histologic involvement of the most distal node from the primary tumor
III	~48%	Localized tumor, incompletely removed with gross, residual disease after (a) biopsy only **or** (b) gross major resection of the primary tumor (>50%)
IV	~18%	Distant metastases are present at diagnosis. This category includes (a) radiographically identified evidence of tumor spread **and** (b) positive tumor cells in cerebral spinal fluid, pleural, or peritoneal fluids, or implants in these regions

From National Cancer Institute: PDQ® Childhood Rhabdomyosarcoma Treatment. 2014.

Table 24.6 Children's Oncology Group: Risk Group Classification for Rhabdomyosarcoma

Risk Group	Histology	Stage	Group
Low risk	Embryonal Embryonal	1 2, 3	I, II, III I, II
Intermediate risk	Embryonal Alveolar	2, 3 1, 2, 3	III I, II, III
High risk	Embryonal or alveolar	4	IV

From National Cancer Institute: PDQ® Childhood Rhabdomyosarcoma Treatment. 2014.

The nature and intensity of treatment, and subsequent outcomes, depend on appropriate staging and pathologic delineation of rhabdomyosarcomas, including tumor biology.

In comparison with children and adolescents with rhabdomyosarcoma, adult patients are more likely to present with disease in unfavorable primary sites, and exhibit pleomorphic histology, which is rarely seen in the pediatric population.[44]

Although the majority of cases of rhabdomyosarcoma are apparently sporadic in origin, reported associated familial and genetic conditions include Li-Fraumeni syndrome (with TP53 mutations), Costello syndrome,

Beckwith-Wiedemann syndrome, neurofibromatosis, and Noonan syndrome.[34,45] Additional studies are needed to evaluate the role of environmental factors, such as immune function and atopic exposure as potential protective factors in pediatric rhabdomyosarcoma.[46]

Standard chemotherapy consists typically of vincristine, actinomycin-D (also known as dactinomycin), and cyclophosphamide, in a regimen commonly known as VAC.[47] Additional agents have not convincingly altered the outcomes of this therapeutic backbone.[48] Focus continues to hone in on advancing cure rates while minimizing potential late effects of therapy. For patients who initially present with localized rhabdomyosarcoma, preventing local recurrence with surgery and/or radiotherapy remains vital.

Local therapy for rhabdomyosarcoma follows an approach of risk-adapted therapy with selection of modality (surgery vs. radiotherapy) designed to limit morbidity while optimizing local control. Maximal safe resection is performed at diagnosis when possible, followed by systemic therapy and additional local control measures including radiation therapy and additional surgery as determined by tumor histology, resectability, and the status of the surgical margins. Second-look surgery is an acceptable approach in order to balance outcome with toxicity. This approach enhances local control while minimizing long-term late effects. Defining appropriate patients for postoperative adjuvant radiotherapy remains somewhat controversial. Historically, patients have been selected for adjuvant radiotherapy based on histology (alveolar vs. embryonal). The basis for this approach derives from subset analyses of IRSG III to IV trials that have suggested no decrement to local control in children with alveolar rhabdomyosarcoma managed with surgery alone.[49]

Primary surgical resection can be considered prior to chemotherapy, but only if this would be safely achieved without adverse functional or cosmetic outcomes. Aggressive primary surgical approaches are not recommended, as attempts to debulk the tumor (with gross residual tumor) are not associated with improved outcomes compared to biopsy alone.[50] Particularly for head and neck rhabdomyosarcomas, typically only a biopsy is performed prior to chemotherapy; hence, most patients will have gross residual (group III) tumor and receive radiotherapy as primary means of local control.[36] Orbital rhabdomyosarcomas should be biopsied only; upfront exenteration should not

be performed, and later orbital exenteration should only be considered for those few patients with persistent or recurrent disease after chemotherapy and radiation therapy, which can achieve survival rates of 90% and above. For nonparameningeal and nonorbital rhabdomyosarcomas of the head and neck, such as those with superficial facial tumors, primary tumor excision (accepting narrow margins due to anatomy) and ipsilateral neck sampling of clinically concerning nodes can be considered.[8,51] Selected patients may be considered for second-look surgery to remove residual tumor (i.e., delayed primary excision) after initial therapy or in cases where this may modify the radiation dose required or have anticipated net positive impact on a given patient's functional outcome. The detection of viable tumor at the time of second-look surgery has not been found to impact overall survival.[49]

As only an estimated 15% of pediatric rhabdomyosarcoma patients have completely resected (group 1) disease, radiation therapy is included for local control in most cases.[36]

Recent data suggest the proton radiotherapy may be a comparably effective modality to photon radiotherapy for selected pediatric rhabdomyosarcoma patients, with future larger studies with sustained follow-up awaited to clarify whether it may indeed definitively reduce late effects.[52]

With modern therapy, typical survival rates for pediatric patients with rhabdomyosarcoma in the orbit are in the range of 90% or greater and 70% or greater for nonparameningeal head and neck rhabdomyosarcoma. Patients with parameningeal rhabdomyosarcoma are typically associated with poorer prognosis.[8,53] Cranial nerve palsies or skull base erosion is noted in approximately a third of children with parameningeal rhabdomyosarcoma and is associated with increased risk of recurrence. Urgent management typically includes earlier initiation of radiation therapy, with incomplete or longer-term clinical neurologic recovery from cranial nerve palsies possible.[8,54]

Generally, patients with recurrent and refractory rhabdomyosarcoma have a guarded long-term prognosis, but selected patients can achieve complete remission and more favorable 5-year survival rates with intensive salvage therapy, including those with initially localized presentation in favorable sites such as the orbit.[55,56]

Other Soft Tissue Sarcomas and Related Tumors

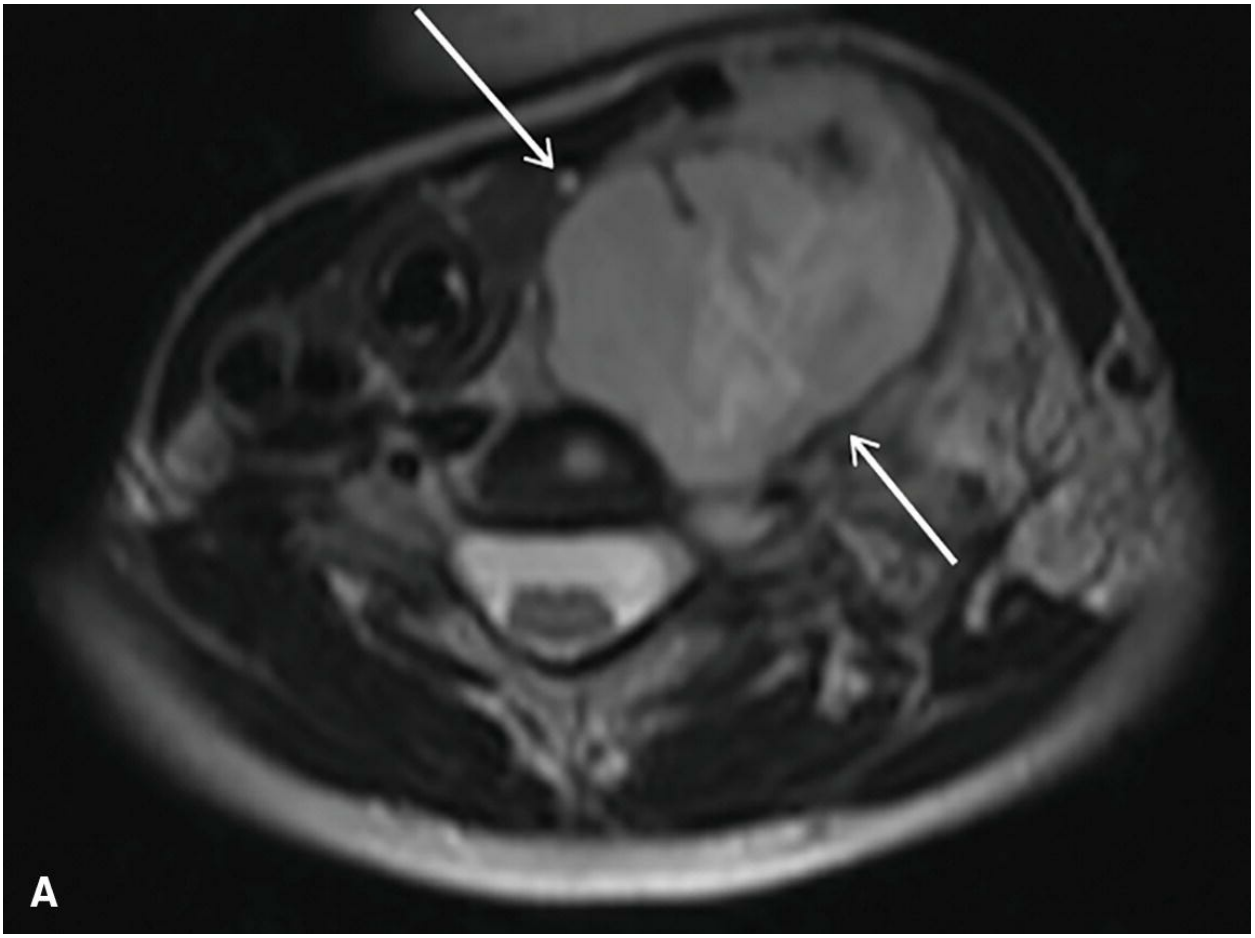
A number of soft tissue sarcomas constitute the varied group of sarcoma malignancies, apart from rhabdomyosarcoma, that can arise in the head and neck. The various nonrhabdomyosarcomatous soft tissue sarcomas (NRSTSs) altogether constitute <5% of pediatric malignancies; most pose challenges for local management, with infrequent lymph node or distant metastatic involvement.[57]

Synovial sarcoma is the most common NRSTS, with head and neck primary involvement in ~6%.[58] Synovial sarcomas are frequently small and, particularly when they present in the head and neck region, are often missed as a malignant entity due to its slow growth and well-circumscribed appearance.[59] Immunohistochemical staining typically demonstrates reduced INI1 nuclear reactivity, with a typical and specific chromosomal translocation, t(X;18)(p11.2;q11.2), associated with this diagnosis in 95% of cases, leading to rearrangement of the SYT gene (located on chromosome 18) with SSX1 or SSX2 (on chromosome X).[59] Better outcomes have generally been described among children than in adults, with SEER database analysis of 5-year survival estimates of 83% for children and adolescents and 62% for adults.[58] Typical management approaches are centered on surgical resection, with ongoing need for prospective data to definitively delineate the contribution of radiation therapy and chemotherapy.[59,60] Although various approaches have been used, a common chemotherapy regimen considered for NRSTSs selected for systemic therapy is doxorubicin with ifosfamide.[59,60]

In a recent analysis of the National Cancer Institute's SEER database, among 1,244 pediatric cases, MFH was among the most common diagnoses reported.[4] Whereas MFH is a common soft tissue sarcoma in adult patients, it has been inconsistently recognized and reported in the pediatric literature.[61,62] Although the nomenclature and classification of MFH and related tumors were revised by the World Health Organization in recent years, including in 1994 and 2002, studies reporting on MFH unfortunately have often aggregated MFH with other less aggressive subtypes, such as angiomatoid fibrous histiocytoma and plexiform fibrohistiocytic tumors,[61] with caution thus warranted in interpreting studies that may not have had the benefit of MFH as defined consistently on contemporary pathology review. One institutional retrospective study from 1971 to 2000 identified 28 patients

initially diagnosed with MFH, including 6 in the head and neck; 10 were reclassified as angiomatoid fibrous histiocytoma and one with plexiform fibrohistiocytic tumor; among the 17 patients with confirmed MFH, 5-year event-free survival is ~71%, compared to 100% for those reclassified with angiomatoid fibrous histiocytoma and plexiform fibrohistiocytic tumor. Wide local excision was favorably associated with event-free survival for localized tumors.[61]

Malignant peripheral nerve sheath tumors (MPNSTs) constitute another relatively common diagnosis within this rare group of pediatric head and neck NRSTSs.[57,63] A recent SEER analysis[64] demonstrated that in pediatric MPNST patients, the incidence was higher among adolescents; localized disease and surgical resection were positive prognostic factors, and median overall survival was only 30 months, consistent with other reports suggesting less favorable outcomes for MPNST among challenging NRSTS cases.[63] Unfortunately, MPNSTs often present with large tumors in axial locations, both of which are clinical factors reported to adversely impact outcome[63] (**Figs. 24.3** and **24.4**).



A

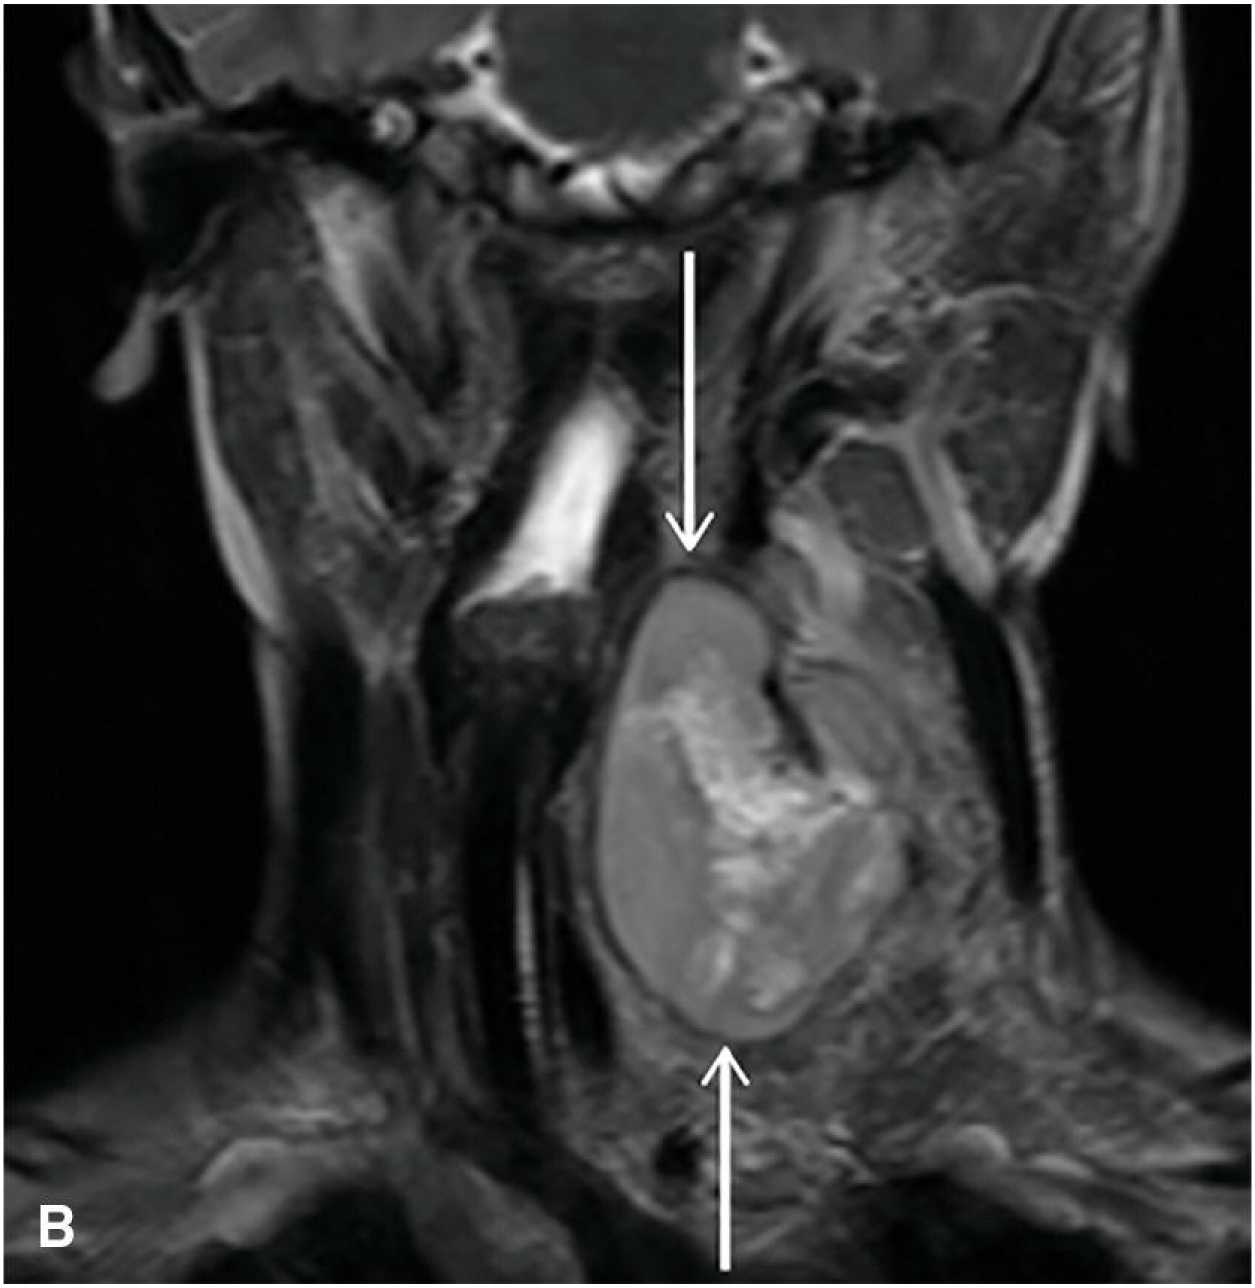


Figure 24.3. Axial **(A)** and coronal **(B)** T2-weighted images through the neck of a 7-year-old child show a heterogeneous, fairly well-marginated mass (*arrows*) involving the retrostyloid parapharyngeal space. The lesion was subtotally resected and found to be a malignant peripheral nerve sheath tumor (MPNST).

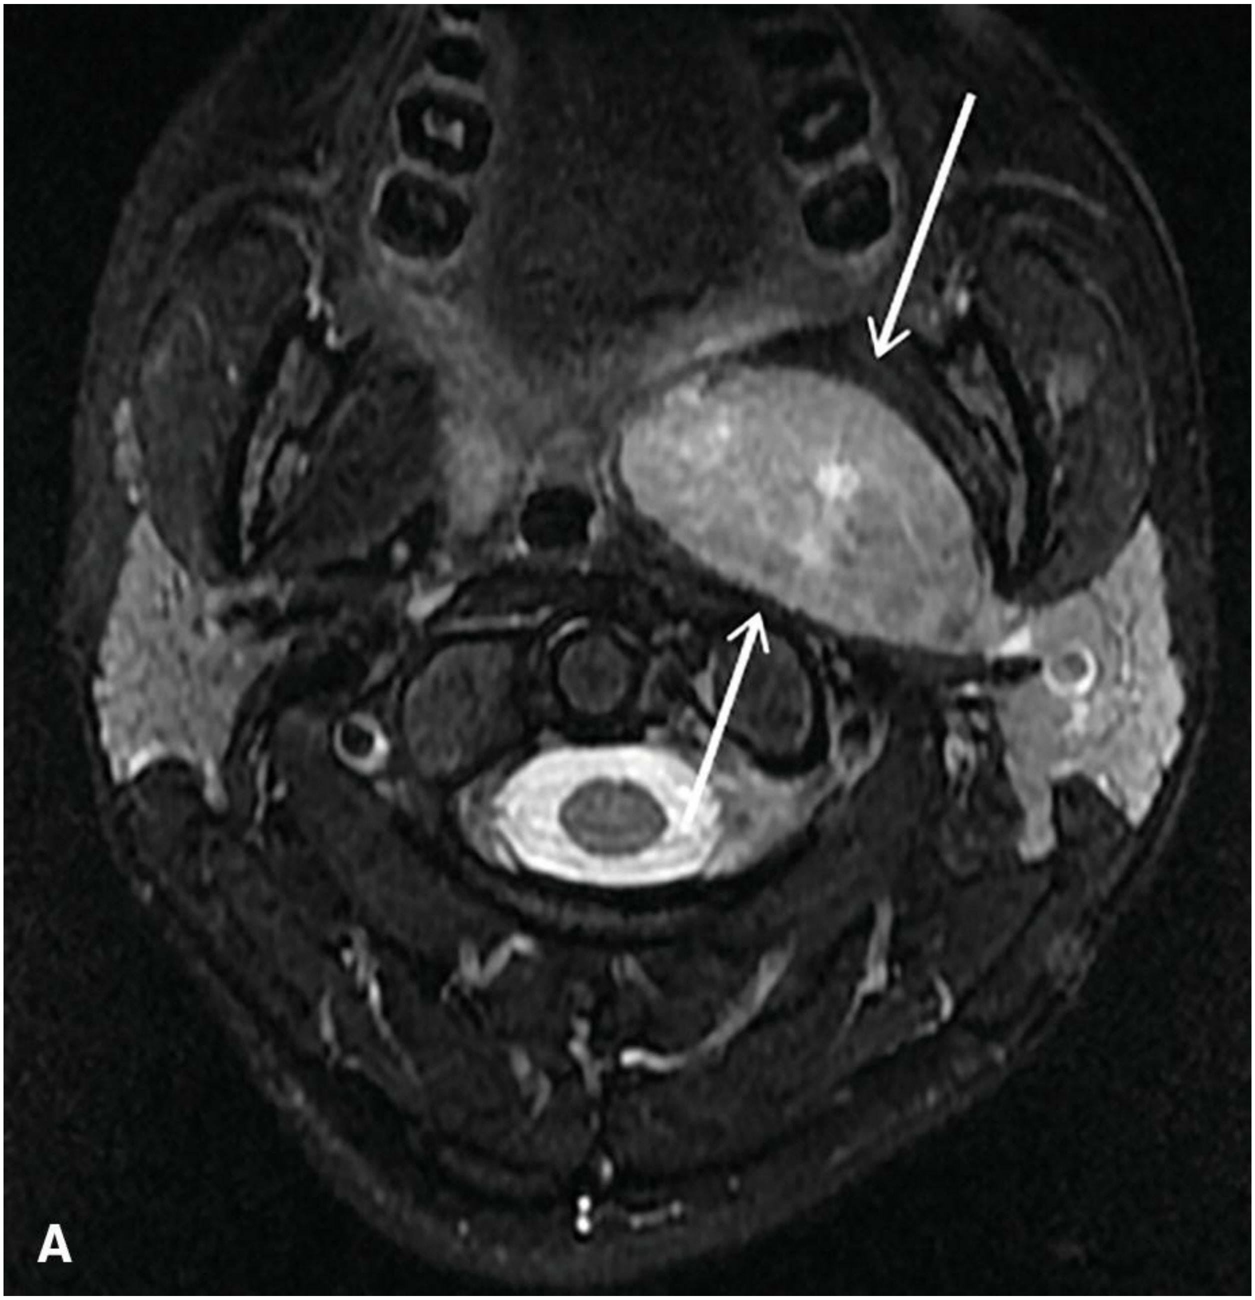

A

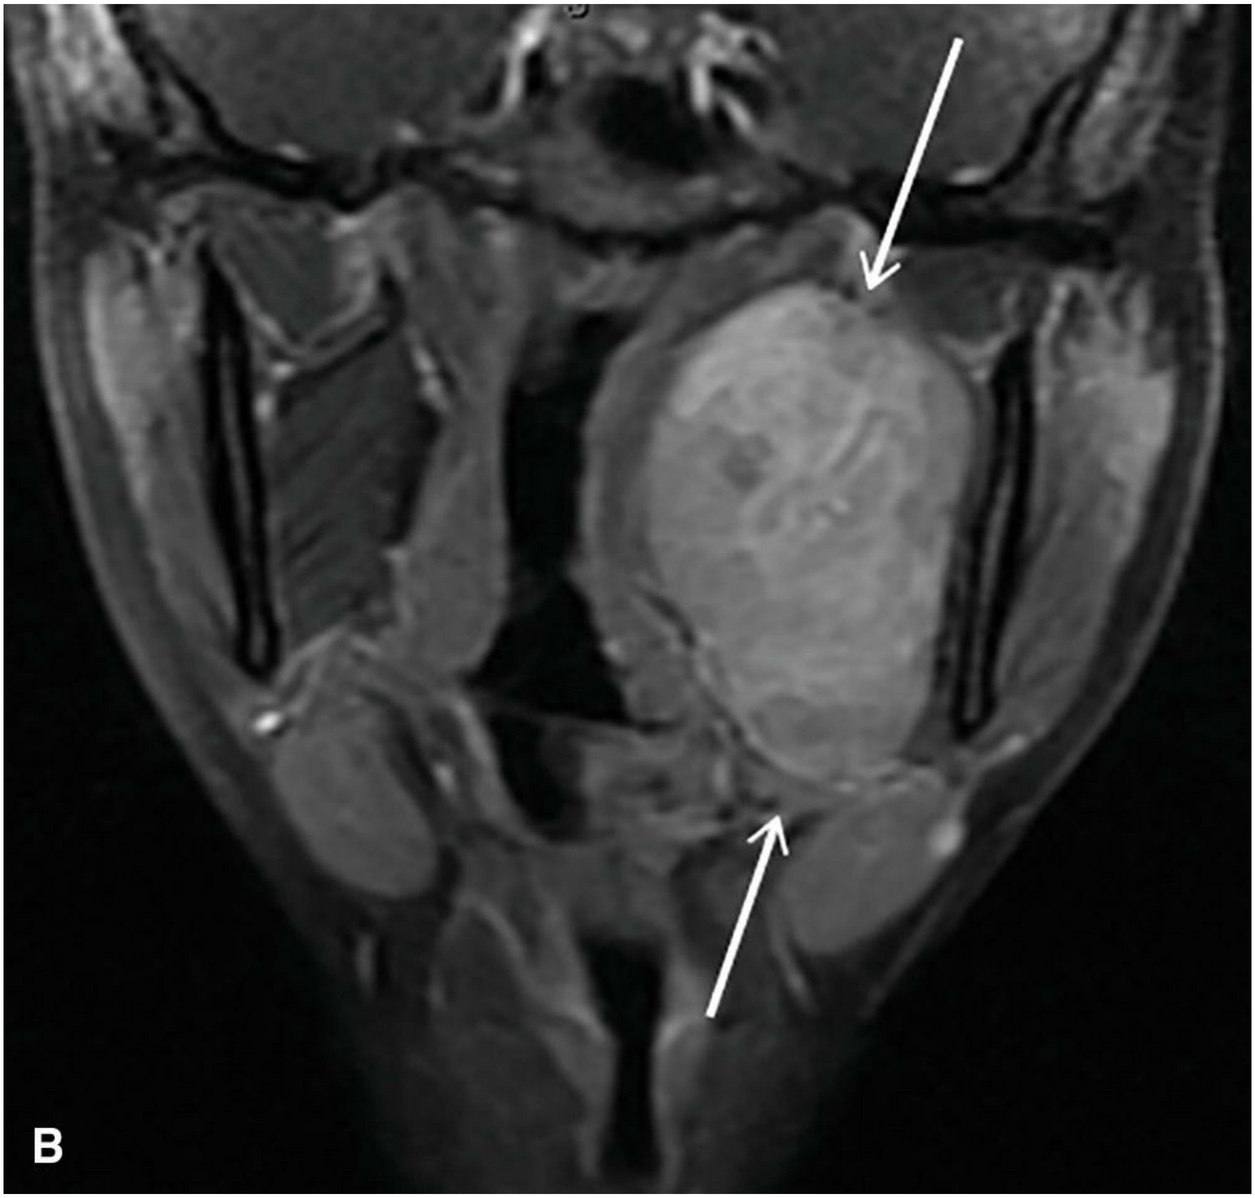

Figure 24.4. Axial fat-saturated T2-weighted **(A)** and coronal postgadolinium fat-saturated T1-weighted **(B)** images of the neck of a 27-year-old survivor of childhood neuroblastoma demonstrate a mildly heterogeneous well-defined mass in the left parapharyngeal space. The lesion was resected and determined to be an MPNST.

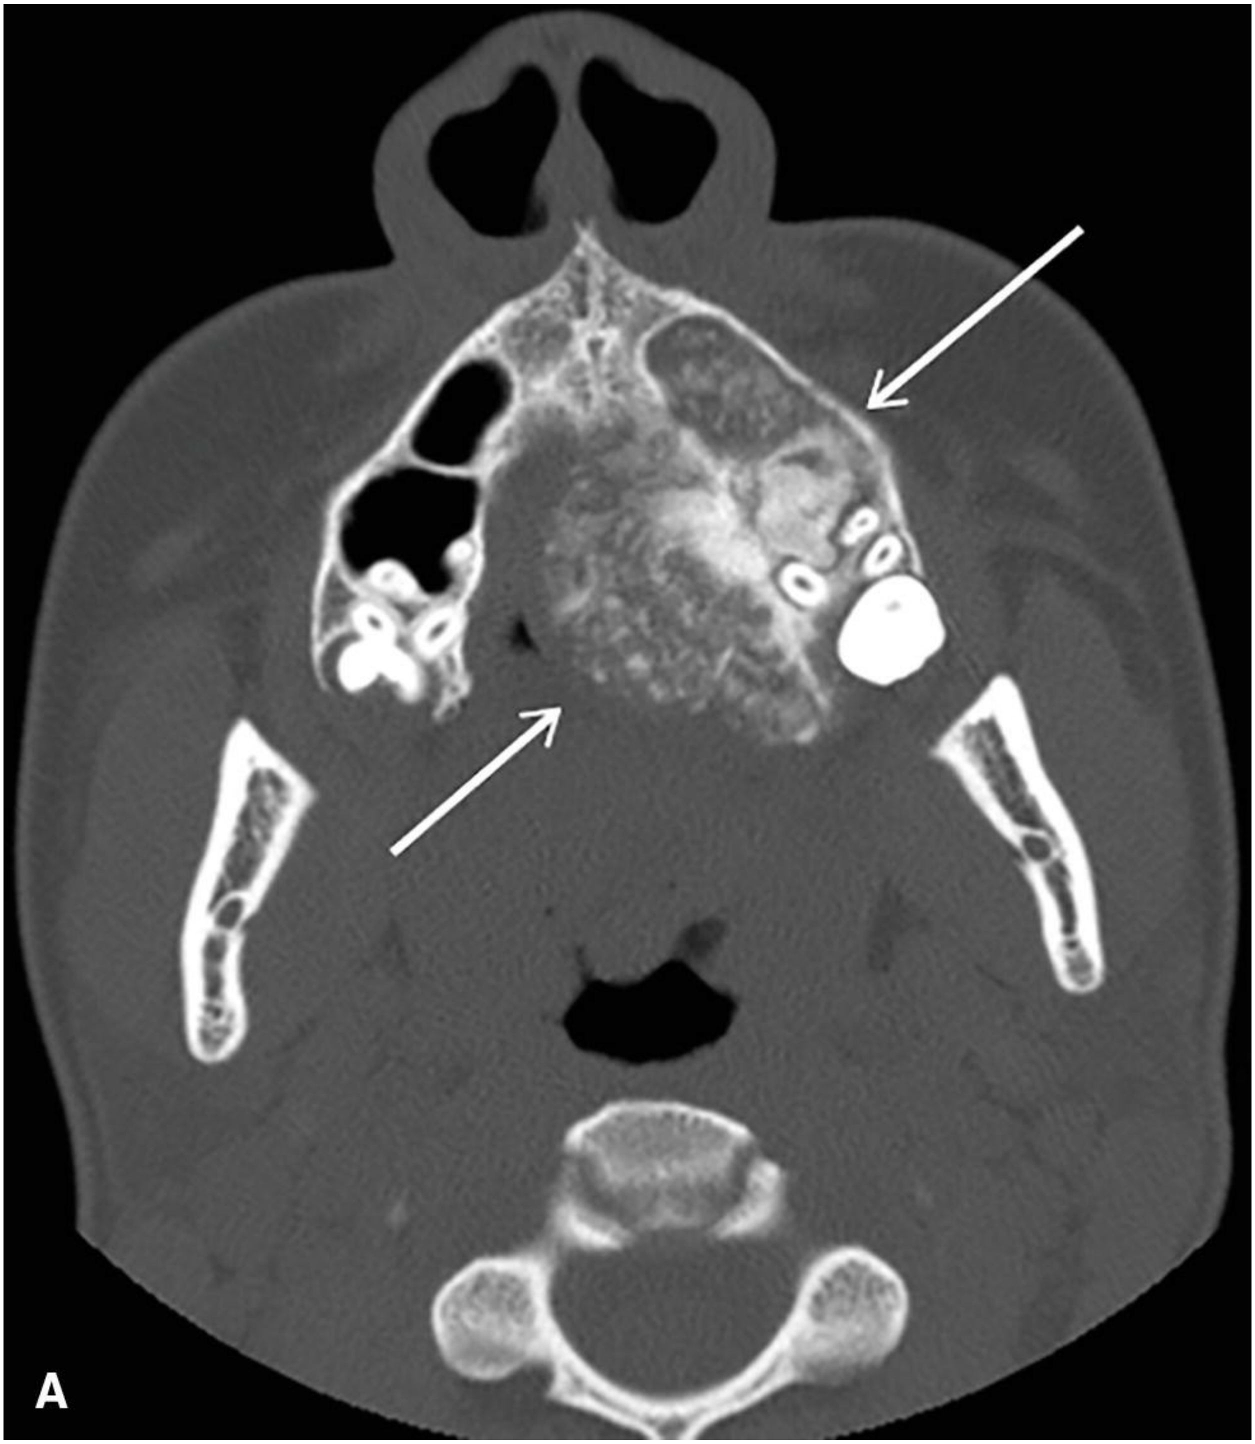
Other reported NRSTSs presenting in the head and neck in children and adolescents have included alveolar soft part sarcoma, epithelioid sarcoma, dermatofibrosarcoma protuberans, malignant hemangiopericytoma, leiomyosarcoma, fibrosarcoma, myofibroblastic sarcoma, inflammatory myofibroblastic tumor, and undifferentiated sarcoma.[8,57,62,63,65] Definitive

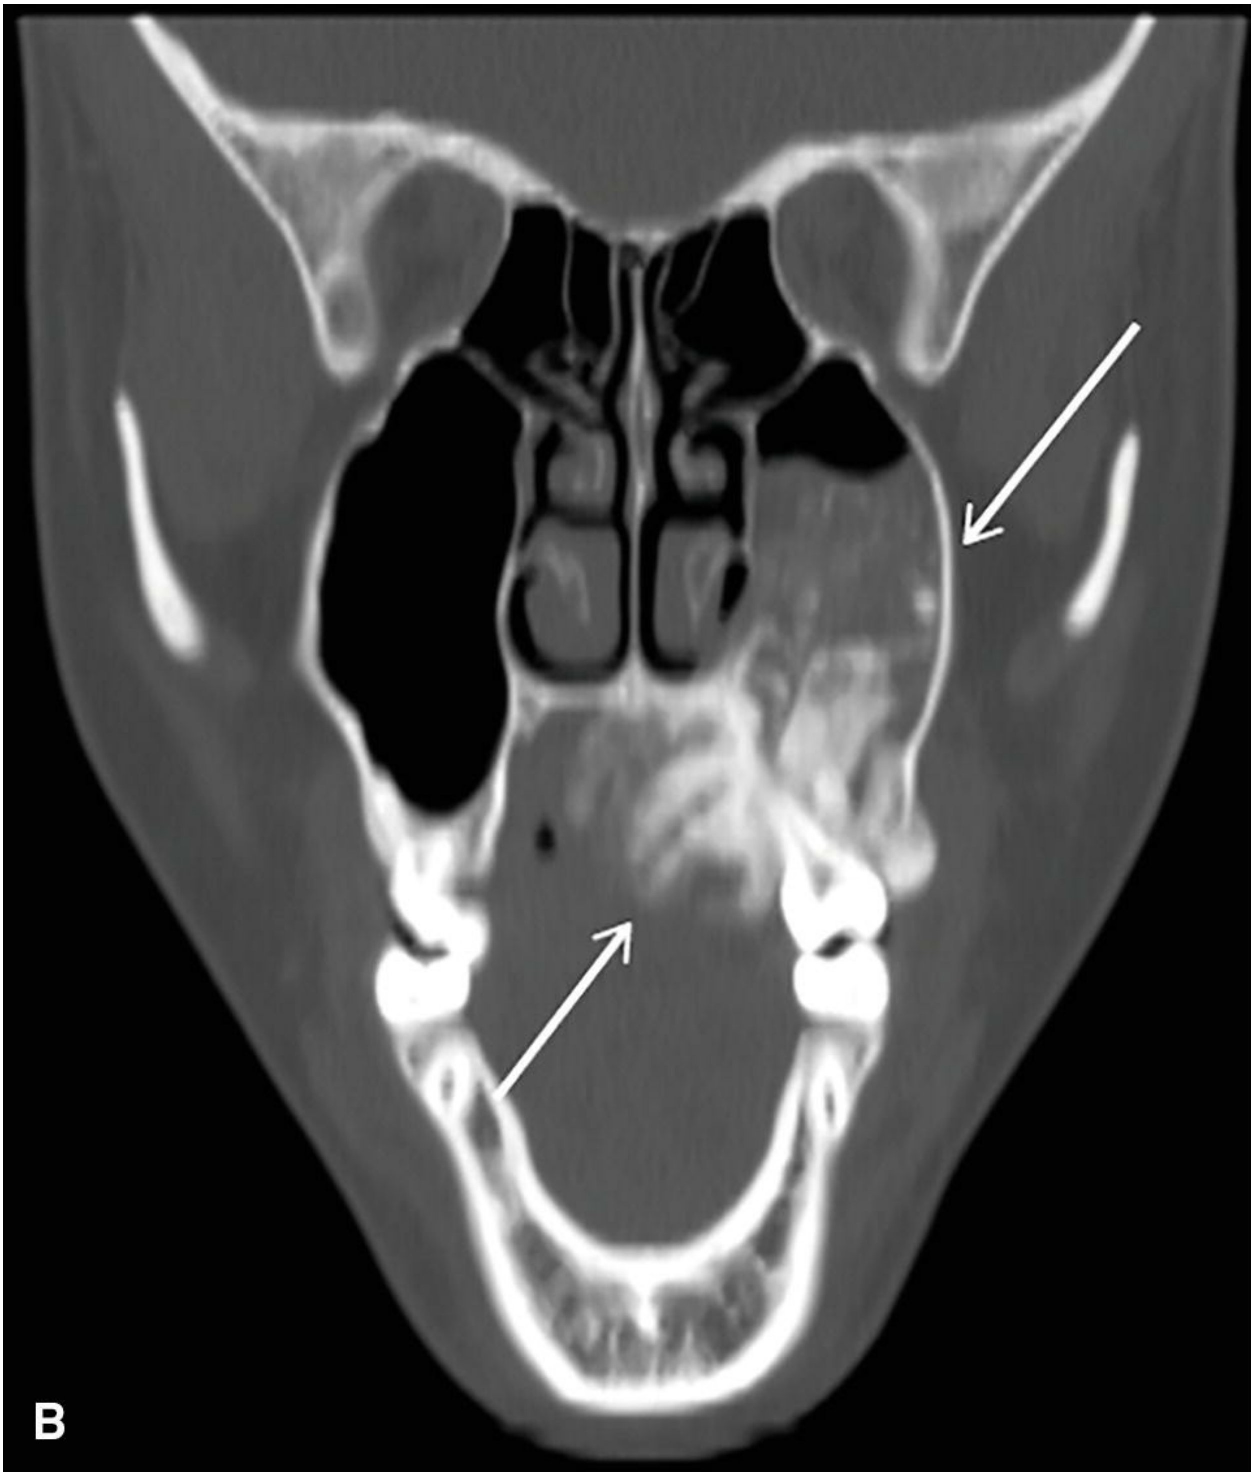
management is predicated on accurate diagnosis and coordinated multidisciplinary care. In the largest single-institutional retrospective review to date, Federico et al. described 58 pediatric and young adult patients with head and neck NRSTSs from 1964 to 2003.[57] Most patients were found to have small, high-grade tumors. Rates for event-free and overall survival at 10 years were 53% and 63% respectively. High grade, large size (>5 cm), invasiveness, and gross residual disease after surgery were associated with worse prognosis.[57] Novel approaches and further prospective data are needed to define optimal standardized management for children with NRSTSs.

Bone Sarcomas and Related Tumors

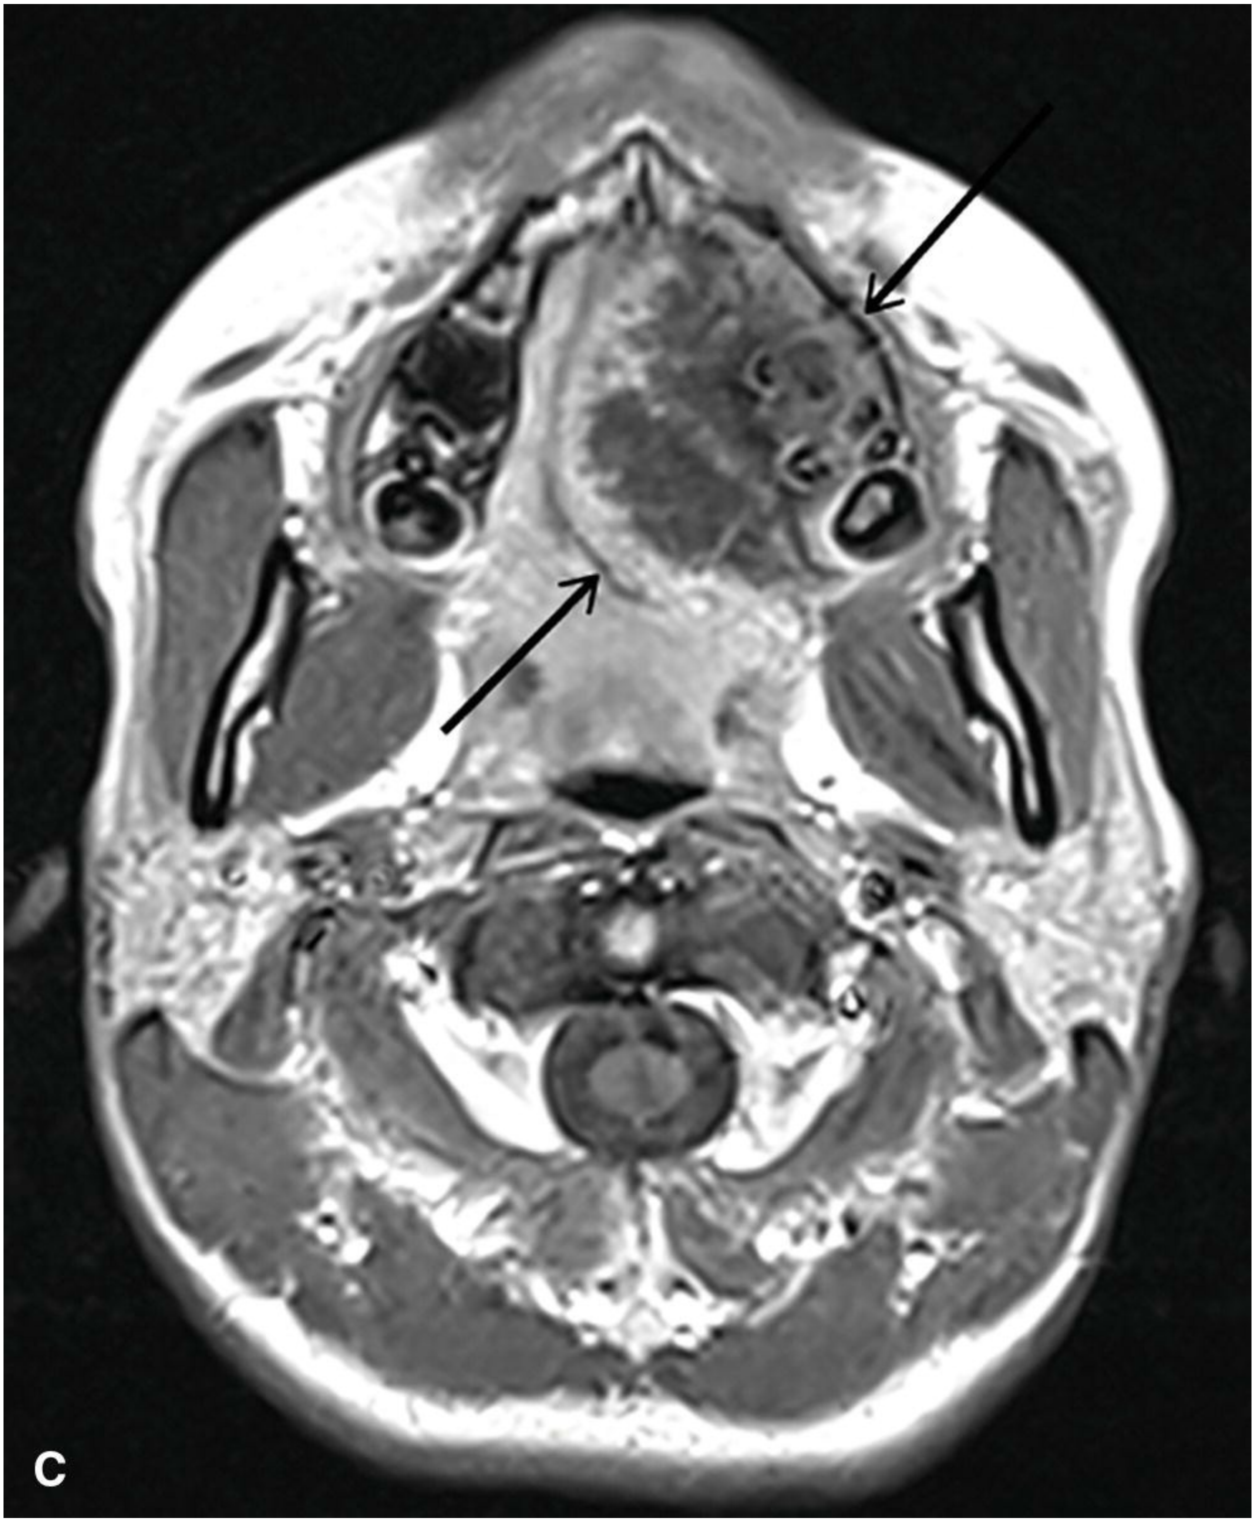
Pediatric bone sarcomas of the head and neck are generally rare and typically are localized at diagnosis.[66] Although osteosarcoma represents the most common pediatric bone sarcoma, only ~6% to 13% arise in the head and neck.[67] The maxilla and mandible are the most common sites and are also associated with better prognosis than are other, extragnathic sites in the head and neck.[67,68] Osteosarcomas in the head and neck appear distinct in a number of ways from the typical osteosarcoma that presents in the extremities, with variable histology, more often involving low or intermediate tumor grade, higher risk for local recurrence and less risk for distant metastatic disease compared to extremity osteosarcomas.[8,68] On CT scan, the tumor appears expansile with a prominent periosteal reaction and/or mineralization associated with osteoid tumor matrix[69] (**Fig. 24.5A and B**). MRI demonstrates a heterogeneous mass with low–signal intensity areas on both T1- and T2-weighted images, consistent with osseous lesion components, and intermediate- (T1-weighted) to high-signal (T2-weighted) tumor components that correspond to soft tissue (Fig. 24.5C and D). Complete surgical resection remains the foundation for improved failure-free and survival outcomes.[66,68] Prospective clinical data are warranted to better verify and define how prognostic factors, such as posttherapy tumor necrosis, as well as treatment approaches utilized for extremity osteosarcomas, including radiation therapy and chemotherapy, should be best interpreted and applied in head and neck osteosarcomas.[8,70] In addition to primary osteosarcoma, secondary osteosarcoma should be considered in older children or adolescents with a prior history of irradiation of the head and neck or prior hereditary retinoblastoma, with potential for similar outcomes as

those with primary osteosarcoma.[68]





B



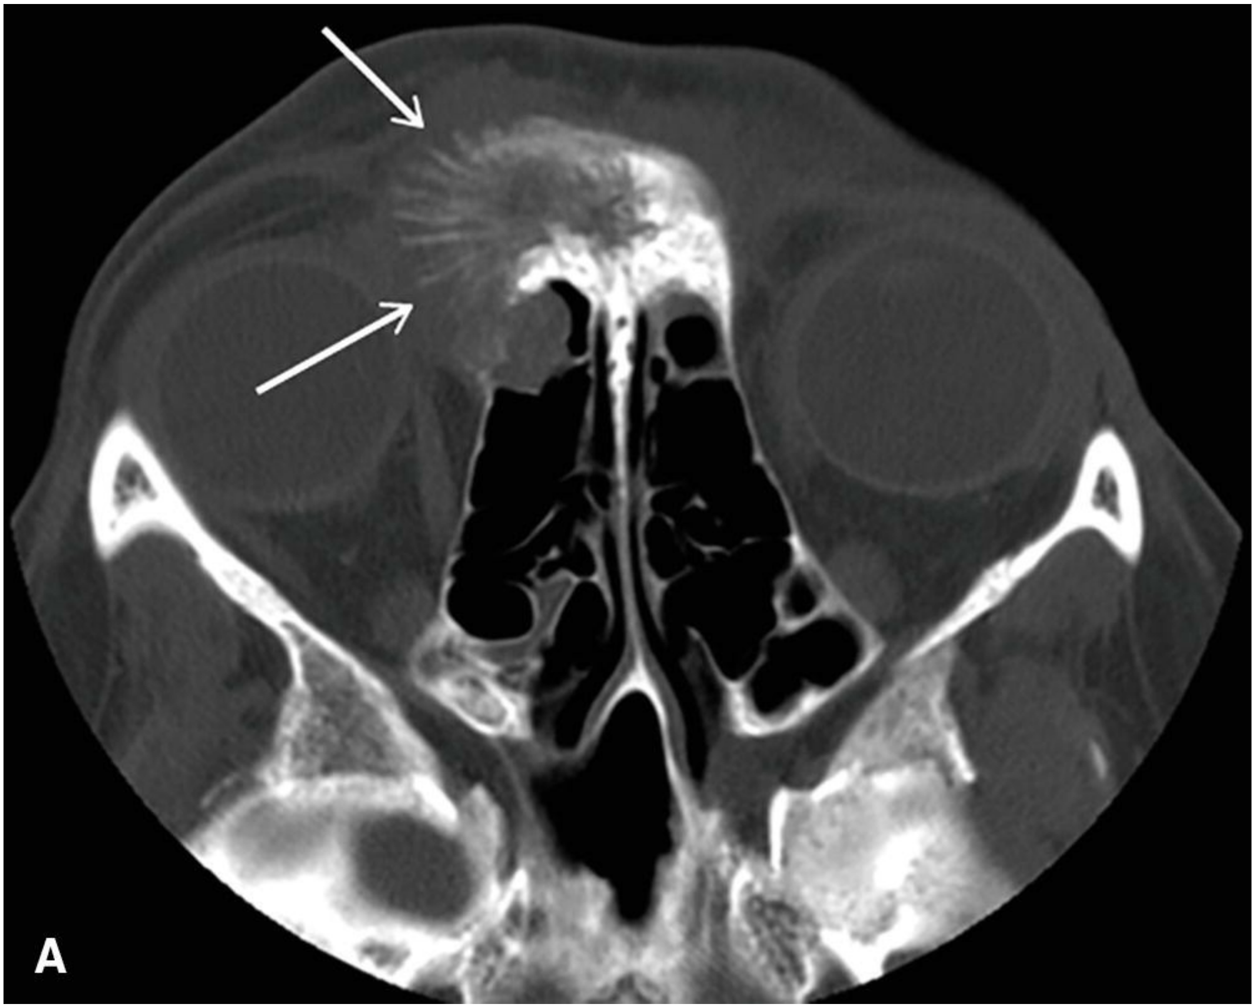
C

Figure 24.5. Axial **(A)** and coronal **(B)** noncontrast CT scan images of the maxillofacial region of a 14-year-old patient demonstrate an expansile,

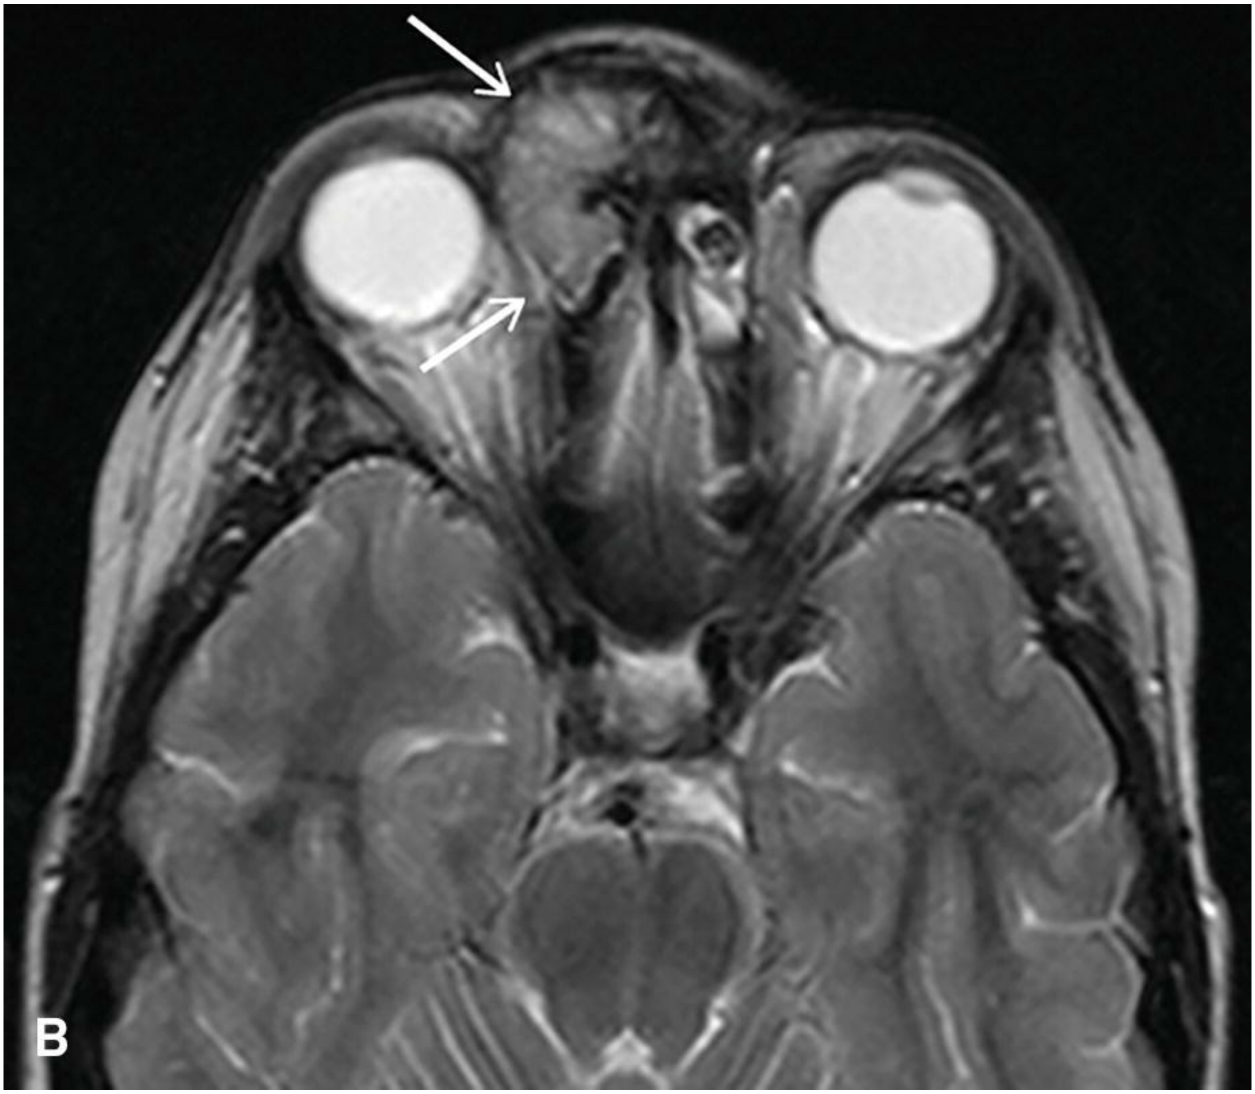
destructive mass (*arrows*) in the left maxilla, including the left maxillary sinus, with a bony matrix. Axial **(C)** and coronal **(D)** postgadolinium T1-weighted images of the same patient's face show the mass (*arrows*) to contain a predominantly peripheral enhancing soft tissue component that surrounds low-signal internal osseous matrix and portions of the eroded maxilla and hard palate. Biopsy showed the lesion to be an osteosarcoma.

In addition to its presentation in the soft tissues, MFH can also develop less commonly as a primary bone tumor, most often involving the maxilla and mandible, and has been conventionally treated similar to osteosarcoma.[66,68]

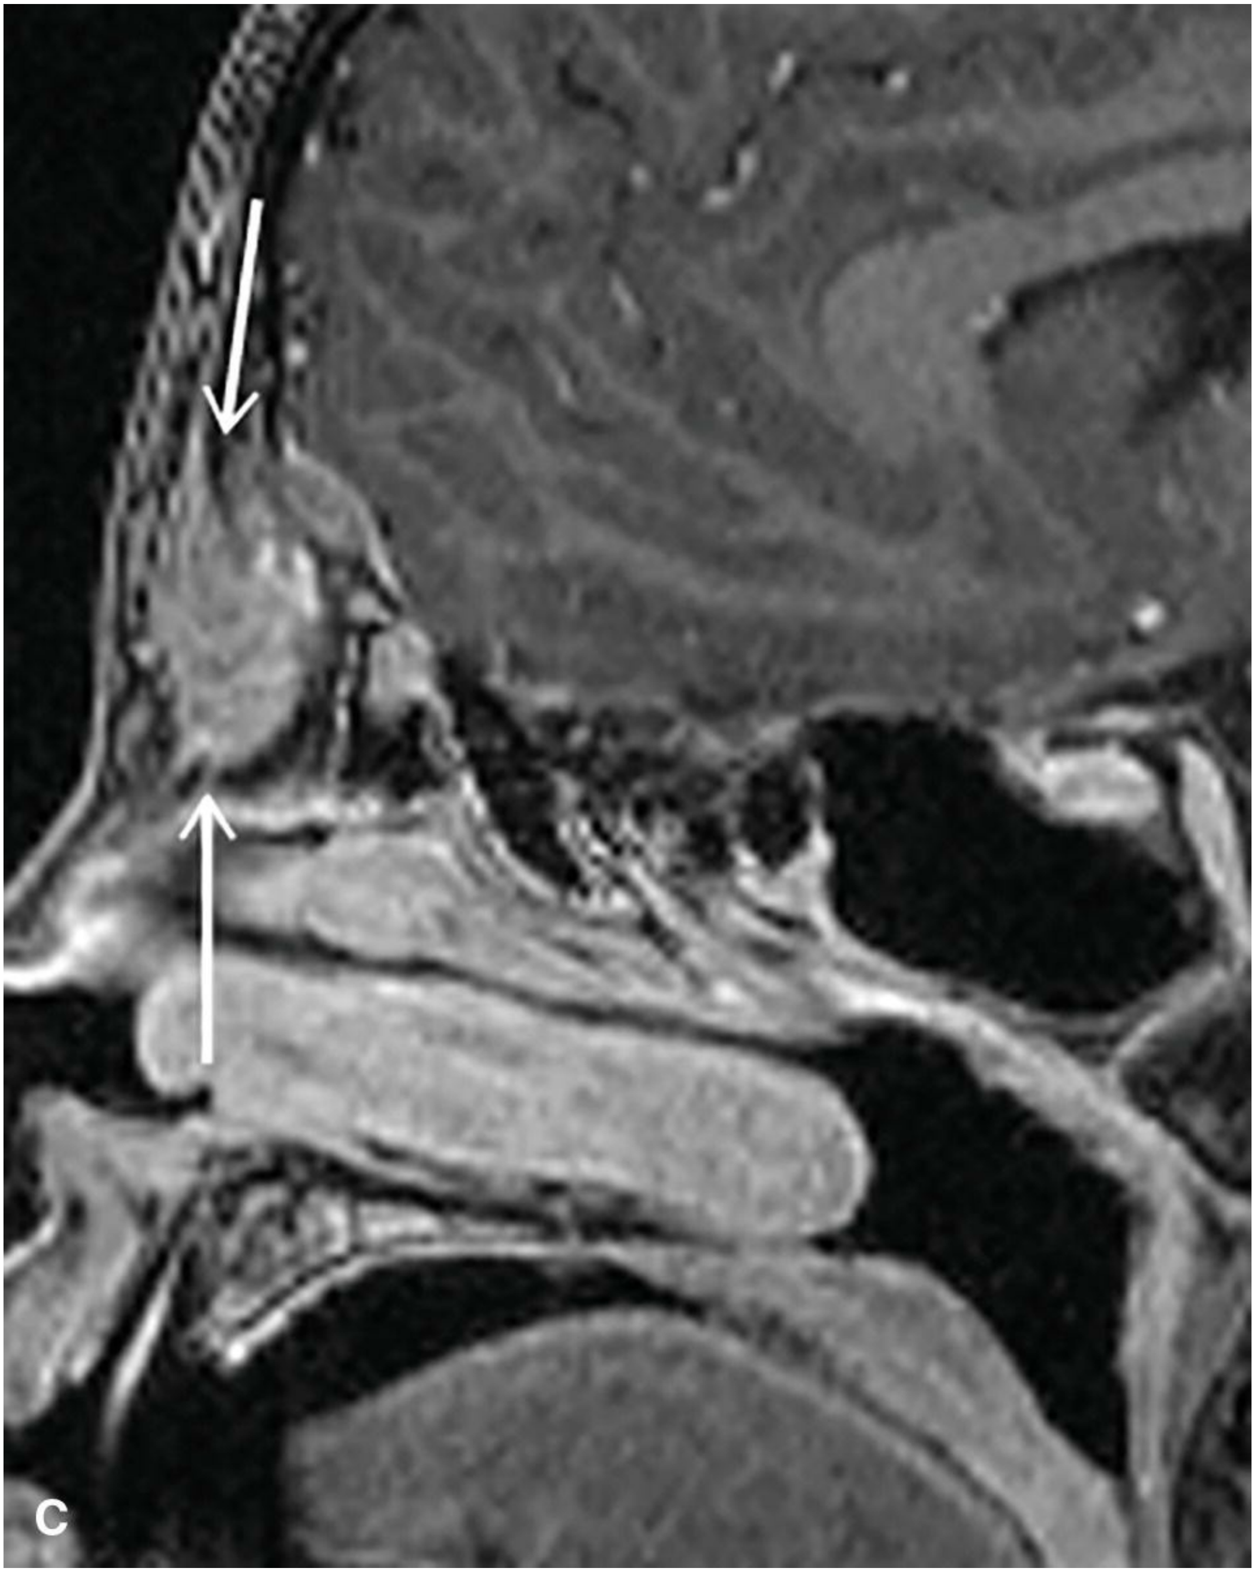
Ewing sarcoma is the second most common pediatric bone sarcoma; similar to osteosarcoma, fewer than 10% of the cases involve the head and head region. The presentation of Ewing sarcoma in the head and neck is heterogeneous and can involve varied parts of the skull. Ewing sarcoma may also present in the soft tissues, cutaneously and subcutaneously, as extraosseous lesions constituting the established Ewing sarcoma family of tumors, with reported pediatric cases in the head and neck.[71] Ewing sarcoma has a variable imaging appearance, usually with aggressive characteristics.[72,73] CT scanning often demonstrates a destructive lesion with a "sunburst" or "hair-on-end" periosteal reaction (**Fig. 24.6A**). On MRI, the tumor may have a heterogeneous appearance with the "hair-on-end" periosteal reaction seen as low–signal intensity bands on T2-weighted images (Fig. 24.6B). Ewing sarcoma usually displays diffuse, heterogeneous enhancement (Fig. 24.6C and D). Systemic chemotherapy, coupled with surgery and/or radiation therapy, is typically a mainstay in management, with a less clearly defined role for aggressive surgery as compared to the use of surgery in the management of osteosarcoma or other bone sarcomas of the head and neck in children.[8,66]



A



B



C

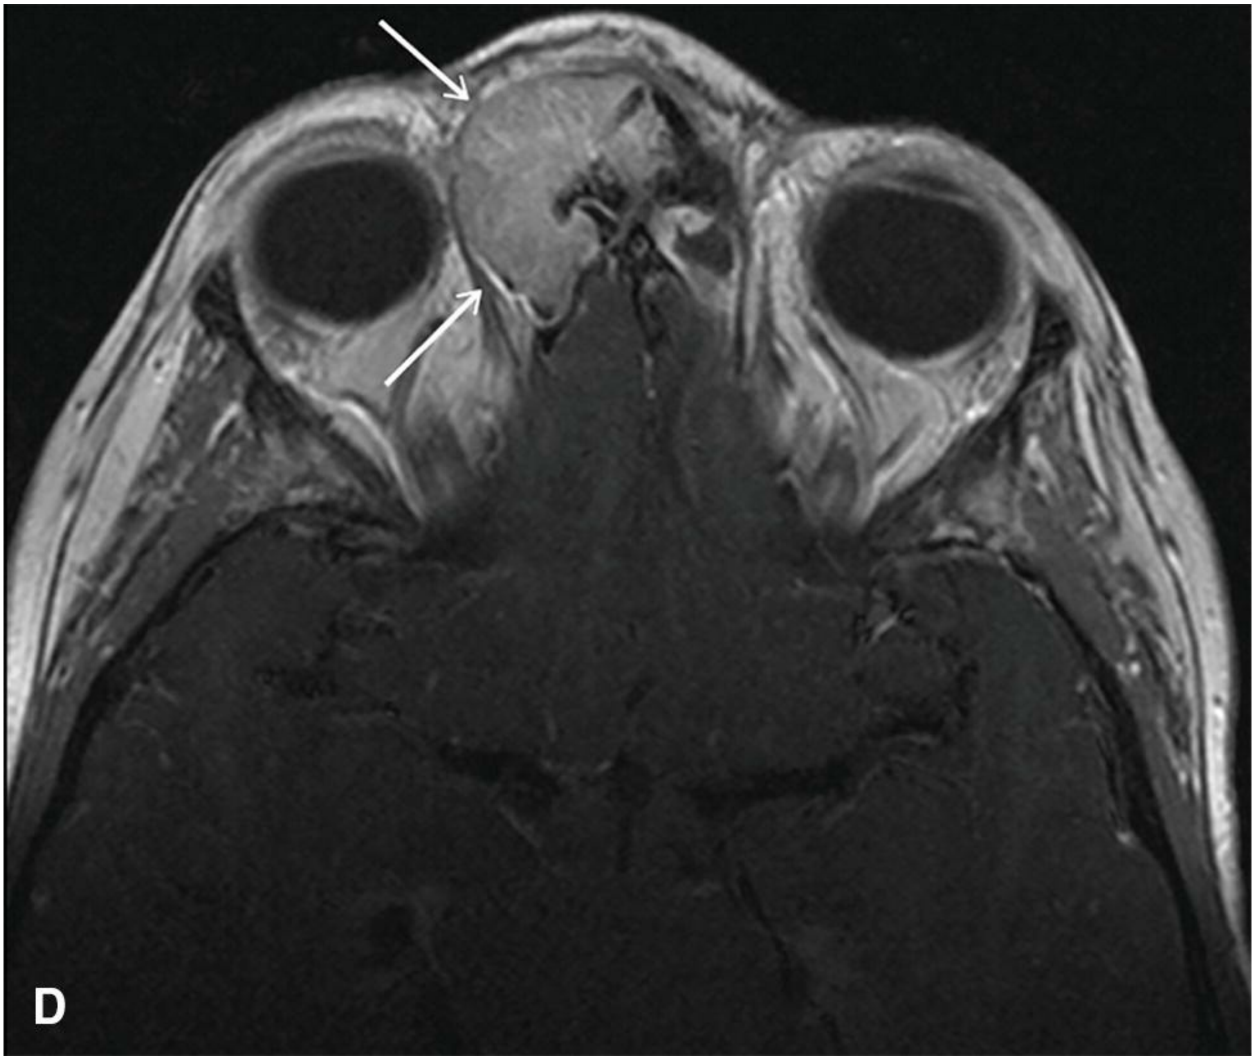


Figure 24.6. A: An axial CT scan image demonstrates a destructive lesion in the right orbitofrontal region of a 12-year-old child with a “hair-on-end” periosteal reaction (*arrows*). **B:** On axial T2-weighted image the “hair-on-end” spiculations appear as low–signal intensity bands that extend through predominantly high–signal intensity tumor (*arrows*). Sagittal **(C)** and axial **(D)** postgadolinium T1-weighted images reveal diffuse mildly heterogeneous enhancement within the mass. The lesion was resected and found to be Ewing sarcoma.

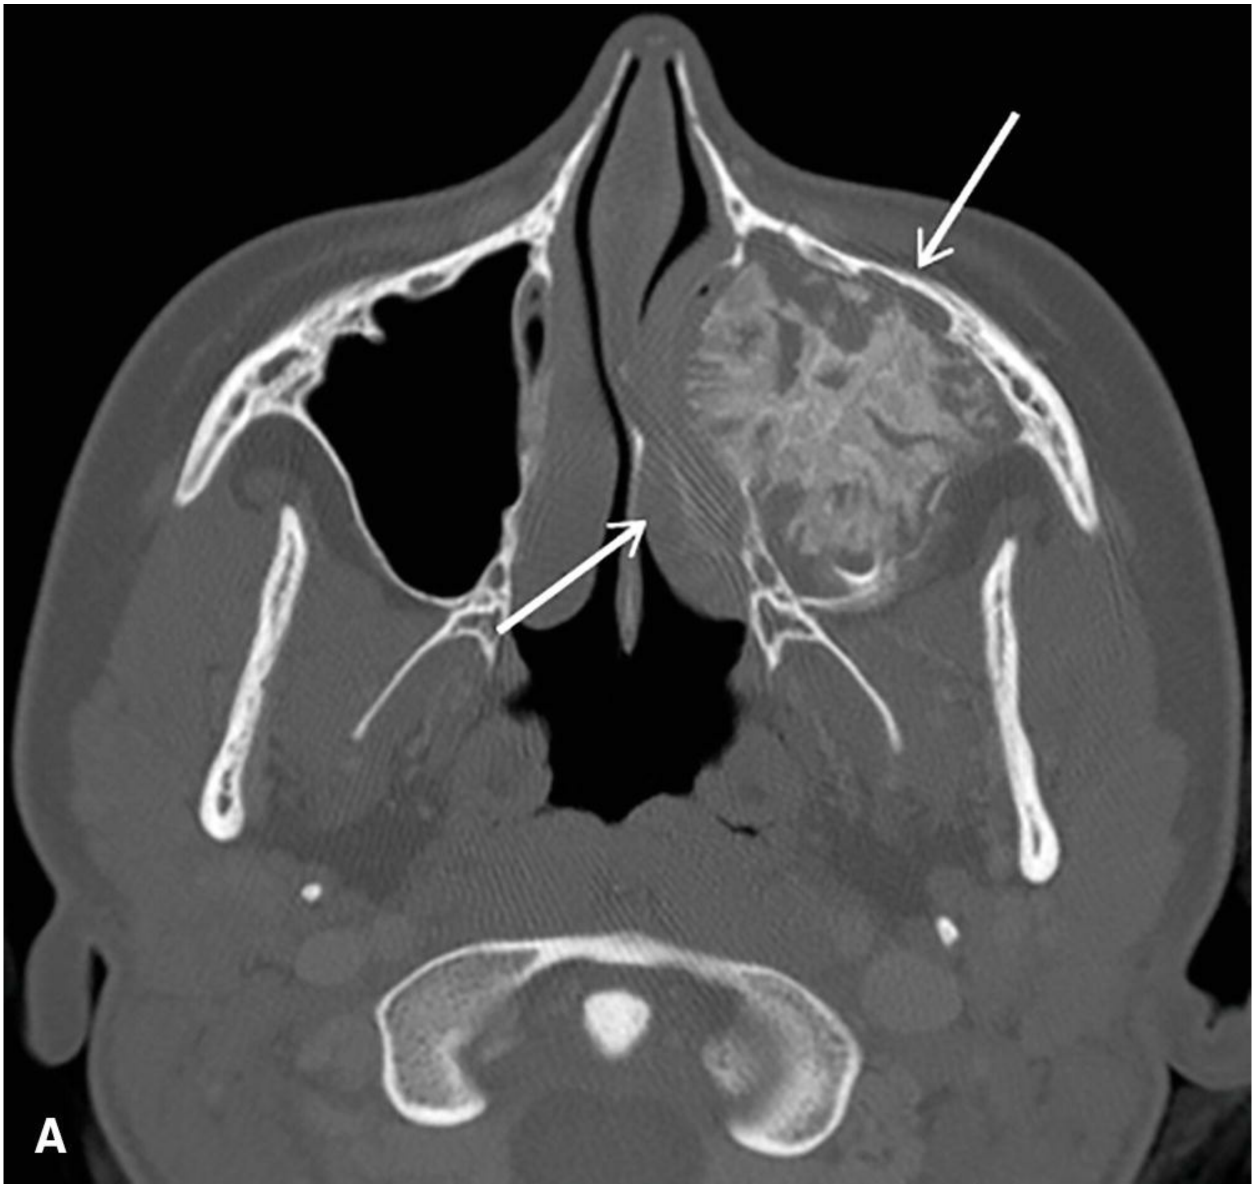
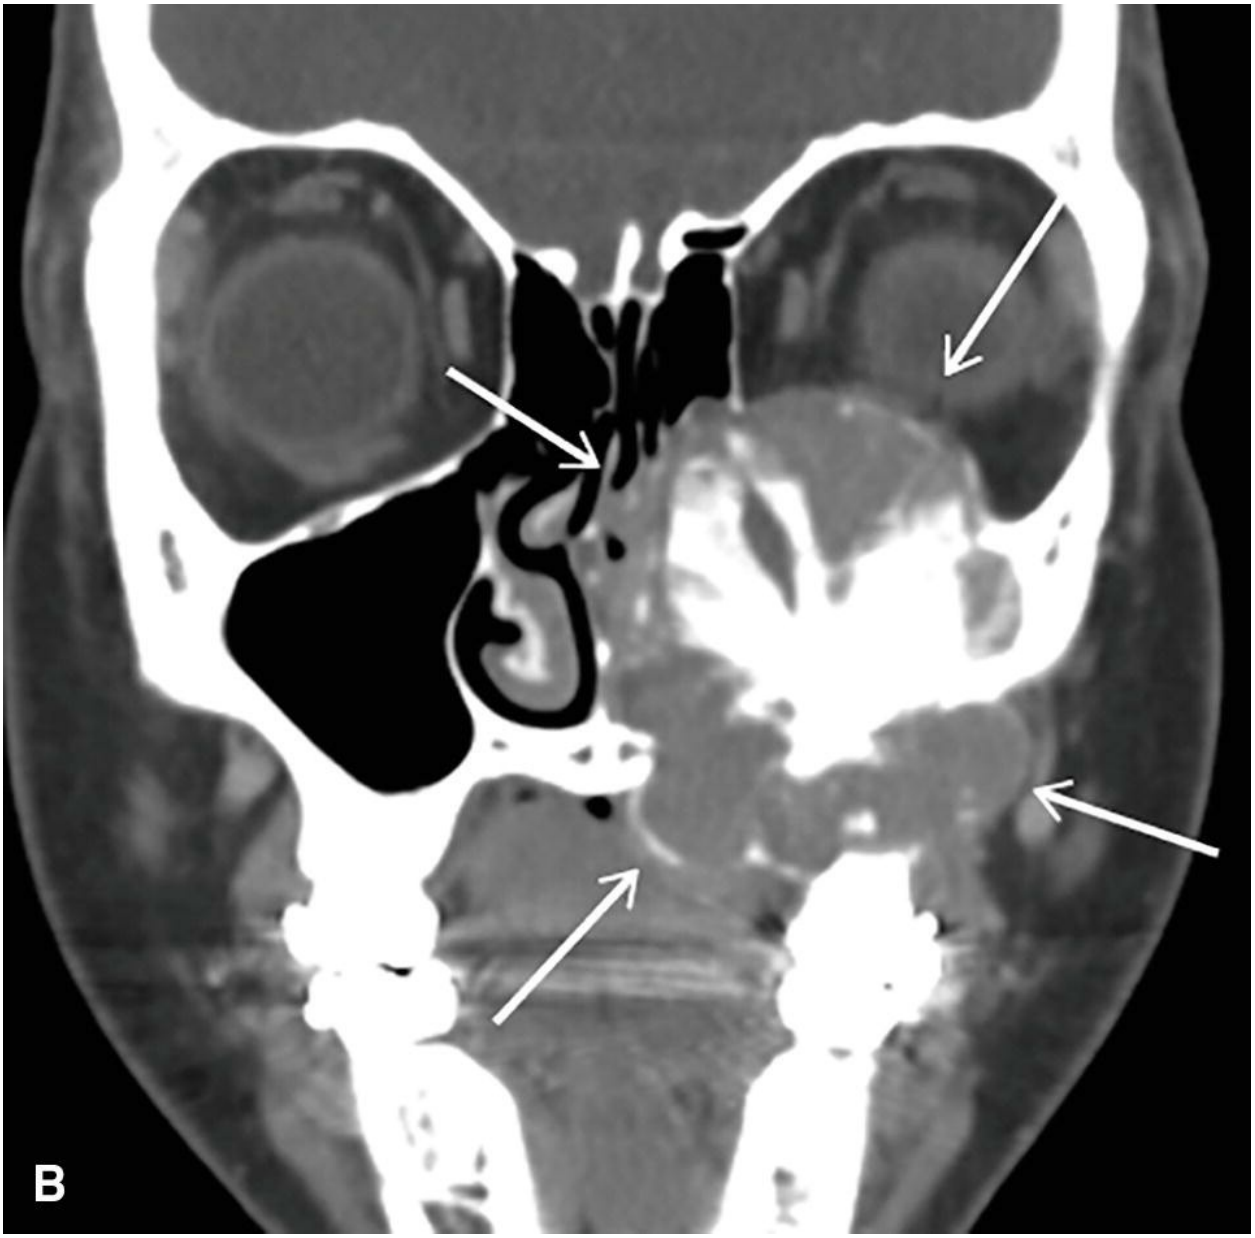
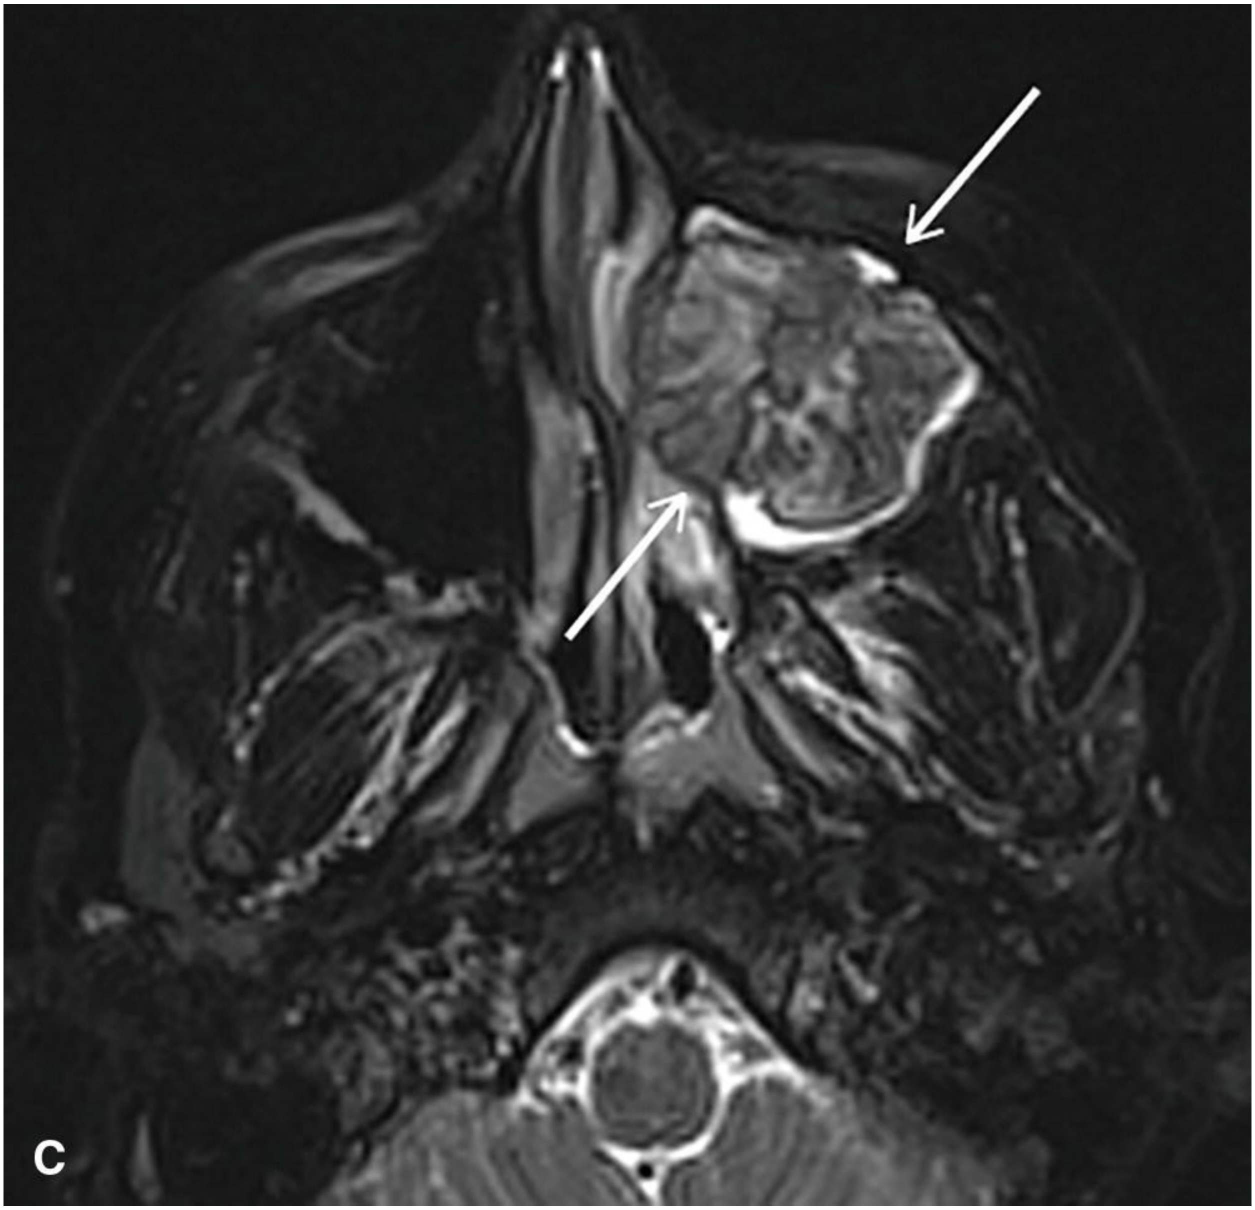
Chondrosarcoma can also occur in children and adolescents and is usually low grade, but can also include higher-grade and aggressive subtypes.[8] Chondrosarcoma has a varied appearance on imaging that may include coarse calcifications and destructive changes on CT scan, high signal intensity on T2-weighted MR images, low signal intensity on unenhanced

T1-weighted images, and variable enhancement[74,75] (**Fig. 24.7**). The mainstay of therapy is typically surgical resection, with exploration of radiation therapy and chemotherapy in selected cases.[8,76,77] Fibrosarcoma can also manifest as an uncommon pediatric primary bone tumor and is typically managed with wide surgical resection.[66] Overall, ongoing efforts are warranted to continue optimizing survival alongside functional and long-term outcomes for pediatric head and neck sarcomas.





B



C

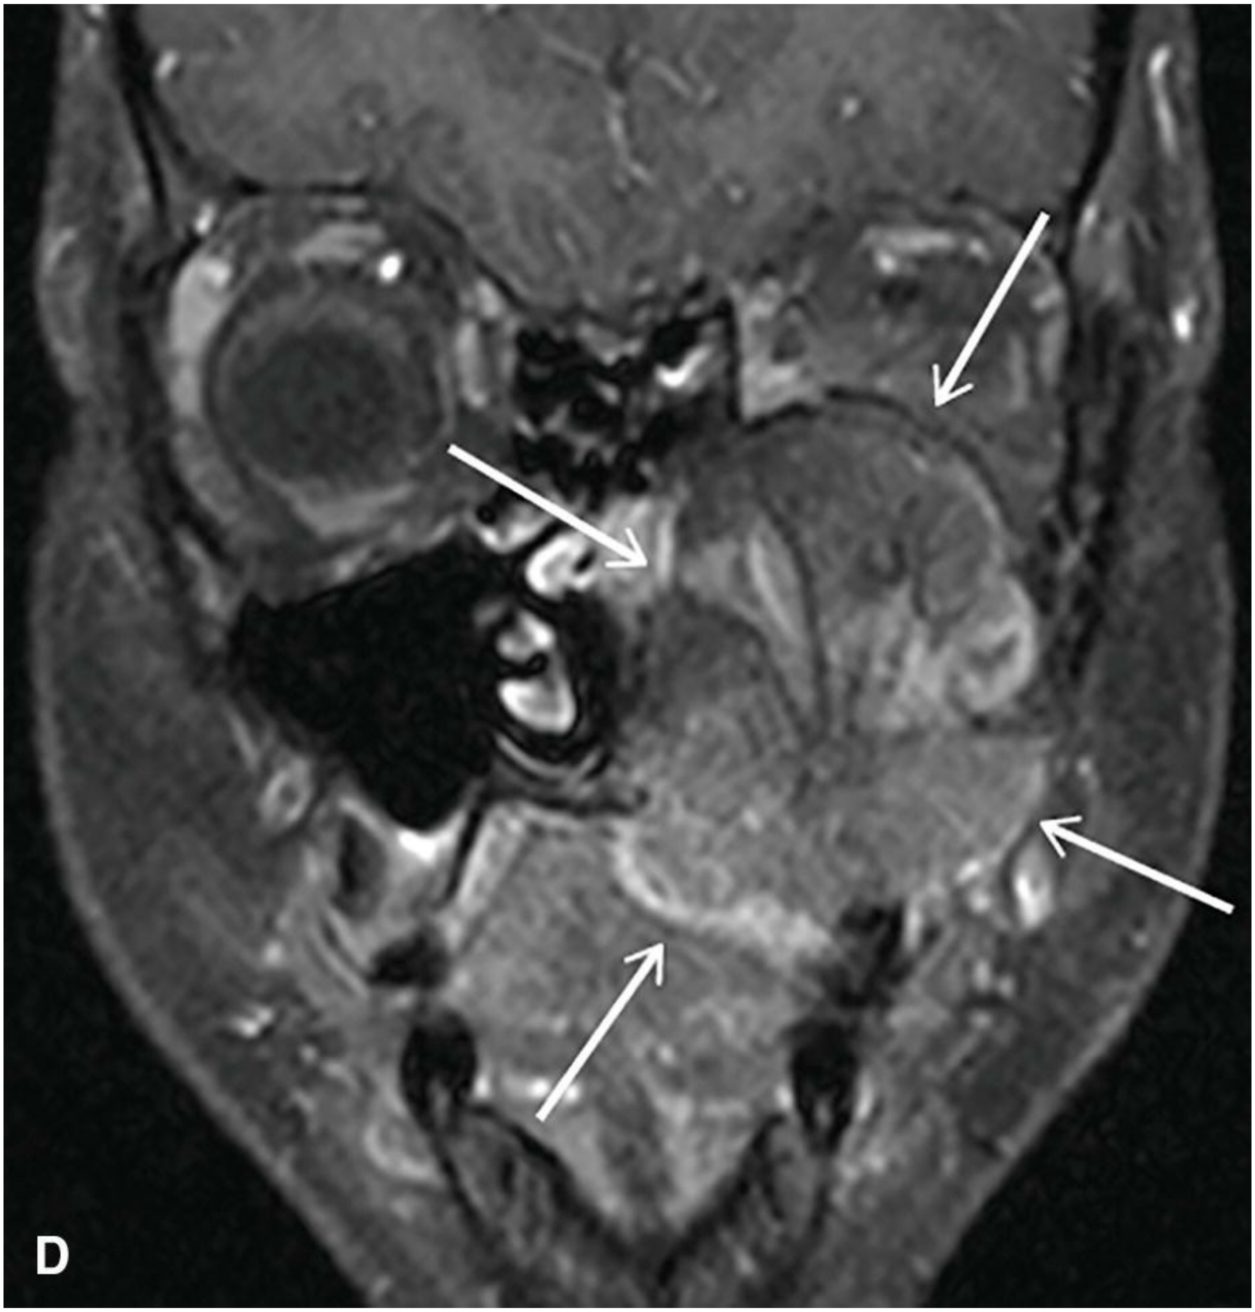


Figure 24.7. An axial CT scan image **(A)** with bone windows and a coronal CT scan image **(B)** with soft tissue windows reveal an erosive mass (*arrows*) centered in the left maxillary sinus of a 13-year-old patient that contains prominent coarse calcifications. The lesion extends into the left nasal cavity and left orbit and through the left side of the hard palate. **C:** A fat-saturated T2-weighted image demonstrates hyper- and hypointense areas within the mass (*arrows*) that correspond to noncalcified and calcified tumor components respectively. **D:** A postgadolinium fat-saturated coronal T1-weighted image shows heterogeneous enhancement of the tumor (arrows)

which, after resection, was determined to be a mesenchymal chondrosarcoma.

A

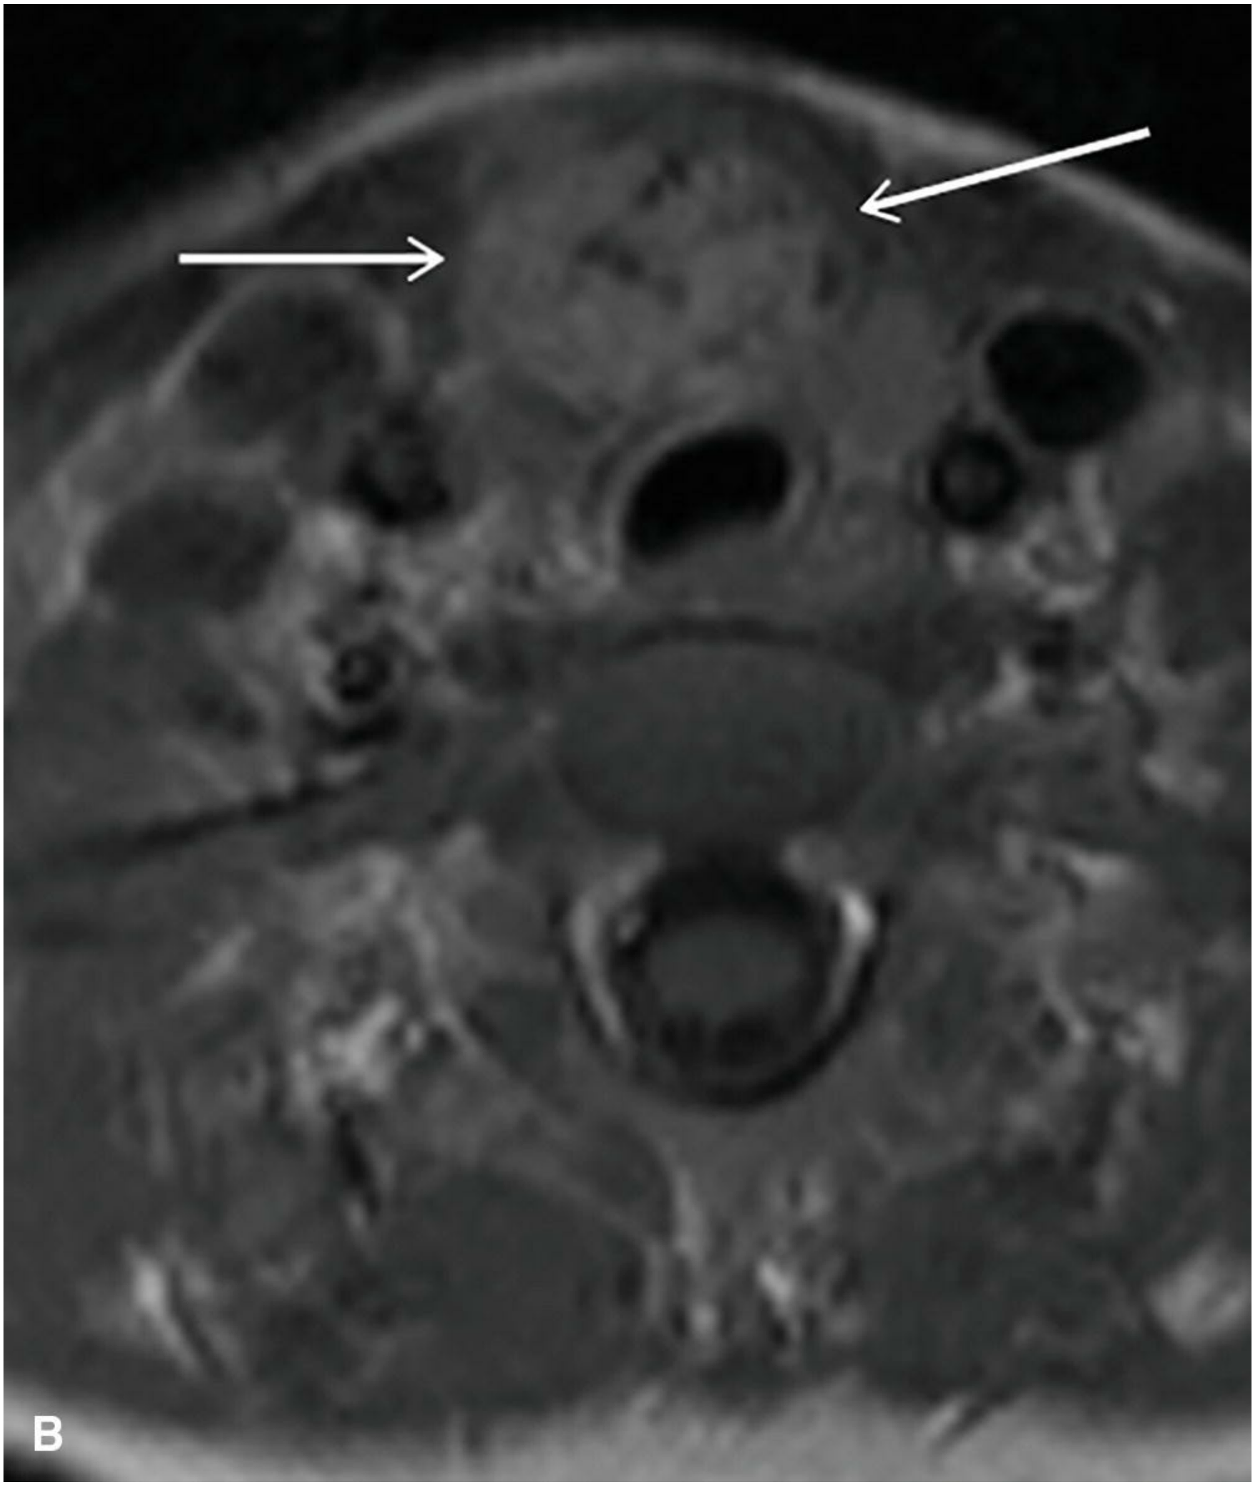

Figure 24.8. Axial T1-weighted **(A)** and postgadolinium T1-weighted **(B)** MRI images through the neck of a 3-year-old child demonstrate a mildly heterogeneous mass (*arrows*) anterior to the trachea. Almost all of the lesion enhances. Biopsy revealed a desmoid tumor.

Desmoid Tumors

Desmoid tumors (DT, also known as aggressive fibromatosis, desmoid-type fibromatosis, and musculoaponeurotic fibromatosis), first categorized in the 1960s, consist of a mesenchymal monoclonal proliferation that arises in musculoaponeurotic structures.[78,79] Incidence of 0.2 to 0.4 per 100,000 population has been reported with a relative peak incidence between puberty and age 40 years in women.[80] The incidence of childhood aggressive fibromatosis or pediatric desmoid tumors (PDT) peaks at about 8 years of age, with a range between birth and 19 years.[81,82] The broad histologic spectrum of DT falls between benign fibrous tissue proliferation and fibrosarcoma.[83] Although these tumors lack metastatic potential, they frequently recur locally owing to their capacity to infiltrate local tissues with a potential for significant local morbidity, even leading to death.[84] They also have a high incidence of recurrence after treatment, estimated between 24% and 77%. Two different types of DT are described: the isolated desmoid tumor and one seen in relationship with familial adenomatous polyposis/Gardner syndrome.[85,86] Interestingly, the progression of the tumor appears to be hormonally based, with regression occurring in females during menarche and menopause.[87]

Unlike their adult counterpart, data pertaining to PDT are sparse, and published reports suggest that pediatric desmoids may be particularly aggressive and difficult to control.[88,89] Recent data have emphasized the propensity of adult DT toward “biologic burnout.”[90,91] One recent study found that in 50% of adult patients affected by primary disease, and treated with observation only, progression did not occur by 5 years. Thus, a policy of initial observation has been advocated by some authors. Concurrent research has focused on the search for prognostic indicators for the purpose of patient risk stratification. Surgery has been considered the mainstay of treatment, with studies indicating that local recurrence rates after surgical resection range from 10% to 80%, when margins are negative or positive, respectively.[92,93] These data are in contrast to other adult studies reporting recurrence rates from 30% to 50%, regardless of margin status.[94] The pathogenesis of DT likely represents a “field effect,” whereby subclinical spread is not detectable at the time of extirpation. The role of radiation therapy in the management of adult DT is controversial.[95,96] Many studies

have demonstrated durable local control in patients with marginally resectable or unresectable tumors treated definitively with radiation therapy. Radiation doses of 50 to 60 Gy achieve local control in 70% to 80% of adults treated for gross residual disease and may improve recurrence-free survival (RFS) compared with surgery alone; however, results in children are controversial. Chemotherapy may be used for tumors that are unresectable, recurrent, or whose surgical removal would result in significant morbidity.[95]–[99] Tumor size has not been found to consistently predict outcome, given that desmoid behavior is likely ultimately determined by multiple factors.[100] The anatomic site of the primary tumor can influence treatment strategies, particularly in prepubertal children for whom effects of surgery and radiation on growth and development must be considered.

On CT scan, desmoid tumors are often poorly defined and may erode adjacent bone. They have a variable appearance on T1-weighted MRI and may appear bright with small areas of low signal intensity on T2-weighted imaging. Following gadolinium contrast administration, desmoid tumors usually demonstrate diffuse or peripheral enhancement (**Fig. 24.8**).[101]

In a recent study from St. Jude Children’s Hospital, 39 patients with PDT, of whom 8 (21%) arose in the head and neck, were treated over a 12-year period. In the entire series, only 18% of patients had microscopically negative margins.[102] RFS at 5 years was 73.1%. Factors associated with decreased RFS were patient age >12 years, and tumor size >5 cm. Margin status did not affect RFS, and the selective use of radiation therapy appeared to improve RFS. Although most defects could be closed primarily, head and neck defects, in particular, more frequently required flap closure. Similarly, long-term issues with appearance, facial nerve function, and functional outcomes including dental rehabilitation were more common in lesions in the head and neck.

Hodgkin Lymphoma

HL is a malignancy of the lymphoreticular system that most often affects adolescents and young adults. HL is uncommon in preadolescent children and is rarely seen in children younger than 5 years. Initial attempts to treat HL were based on the use of radiotherapy alone by René Gilbert in the early 1920s, who first treated adjacent lymph node regions electively in patients

with classical HL. The trend of delivering low-dose irradiation to sites with gross disease remained standard for many years, until the advent of effective systemic chemotherapy. In the interim, Henry Kaplan and Saul Rosenberg helped to optimize survival outcomes with radiotherapy. Since approximately the 1980s, the clinical approach has been to treat children with classical HL with chemotherapy followed by radiotherapy or with chemotherapy alone as was established in children diagnosed with favorable stage IA or IIA disease.[103,104] In children with favorable classical HL, the early response to multiagent chemotherapy (~2 months) is used to determine whether radiotherapeutic consolidation is required, thus allowing some proportion of children to be managed without radiotherapy at all.[105] In children with unfavorable early-stage, classical HL, multiagent chemotherapy is followed by involved-nodal or modified involved-field radiotherapy to 21 to 25.5 Gy. Children with advanced-stage, classical HL, regardless of bulk, receive multiagent chemotherapy followed by involved-field radiotherapy to sites of initial disease. The combined modality approach seeks to reduce toxicities from either intervention, while maximizing cure rates. Radiation volumes have been slowly shrinking and, in many instances, no longer include classical involved fields, which reflects a growing respect for the increased efficacy of current systemic therapies.

HL arises within lymph nodes in more than 90% of childhood cases. Extranodal primary sites are rare, but systemic involvement does occur with progression of the disease. The spleen is the most common extranodal site for HL, with the liver and lymph nodes in the abdomen and retroperitoneum also being common sites.[106,107] Mediastinal lymph node involvement is common, particularly in association with right supraclavicular cervical disease.[108] Pulmonary involvement is often due to extranodal spread from contiguous mediastinal and hilar lymph nodes.[109] In contrast, bone and bone marrow involvement arise from hematogenous spread.[110] One-third of children with HL have nonspecific systemic symptoms at the time of presentation; these so-called B symptoms include unexplained fever, night sweats, and unintended weight loss.[108]

HL is distinguished morphologically from non-Hodgkin lymphoma by the diagnostic presence of Reed-Sternberg cells. Reed-Sternberg cells are binucleate or multinucleate giant cells with a clear halo zone around the nucleolus; they are suspected to be of B-cell lineage.[108,111] The historically

used Rye classification system recognizes four such subtypes: (1) lymphocyte predominance, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocyte depletion.[112] Overall, about two-thirds of children have nodular sclerosis HL at the time of presentation; the lymphocyte predominance and mixed cellularity subtypes are relatively more common in children 10 years of age and younger.[113]

These histopathologic HL subtypes have prognostic implications.[114] Lymphocyte predominant HL has the most favorable prognosis, with poorer survival (in prognostic order) associated with nodular sclerosis, mixed cellularity, and lymphocyte-depleted HL.[114] The more recent Revised European-American Lymphoma (REAL) classification separates HL into classic HL and nodular lymphocyte predominant HL (NLPHL)[115] (Harris NL 1994). This system is based on the observation that NLPHL is clinically less aggressive than the other subtypes that constitute classic HL, with NLPHL having a decreased incidence of B symptoms and mediastinal involvement, as well as typically presenting at an earlier stage.[115]

The vast majority of patients with cervicofacial HL have disease outside of the head and neck region at presentation, and the diagnosis is established by lymph node biopsy. Although fine needle aspiration biopsy has been used to diagnose HL by the identification of Reed-Sternberg cells,[116] open excisional biopsy is recommended in newly diagnosed cases for adequate tissue sampling.

It is essential that the full extent of the disease be defined in each patient before specific treatment is instituted. The Rye symposium, held in 1965, provided an anatomic breakdown by lymph node groups for staging purposes. This was superseded in 1970 by the Ann Arbor staging system, or a modification thereof,[117] which is presently in use (see **Tables 24.7 and 24.8**). The Ann Arbor staging system recognizes the fact that HL spreads via lymphatics in a contiguous fashion and can involve extralymphatic sites. The involvement of extranodal sites in HL is designated by E. The presence or absence of B symptoms is designated by B or A, respectively. Cotswold staging classification addresses patients with bulky disease.

Table 24.8 Ann Arbor Staging System (1970)

Stage	Description
I	Involvement of a single lymph node region (I) or localized involvement of a single extralymphatic organ or site (I_E)
II	Involvement of 2 or more lymph node regions on the same side of the diaphragm (II) or localized involvement of a single associated extralymphatic organ or site and its regional lymph node(s) with or without involvement of other lymph node regions on the same side of the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an extralymphatic organ or site (III_E), by involvement of the spleen (III_S), or both (III_{E+S})
IV	Disseminated (multifocal) involvement of one or more extralymphatic organs, with or without associated lymph node involvement, or isolated extralymphatic organ involvement with distant (nonregional) nodal involvement

Clinical staging includes history, physical examination, radiographic studies, and laboratory tests in addition to biopsy. Chest radiography with anteroposterior and lateral views may be required for the assessment of airway patency or bulk of disease; masses that occupy more than one-third of the thoracic diameter are associated with a poor prognosis (Roskos 1982, Robinson 1984). CT of the neck and chest is additionally important for assessment of mediastinal lymphadenopathy readily missed on plain films (Rostock 1983). Abdominal–pelvic CT allows for the preoperative identification of suspicious nodal areas, helps in the determination of radiotherapy treatment ports, and provides a baseline for comparative assessment of response to treatment.[107] Increasingly, PET or MRI appears to

be more accurate than CT in determining HL involvement of bone marrow or extranodal sites.[118–122]

The treatment of HL varies according to stage, and risk groupings stratified by known prognostic markers, as determined by various clinical research consortia. Chemotherapy with or without radiotherapy may be used for patients with stage IA or IIA disease.[103,104] Low-dose (15 to 25.5 Gy) radiotherapy combined with chemotherapy has been shown to be effective and to lessen growth impairment in treated children.[123] Management protocols are also different for children who have attained full growth versus those who are still growing, because the standard, high-dose, involved-field radiation therapy used for HL can lead to considerable long-term growth effects in children and young adolescents. A multi-institutional study has shown that children with stage IA or IIA disease who obtain a complete response following two cycles of multiagent chemotherapy (VAMP) may complete an additional two cycles and receive no radiation therapy with similar outcomes.[105] Low-dose radiotherapy combined with multiagent chemotherapy is recommended for children who have stage IB, IIB, or IIIA disease, who have bulky disease, or who have extranodal lesions.[103–105] Children of a similar age with stages IIIB, IVA, or IVB disease are treated with more intensive chemotherapy in combination with low-dose involved-nodal or involved-field irradiation.[3,124,125] Unlike adult disease, advanced-stage pediatric disease is routinely treated with radiotherapy to good effect.[124,126] Stem cell transplant with high-dose chemotherapy is an option in patients with relapsing HL.[127]

With current treatments, more than 90% of all patients with HL, regardless of stage, initially achieve complete remission.[105,124] Prolonged remission and cure are achieved in ~90% of patients with early stage I or II disease and in children with high-risk HL; an event-free survival of 94% and overall survival of 97% are achievable in rapid early responders with risk-adapted, multiagent chemotherapy and low-dose involved-field radiotherapy.[125] Partial or slow responders with high-risk HL may yet achieve an event-free survival of 80% to 90% and overall survival of 80% to 95%.[128]

The long-term survival of patients successfully cured of HL has created additional concerns. Radiation therapy during the formative years of

development has resulted in growth arrest in addition to hypothyroidism, sterility, and pulmonary fibrosis.[129–132] All HL survivors, particularly those treated with both chemotherapy and radiation, also have an increased future incidence of secondary malignancies, specifically of the thyroid gland, breast, lung, gastrointestinal tract, and hematologic system, including acute nonlymphoblastic leukemia and non-Hodgkin lymphoma.[114,133–136] Such complications can be minimized through precise and proper selection of initial HL therapy and potentially with volume reduction and proton therapy.[137–140] Studies are under way to determine which patients can be treated with reductions in radiation dose and field size as well as tailored chemotherapy without jeopardizing treatment and long-term survival.[128,132]

Non-Hodgkin Lymphoma

Pediatric NHL represents 7% of pediatric cancers among children younger than 20 years, with an annual incidence of 800 cases in the United States.[141] NHL is uncommon among children below age 3 years and more common among males than females. Congenital and acquired immunodeficiency conditions are associated with increased risk of NHL, with most cases in immunocompromised hosts associated with EBV. EBV-associated Burkitt lymphoma accounts for ~85% of the cases in endemic Africa, compared to only ~15% of the cases in North America or Europe.[141] Outside of equatorial Africa, pediatric head and neck lymphomas account for ~10% of pediatric lymphomas.[142]

Prognostic factors in pediatric NHL include the histologic subtype of NHL, stage, age, disease site, tumor burden, chromosomal anomalies, and treatment response. Current clinically relevant categorization of NHL typically considers three groups, in line with the World Health Organization classification: mature B-cell NHL, ~55% (including Burkitt, Burkitt-like lymphoma/leukemia, and diffuse large B-cell lymphoma); lymphoblastic lymphoma, ~25% (including precursor T-cell and precursor B-cell lymphoma); and anaplastic large cell lymphoma, ~15% (mature T-cell and null-cell lymphoma).[141,143]

NHL in the pediatric population is staged with CT scan and/or MRI, plus radionucleotide bone scans for suspected bone disease. PET can identify abnormalities not seen on CT and is routinely done at many institutions in

lieu of gallium scans, although the definitive implication of whether changes on PET in staging and posttherapy should guide management remains debated. Given the potential for false-positive and false-negative results, in the case of residual lesions on imaging, therapeutic decisions should be based on biopsy confirmation or corroborating FDG PET imaging, depending on the protocol.

The most widely used staging system for pediatric NHL is the St. Jude Children's Research Hospital staging,[144] outlined in **Table 24.9**.

Table 24.9 St. Jude Staging Classification for Pediatric Non-Hodgkin Lymphoma

Stage	Characteristic
I	■ A single tumor (extranodal) or single anatomical area (nodal), excluding the mediastinum or abdomen
II	■ A single tumor (extranodal) with regional node involvement ■ Two or more tumors or nodal areas on the same side of the diaphragm ■ A primary gastrointestinal tract tumor, completely resected with or without involvement of associated regional nodes
III	■ Tumors (extranodal) or nodal areas on opposite sides of the diaphragm ■ All primary intrathoracic tumors (mediastinal, pleural, thymic) ■ All extensive primary intra-abdominal disease, unresectable ■ All paraspinal or epidural tumors
IV	■ Any CNS and/or bone marrow involvement

From National Cancer Institute: PDQ® Childhood Non-Hodgkin Lymphoma Treatment.

2014.

Burkitt and Burkitt-like lymphoma/leukemia are classically recognized for rapidly evolving and aggressive clinical presentations, commonly involving the abdomen and nonjaw head and neck region for sporadic cases and typical jaw involvement for EBV-associated endemic cases.

Rapid diagnosis and immediate initiation of therapy are critical for these fast-growing cancers, because metabolic complications pose significant risk during the first week of treatment and any delays can be fatal. A number of effective treatment regimens have been described, consisting of short, pulsed therapies, including cyclophosphamide-based regimens over 4 to 8 months, for instance, CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) with triple-drug intrathecal therapy.[141,145] Head and neck presentations of B-cell NHL are associated with increased likelihood of central nervous system (CNS) involvement—a recognized adverse prognostic factor—as well as with less advanced disease or smaller tumors than those with other primary sites.[146] Using intensive therapy, as in the French Society of Paediatric Oncology LMB89 trial, outcomes for children presenting with head and neck B-cell NHL can be excellent and similar to patients presenting with primary sites outside the head and neck; 95.5% 4-year event-free and overall survival were reported in the LMB89 subcohort of 112 patients with B-cell NHL, 26% of whom had CNS involvement at diagnosis.[146]

Most pediatric patients with lymphoblastic lymphoma present with an anterior mediastinal mass, which may cause superior vena cava syndrome and manifest as swelling of the head and neck with or without evident respiratory distress. Typically, treatment regimens have been adopted from those for pediatric acute lymphoblastic leukemia, with multiagent chemotherapy regimens for 18 to 30 months.[147] With this strategy, the Berlin-Frankfurt-Munster (BFM) group reported 5-year disease-free survival of up to 90%.[141,143]

Tumor lysis syndrome is an oncologic emergency that is particularly common in children with NHL, due to rapid cellular proliferation and turnover. Tumor lysis syndrome may occur spontaneously or upon initiation of therapy. The resultant metabolic derangements (hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia) and associated sequelae can be acutely life threatening, warranting anticipatory and vigilant

management.[148]

Large cell lymphomas can be heterogeneous in biology and response to therapy, and various treatment approaches have been adopted over time, including shorter-term multiagent therapies requiring hospitalization for fewer than 6 months, and year-long regimens that may be administered on an outpatient basis, such as those based on the APO backbone (doxorubicin, prednisone, vincristine).[141,147,149] Event-free survival rates approximate 70%.[145]

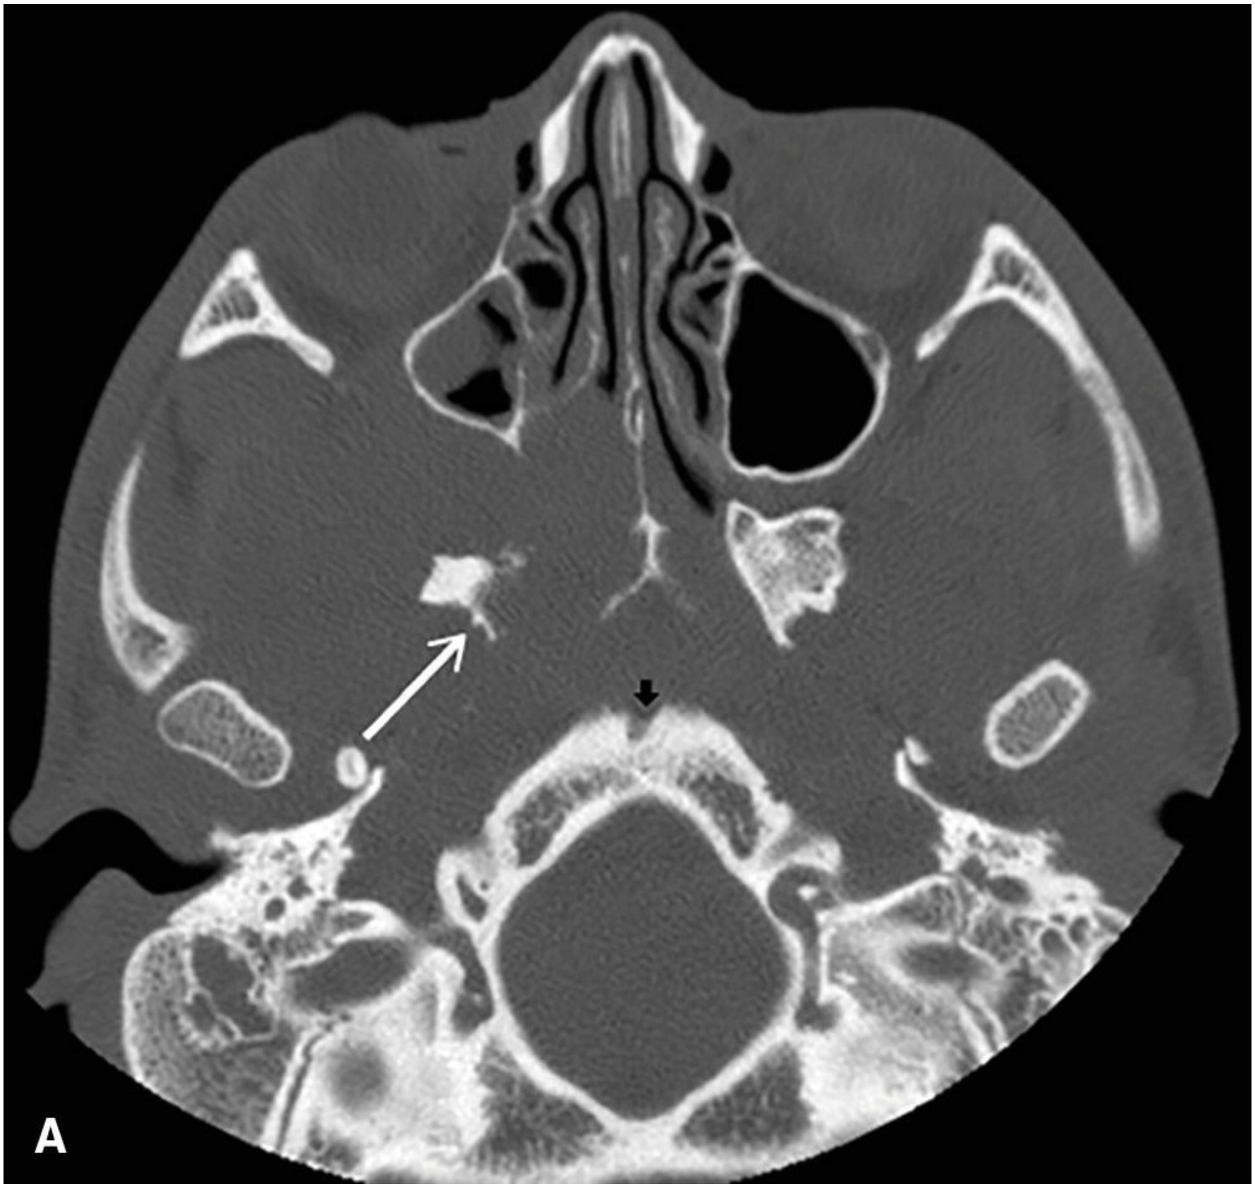
Radiation therapy is rarely needed in children with NHL, given excellent outcomes with chemotherapy and intrathecal therapy for CNS control.[141] Over time, prophylactic CNS radiation has been safely omitted for lymphoblastic lymphoma without increased CNS relapse, allowing CNS radiation to be reserved for children presenting with CNS disease.[150] Therapeutic CNS radiation has also been safely omitted for patients with B-cell NHL and anaplastic large cell lymphoma, even in the presence of CNS disease. Appropriate staging and judicious use of intrathecal chemotherapy remain keys to attaining successful oncologic outcomes with minimization of morbidity.[141]

Nasopharyngeal Carcinoma

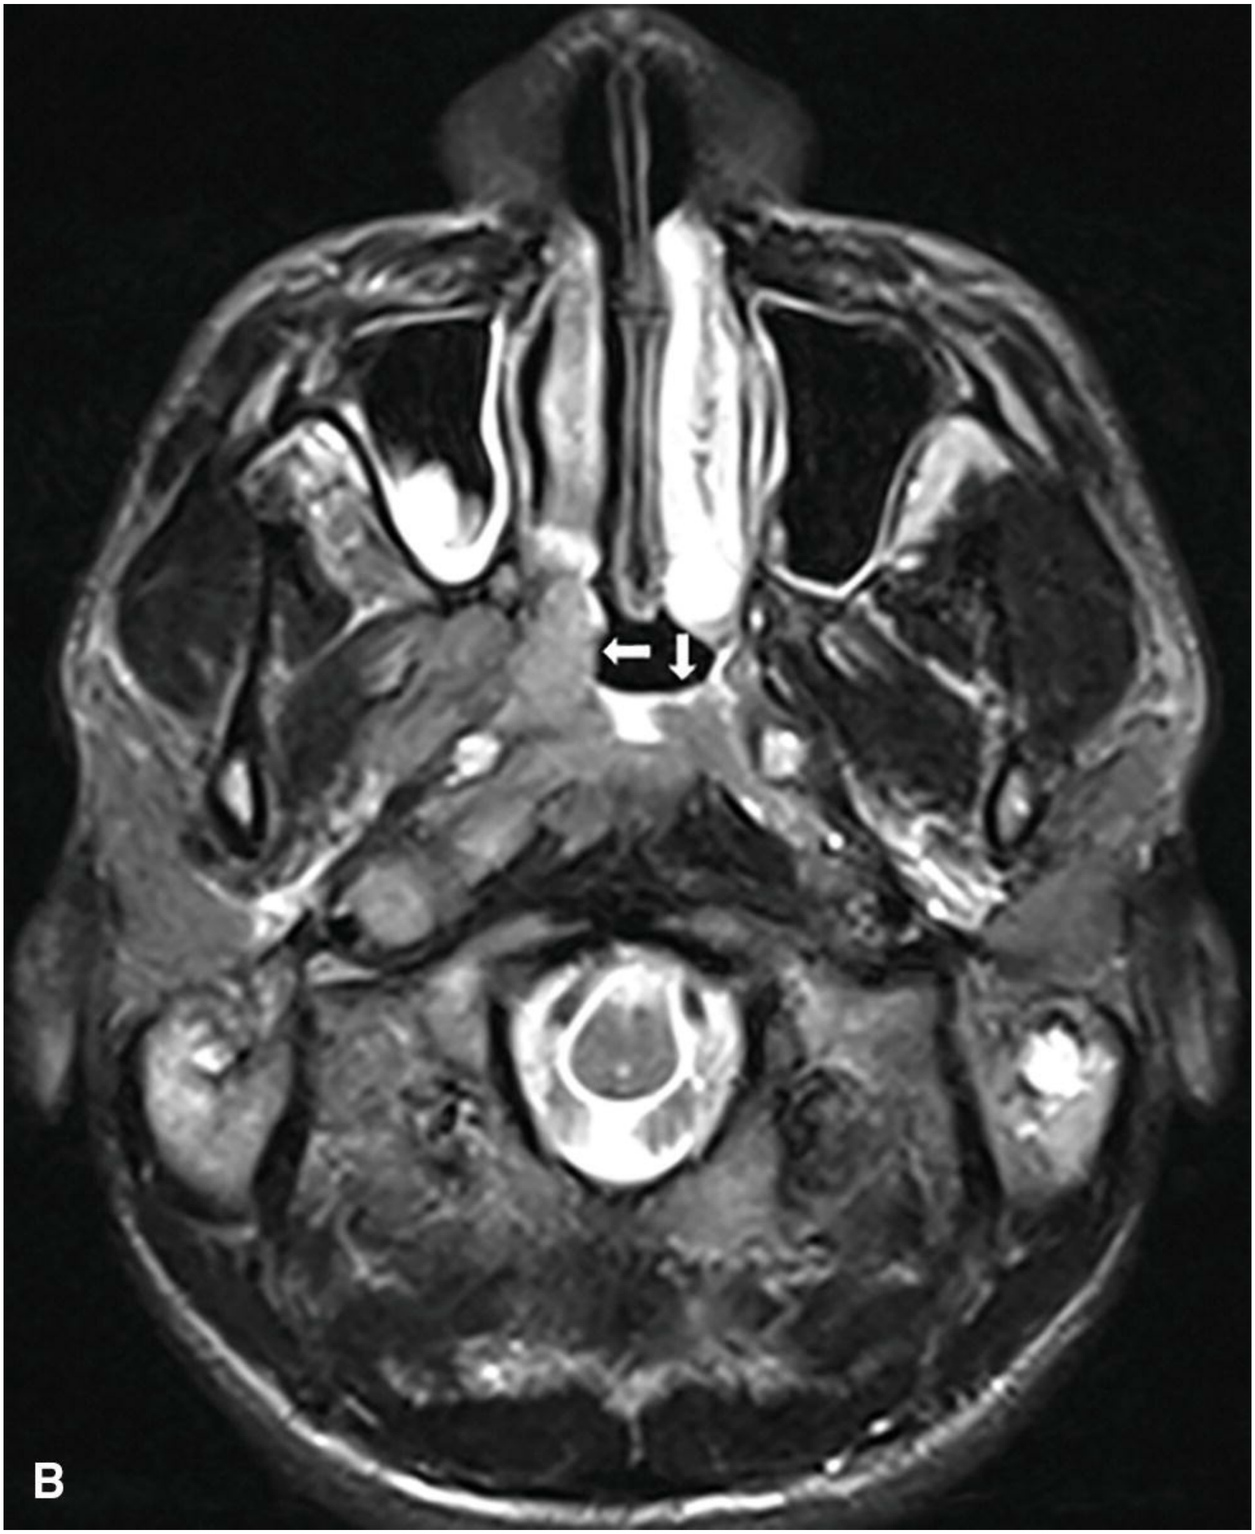
Nasopharyngeal carcinoma (NPC) contributes to ~30% of cancers involving the upper airway, with an annual incidence of ~0.8 per million children below age 15 years and 1.3 per million children between 15 to 19 years of age in North America.[151] Racial and geographic variability has been demonstrated, including increased incidence in Southeast Asia, North Africa, and the Mediterranean region and among males and black young people.[151–153] Of the three WHO histologic subtypes of NPC, type III undifferentiated carcinoma is the most commonly seen in children.[151,153,154] Among other distinctions from adult NPC patients, an analysis of SEER data found that children and adolescents below age 20 years more often exhibited advanced NPC disease, yet had improved 5-year survival of 83% compared to 62% in adults.[153]

NPC is well associated with EBV; in some settings, EBV serology as well as circulating EBV DNA levels have been used to support early diagnosis and disease prognostication.[151,155]

Common clinical presentation for pediatric NPC includes cervical adenopathy, often bilateral in nature, along with hearing loss, epistaxis or nasal obstruction, and headache.[154,156] MRI of the head and neck, with and without contrast, is recommended and should include sequences to assess cervical and supraclavicular lymphadenopathy for accurate staging (**Fig. 24.9**). CT scan may help detect destructive changes involving the skull base although MRI is preferred for determining the extent of intracranial tumor extension and skull base involvement.[157] Baseline and follow-up dental x-ray (panorex) with dedicated otolaryngology and dental evaluations are also warranted. Metastatic workup should be done, typically including a CT chest (with contrast, to include evaluation of lymphadenopathy) and a bone scan.



A



B

C

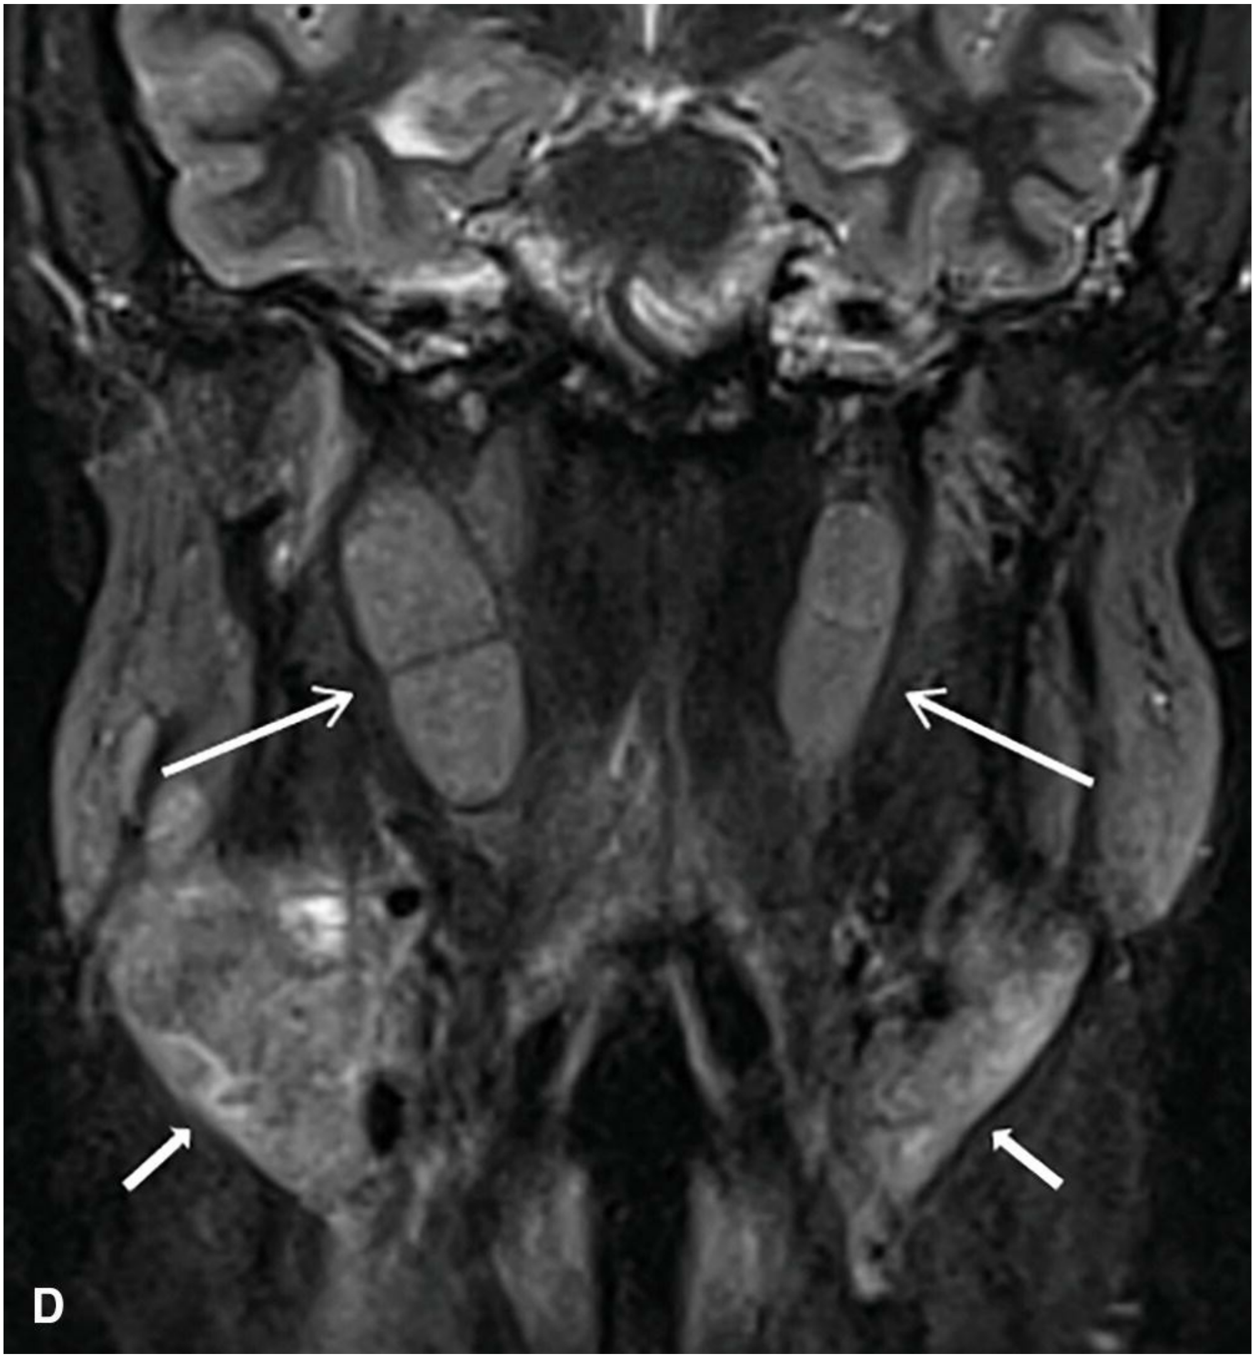


Figure 24.9. A: An axial CT scan image of the skull base of an 18-year-old patient with biopsy-proven NPC shows destruction and sclerosis of the right pterygoid process (*white arrow*) and erosion of the clivus (*small black arrow*). **B:** An axial T2-weighted image through the skull base demonstrates prominent soft tissue in the nasopharynx (*arrows*), more prominent on the right than on the left. **C:** A postgadolinium axial T1-weighted image reveal enhancing tumor expanding and extending from the right pterygopalatine fossa (*small arrow*) into adjacent skull base structures (*large arrow*). **D:** A

coronal STIR image shows markedly enlarged retropharyngeal lymph nodes (*large arrows*) and prominent bilateral lymph nodes at level II of the neck bilaterally (*small arrows*).

FDG PET-CT may also be helpful in the staging and follow-up of pediatric NPC patients; although potentially underestimating tumor extent and adenopathy compared to MRI at baseline, it can help to delineate nonspecific findings and metastatic disease and may reflect earlier disease clearance on therapy than on MRI.[158] Baseline audiogram should be performed. Stage is described as in adults, according to the American Joint Committee on Cancer.[151]

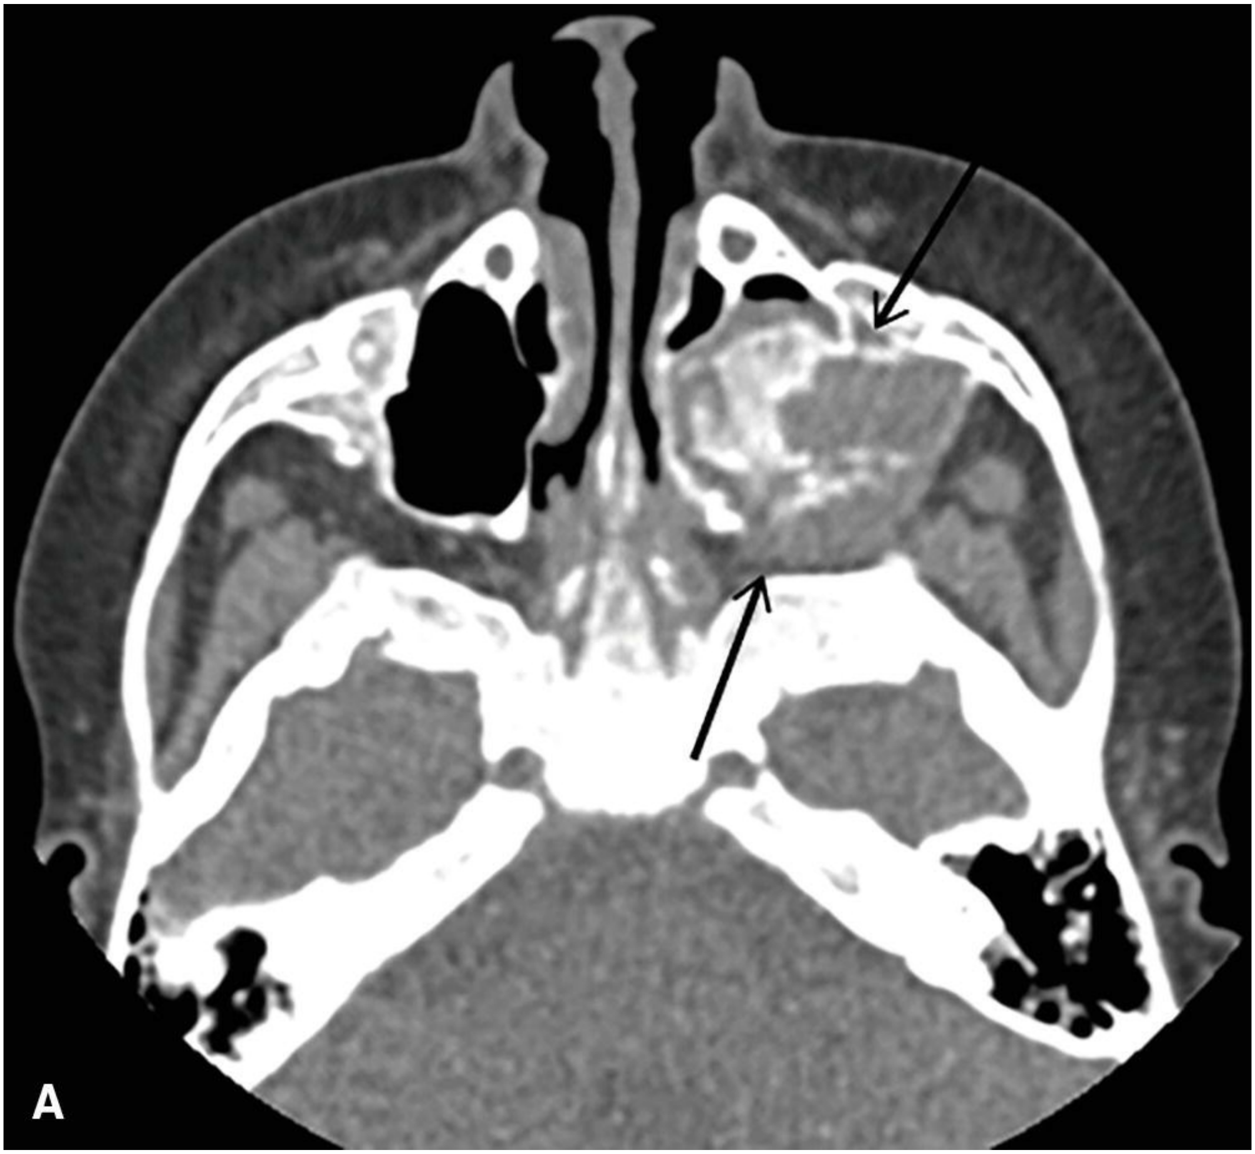
Multimodality therapy, including cisplatin-based chemotherapy and targeted radiotherapy, has optimized the survival of children with NPC in recent decades, with overall and event-free survival approximating 80% and higher.[159,160] The backbone of current international pediatric NPC therapy for most children who present with advanced disease involves cisplatin-based induction chemotherapy, followed by concomitant radiation (dose tailored to stage and/or response) and cisplatin chemotherapy.[159,160] The location and local spread of NPC renders it an unlikely candidate for extensive surgery, such that surgery is typically limited to diagnostic biopsy, often with involved accessible lymph nodes.[151] Treatment-related complications among survivors warrant ongoing evaluation.[154,159] An institutional retrospective review of 59 pediatric patients from 1961 to 2004 found 15-year event-free survival rates of 64%, with improved survival (to 75%) after 1980. However, in this cohort where all received primary tumor radiation, and 98% received cervical radiation therapy and 88% received chemotherapy, the analysis also identified the 15-year cumulative incidence of significant morbidity to be 84%, including estimated specific cumulative incidences of 53% for sensorineural hearing loss, 43% for primary hypothyroidism, and 14% for growth hormone deficiency.[154] In this group, 8.5% of (n = 5) patients developed secondary malignancy, consistent with other analyses suggesting increased risk of second malignancy in pediatric NPC survivors than adult patients.[153] With the interest to ameliorate acute and late toxicities while maintaining optimal outcomes, a response-based radiotherapy treatment approach has been proposed. Orbach et al.[161] retrospectively analyzed outcomes in 34 children with advanced NPC over nearly three decades. They

found that approximately half of these children could be treated with reduced doses below 50 Gy to the involved neck when a good clinicoradiologic response from neoadjuvant chemotherapy was obtained, without compromising outcomes compared with others receiving a median of 60 Gy. The authors concluded that a response-based treatment paradigm is feasible.[161] This, in part, aided the rationale for the latest Children's Oncology Group study, ARAR0331, which, at the time of writing, has been closed to accrual with reported outcomes pending.

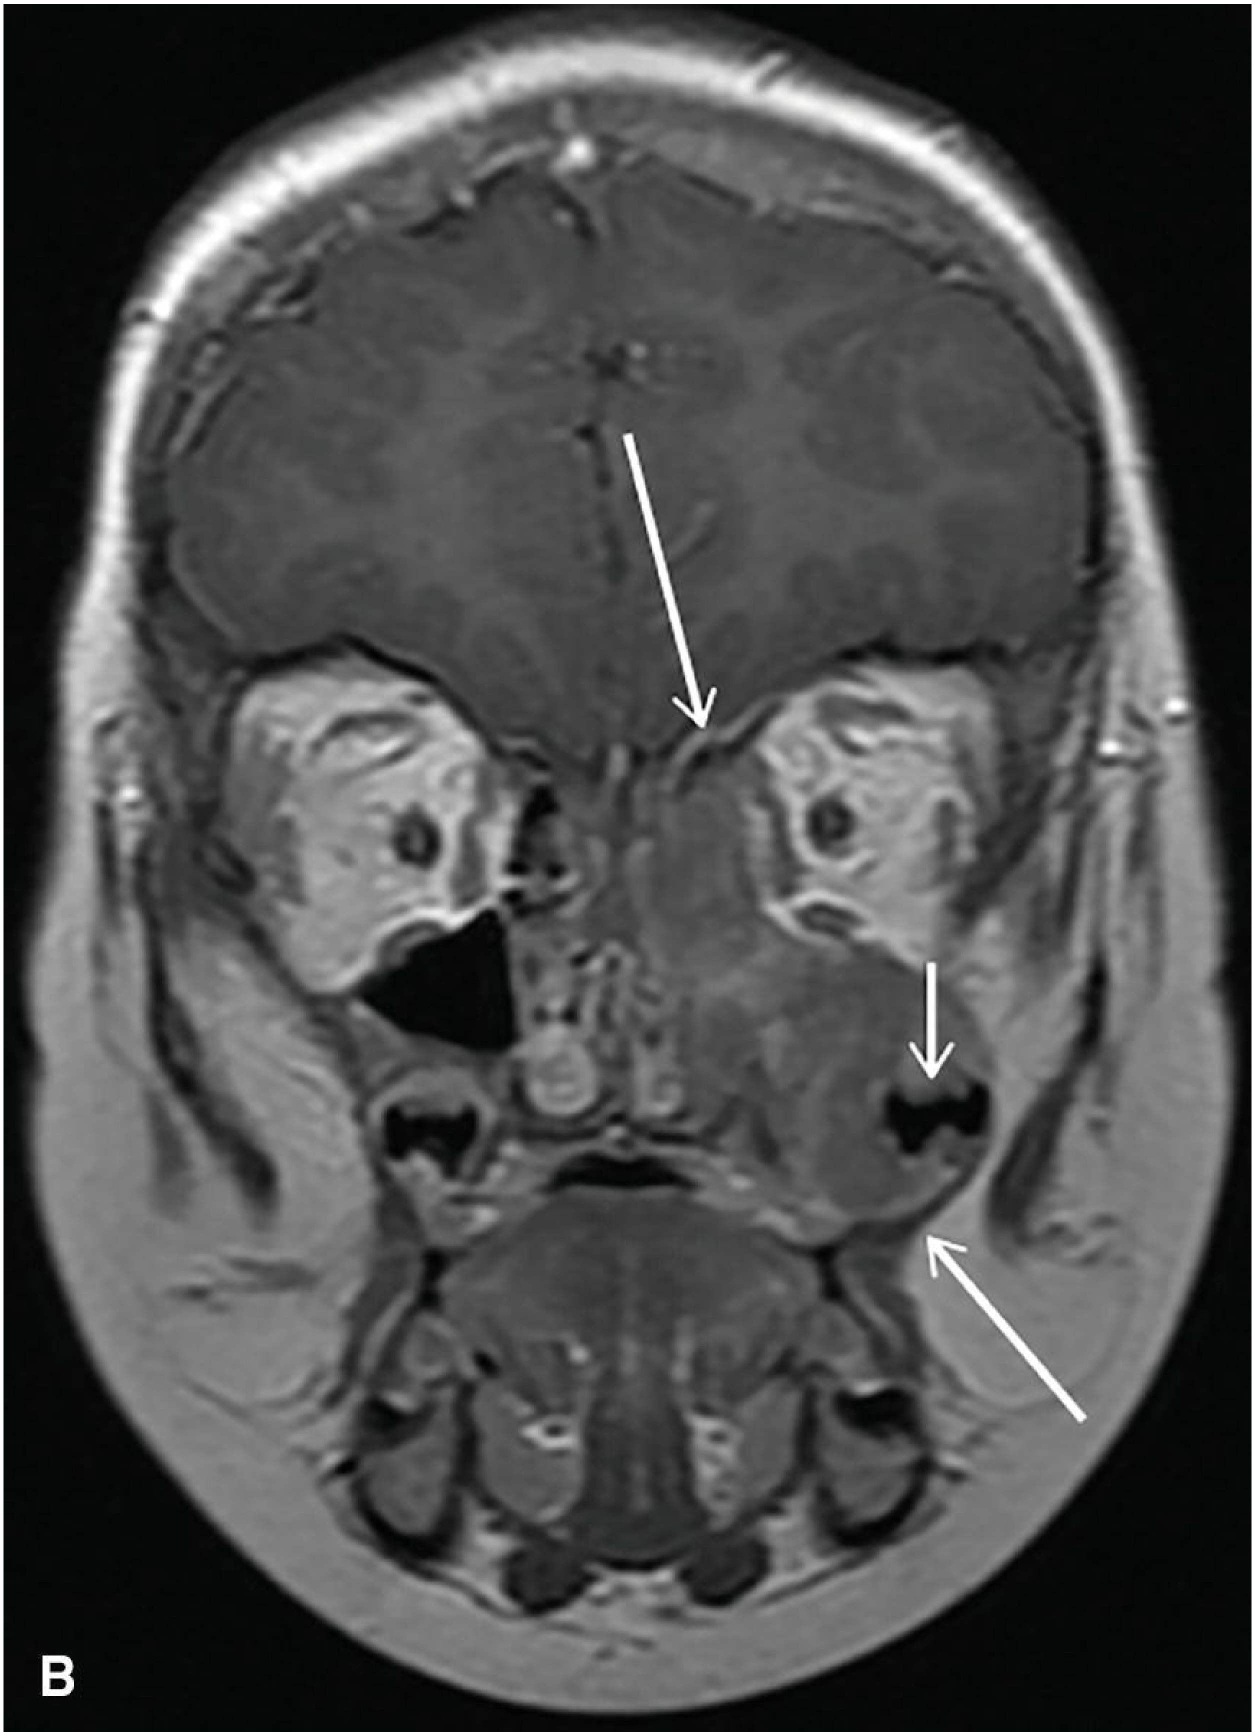
In the setting of refractory or relapsed NPC, emerging therapies under investigation have included EBV-specific cytotoxic T lymphocytes, with potential sustained benefit for those with locoregional disease.[162,163] Surgery can have a role in the treatment of patients with limited local or regional recurrences.

Neuroblastoma

Neuroblastoma represents the most common extracranial solid tumor seen in childhood. It is a tumor of the neural crest cells in the sympathetic nervous system, and 90% of cases are diagnosed in patients below 5 years of age. More commonly a metastatic lesion than a primary tumor of the head and neck, metastatic neuroblastoma to the head and neck may take various forms[164] (**Fig. 24.10**). Proptosis and periorbital ecchymosis (classically described as "raccoon eyes") may be seen in patients with retrobulbar metastatic disease. Stellate ganglion involvement may lead to presentation with Horner syndrome. Subcutaneous skin nodules may be seen diffusely, including in the scalp, most often in infants. Infrequent cases of adolescents presenting with neuroblastoma may more likely involve less typical metastatic sites, including the brain. Paraneoplastic phenomena, including opsoclonus/myoclonus, may also be seen with neuroblastoma; although often associated with favorable biology tumors, neurologic sequelae may be persistent even after therapy.



A



B

C

D

Figure 24.10. A: An axial unenhanced CT scan image through the paranasal sinuses reveals a destructive mass (*arrows*) centered in the left maxillary sinus of a 2-year-old child that extends into the left pterygopalatine fossa. **B:** A postgadolinium coronal T1-weighted image shows the lesion (*arrows*) to also involve the ethmoid air cells on the left. A maxillary tooth (*small arrow*) is enveloped by the mass. Axial T2-weighted **(C)** and postgadolinium coronal T1-weighted **(D)** images demonstrate marked expansion of the skull base (*arrows*) with intracranial epidural extension of tumor. After biopsy, the mass was determined to be neuroblastoma, likely metastatic from an adrenal gland primary.

Primary cervical neuroblastoma is generally uncommon, representing fewer than 5% of all cases.[165] In a recent analysis of 8,369 patients in an international registry cohort, primary tumor site was the adrenal in 47%, abdomen/peritoneum in 24%, thorax in 15%, and pelvis in 3%, with only 3% in the neck and 8% in varied other sites.[166] As the largest multivariate analysis to date of neuroblastoma primary site on outcomes, it supported earlier smaller series that suggested patients with primary cervical neuroblastomas as typically having favorable biologic features such as absence of MYCN amplification and also as independently having more favorable overall outcomes even after controlling for age, stage, and MYCN amplification status. Notably, patients with cervical neuroblastoma remained at risk for local recurrence, likely related to its challenging location for complete resection.[166]

Isolated cases of primary neuroblastoma of the head and neck have also been reported in children in sites such as the maxillary sinus,[167] retropharynx, and parotid gland.[168]

International minimum criteria for definitive diagnosis of neuroblastoma involve either an unequivocal pathologic diagnosis from tumor tissue or a bone marrow involvement with tumor cells coupled with increased urinary catecholamine metabolites.[169] Measurement of urinary catecholamines, typically homovanillic acid (HVA) and vanillylmandelic acid (VMA), can be done via spot urine measurements in lieu of 24-hour urine collections. LDH and ferritin have also been used as key additional laboratory markers at baseline for potential prognostication. Bilateral bone marrow aspirate and biopsy are part of the typical staging. Tumor biology is vital to the

International Neuroblastoma Pathology Classification (INPC), with adequate tumor cells needed to determine key features including MYCN copy number, tumor cell ploidy (DNA index), and segmental chromosomal changes. Expert cellular classification is warranted to distinguish the spectrum of neuroblastic tumors that may be seen, from benign mature ganglioneuromas, less mature ganglioneuroblastoma, to malignant immature neuroblastoma, with very different implications for management. In addition to cross-sectional imaging using CT or MRI, metaiodobenzylguanidine (mIBG) scans are used in staging for neuroblastoma, with semiquantitative scoring methods developed to help gauge disease extent and guide prognostication.[170,171] For neonates and infants, ultrasound can be a helpful modality, including for follow-up.

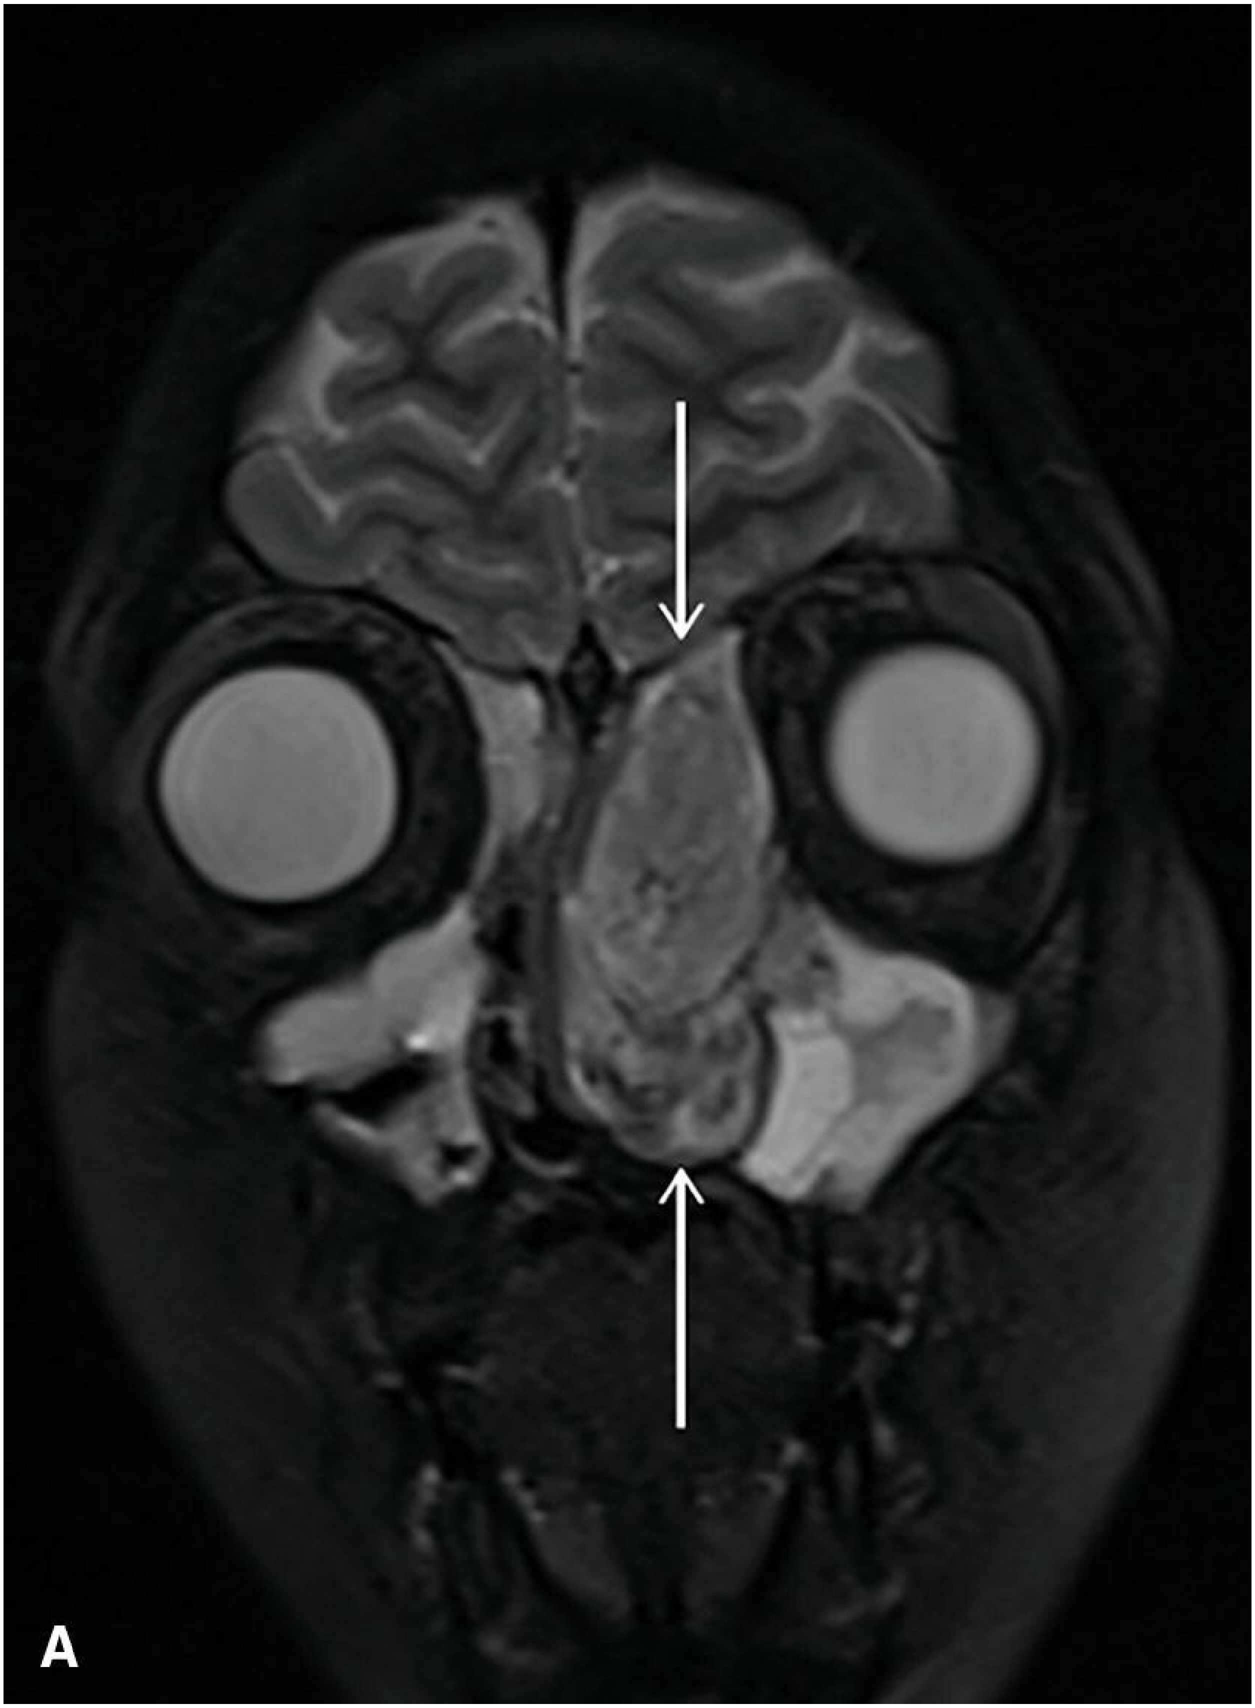
The International Neuroblastoma Staging System (INSS) is a postoperative staging system widely in use for more than two decades to help guide risk group stratification and treatment.[169] With evolving understanding, and to allow preoperative staging and minimize staging inconsistencies due to local surgical access and practices globally, the International Neuroblastoma Risk Group (INRG) staging system was developed, incorporating the presence of image-defined risk factors and metastases prior to surgery or therapy.[172] Staging is incorporated with patient age, pathology classification, and tumor biology into generally three risk categories: low risk (characterized by observation or surgical resection alone), intermediate risk (chemotherapy typically prior to surgical resection; overall well tolerated with excellent overall survival above 95%),[173] and high risk (intensive multimodality therapy including hematopoietic stem cell transplantation, radiation therapy, differentiation therapy, and immunotherapy, with survival rates still typically only ~40%).[174]

Infants constitute a special group of patients with neuroblastoma, in which small asymptomatic localized neuroblastoma tumors may be electively observed with appropriate monitoring and supportive care, with many altogether avoiding all surgery including biopsy[175] and many spontaneously regressing, with initial regression one to 18 months after diagnosis.[176] However, infants below three months of age who have progressive symptomatic neuroblastoma, including abdominal distension with hepatomegaly or cardiorespiratory compromise risk, typically warrant chemotherapy for symptom control. Infants aged 12 to 18 months and below thus constitute a special group, with typically very favorable prognosis even

in the setting of metastatic disease limited to skin, liver, and <10% of the bone marrow, constituting a special stage, 4S (for infants below age 12 months with localized primary tumor) in the INSS classification and MS (expanded to infants below 18 months and regardless of primary tumor extent) in the recent INRG classification. This typically more favorable prognosis for infants also extends to those with advanced metastatic disease (stage 4) without unfavorable MYCN amplification.[173,177] Given the significant biologic and clinical heterogeneity of neuroblastomas, multidisciplinary management by specialized teams is critical.

Esthesioneuroblastoma

Esthesioneuroblastoma, also known as olfactory neuroblastoma, is a tumor arising from the nasal neuroepithelium, distinct from conventional neuroblastoma. It is a rare malignancy in children with fewer than 100 children described to date; most cases develop after age 10 years, commonly with advanced disease.[151,178,179] Presentation is varied, including exophthalmos and nasal obstruction or, in rare instances, hyponatremia.[151,180] Along with CT and MRI, PET-CT may be beneficial in disease staging[151,178] (**Fig. 24.11**). As in adults, the Kadish clinical staging system (stages A to D) is most widely applied. Surgery and radiation therapy have traditionally played dominant roles, with chemotherapy also demonstrating effect in small series of children with advanced disease.[178,181] Favorable 5-year survival rates of 80% to 90% have been described.[178,181]



A

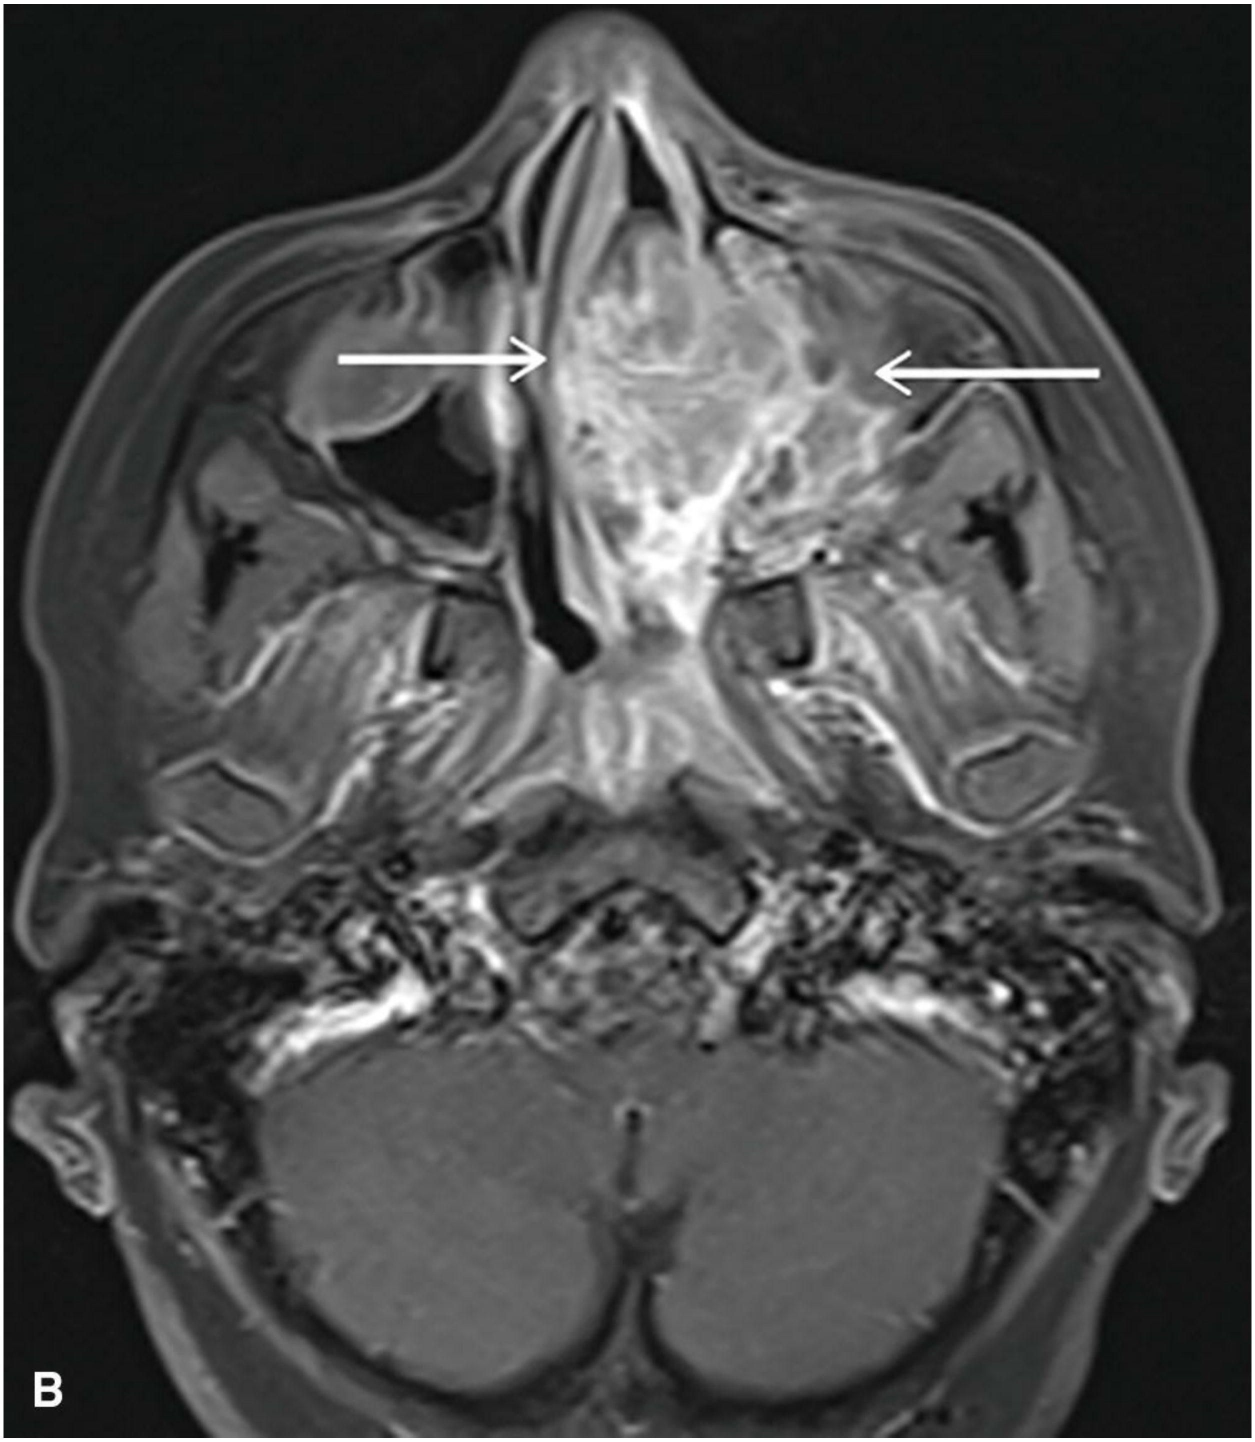


Figure 24.11. Fat-saturated coronal T2-weighted **(A)** and fat-saturated postgadolinium axial T1-weighted **(B)** images of the face for a 14-year-old patient show a large mass (*arrows*) with heterogeneous signal intensity and heterogeneous enhancement in the left nasoethmoidal region with extension into the left maxillary and frontal sinuses. Biopsy demonstrated the lesion to be an esthesioneuroblastoma.

Retinoblastoma

Retinoblastoma arises in the retina and represents the most common intraocular cancer in the pediatric population. Approximately 9,000 new cases of retinoblastoma are expected globally each year,[182] and almost all occur in patients under 5 years of age. Patients with bilateral retinoblastoma present particularly early, most often within the first year of life. Leukocoria is the most common presenting feature symptom in most settings[182]; tumors that have progressed may present with painful buphthalmos, as well as orbital and distant metastatic disease involving the bone marrow and bones. Appropriate examination under anesthesia is critical to guide diagnosis and ongoing management of retinoblastoma. MRI is typically preferred in delineating tumor extent.[183] For suspected advanced disease, additional metastatic workup is typically performed, including bilateral bone marrow aspirates and biopsies, lumbar puncture, and bone scans (**Fig. 24.12**).

Figure 24.12. A: Bicoronal subcranial approach for myxoid chondrosarcoma arising from the frontoethmoid complex. **B:** Excision of tumor via subcranial approach. **C:** Tumor involving the frontal bone.

Approximately 30% of retinoblastoma is heritable, most often characterized by a germline mutation in the RB1 gene (on chromosome 13), of which 75% may be de novo. All children with bilateral retinoblastoma and an estimated 15% of those with unilateral retinoblastoma are expected to have heritable retinoblastoma. Genetic evaluation and counseling constitute an important part of management, as those with germline mutation are at increased risk for developing subsequent tumors, including in the opposite

eye, or as trilateral retinoblastoma, with development of an intracranial malignant tumor, classically involving the pineal gland. They are also at increased risk for subsequent neoplasms that may manifest in adulthood.[182] Emerging genetic insights have also expanded the appreciation of retinoblastoma genetic complexity, with cases that can present at an early age without RB1 inactivation, demonstrating tumor cell–specific MYCN amplification.[184,185]

With modern multidisciplinary management in North America and other developed regions of the world, retinoblastoma has progressed in the last century from a disease associated with almost uniform mortality to one with >95% survival, with progressive treatment focused to allow more than 90% of patients to retain their eyes as well as visual function.[186] Due to the very young age and developmental vulnerability of most patients with retinoblastoma, tailored management and consideration of late effects such as hearing loss from ototoxic chemotherapy, as well as second malignancies, are particularly important.[186,187]

Salivary Gland Tumors

Tumors arising in the salivary glands in children are uncommon. In a review of 80 patients seen over a 58-year period at Children's Hospital in Boston, 25 were found to have epithelial tumors, whereas 55 had nonepithelial tumors. Among the epithelial tumors, 10 were pleomorphic adenomas, whereas the rest were malignant tumors with mucoepidermoid carcinoma being the common pathology. Capillary hemangioma was the most common nonepithelial tumor with a distinct predilection for females.[188]

Less than 5% of all salivary gland carcinomas affect children under the age of 19 years with an annual incidence of 0.8 per million.[189] Salivary gland tumors are more often malignant in the pediatric age group than in adults. Mucoepidermoid carcinoma is the most common tumor followed by acinic cell carcinoma. The parotid gland is the most common site of origin. Adenoid cystic carcinoma, adenocarcinoma, and squamous cell carcinoma occur very rarely in children. Compared to adults, pediatric salivary gland carcinomas are more often localized and of lower histologic grade.[189,190]

Most children with salivary tumors present with a painless mass in the region of the parotid gland. CT is the most commonly employed investigation

to help establish the extent of disease, spread to neighboring tissues, and presence of metastatic lymphadenopathy. MRI may be indicated to evaluate the extent of spread beyond the confines of the parotid into the skull base and along cranial nerve foramina, if such spread is suspected. Chest imaging is indicated for malignant lesions to rule out metastatic spread. Fine needle aspiration cytology is helpful in establishing a pathologic diagnosis, but rates of accuracy in the pediatric population are not well established. An open incisional biopsy is generally discouraged but may be considered in rare selected cases provided it is performed by an experienced head and neck surgeon.

Surgical excision of the involved gland is the mainstay of treatment. A superficial or total parotidectomy with preservation of the facial nerve and its branches must be performed. If the nerve or one of its major branches has to be sacrificed due to encasement by tumor, immediate interposition grafting should be performed along with static facial reanimation as indicated. Excision of the submandibular gland is necessary for tumors arising in this location. A modified radical neck dissection is indicated if there is metastatic lymphadenopathy present. Elective neck dissection in the absence of lymphatic metastasis is not indicated except in cases of high-grade malignancy. Postoperative radiation therapy may be withheld if surgical margins are negative and the tumor is low or intermediate grade. High-grade histology, adenoid cystic carcinoma, perineural or lymphovascular invasion, and presence of metastatic lymphadenopathy warrant postoperative radiation treatment.

Chemotherapy is generally limited to the treatment of metastatic or inoperable recurrent cancers. Cisplatin or carboplatin, paclitaxel, and gemcitabine among other agents have been used singly or in combination with only modest responses and no discernible effect upon survival. There is also considerable interest in therapies directed toward specific molecular targets such as c kit, EGFR, and HER2, but the results thus far have not met expectations. Recently, there has been an interest in cisplatin-based concurrent chemoradiation in the adjuvant setting for high-risk salivary gland cancers. A phase II randomized Radiation Therapy Oncology Group Trial (RTOG 1008) comparing postoperative radiation to chemoradiation in this setting is currently ongoing. However, individuals younger than 18 years of age are not eligible for the study.[191]

For salivary gland carcinomas in the SEER database diagnosed between 1973 and 2006, prognosis was significantly better in the pediatric age group compared to adults (5-year overall survival 95% compared with 59%, $p < 0.001$).[189] Predominance of tumors of a lower histologic grade and more limited extent is thought to have contributed to this more favorable outcome.

Thyroid Carcinoma

Cancer of the thyroid gland is uncommon in children. An analysis of the April 2008 release of SEER data revealed a total of 1,753 cases of thyroid carcinoma diagnosed from 1973 to 2004 in patients younger than 19 years of age. The age-adjusted population incidence was 0.89 cases per 100,000 females and 0.2 cases per 100,000 males. The incidence was highest in the 15 to 19 years age group at 1.6 per 100,000 patients. Tumors were classified as papillary in 60% of the cases, whereas follicular variant of papillary, follicular, and medullary cancers made up 23%, 10%, and 5% of cases, respectively.[192]

The incidence of thyroid cancer in children appears to be rising. Data from the National Program of Cancer Registries and SEER for the years 2001–2009 showed an increasing trend with an annual percentage change of 4.9%.[193] This is in keeping with an increase in incidence noted in adults. The cause is unclear. Exposure to radiation by CT or dental radiographs as well as to chemicals such as perchlorate and polybrominated diphenyl ethers has been proposed, but definitive evidence is lacking. It is also possible that the trend is related to improved diagnosis.

Exposure to radiation increases the risk of thyroid cancer. Dramatic increase in the incidence of thyroid cancer has been noted after the atomic blasts in Japan as well as the Chernobyl disaster in 1986.[194] The latency period between radiation exposure and onset of cancer is typically 10 to 20 years, but thyroid cancer has been seen as early as 5 years after exposure in some children.[195] Thyroid cancer is the most common second malignancy in children treated for Hodgkin and non-Hodgkin lymphoma.[195] Hence, screening with thyroid ultrasound is warranted in individuals with a history of prior radiation exposure starting 5 years after the exposure.

Although most cases of nonmedullary or differentiated thyroid cancer are sporadic, clustering within families has been noted occasionally. Familial

nonmedullary thyroid cancer displays features of clinical “anticipation” with the second generation acquiring the disease at an earlier age and having more advanced disease at presentation.[196] Many rare genetic syndromes such as Cowden syndrome, Gardner syndrome, and Werner syndrome are also associated with an increased incidence of thyroid carcinoma. Additionally, mutations in RET proto-oncogene can cause medullary thyroid carcinoma either as part of multiple endocrine neoplasia, types 2A and 2B, or as familial medullary thyroid carcinoma.

RET/PTC gene rearrangements are common in children with papillary thyroid carcinoma. Although BRAF mutations are seen in as many as 45% of adults with papillary thyroid carcinoma, these mutations are less common in children.[195,197]

A nodule in the thyroid gland is the most common clinical presentation in children with differentiated thyroid carcinoma although occasionally a mass in the lateral neck due to lymphatic metastasis may be the first presenting symptom. A thyroid nodule in the pediatric age group is significantly more likely to harbor malignancy when compared to adults. Although the incidence of malignancy varies widely in the literature, in one study with standardized assessment in a series of 300 consecutive children with thyroid nodules, 22% were found to have cancer compared to 14% in a control population of adults with thyroid nodules from the same center.[198] Children with thyroid carcinoma are much more likely to present with lymph node metastasis compared to adults. Also, distant metastasis is noted in 20% to 30% of children at presentation.[195]

A TSH level must be obtained when assessing a thyroid nodule to rule out a hyperfunctioning nodule. The vast majority will have normal thyroid function and will require a thyroid ultrasound as the next step in diagnostic workup. All nodules that are 1 cm or greater in size must be evaluated with a fine needle aspiration biopsy. Even smaller nodules may need aspiration if there are microcalcifications or abnormal perithyroidal lymph nodes seen on ultrasound. History of thyroid cancer in the family or one of the aforementioned tumor syndromes or prior radiation exposure should also prompt needle aspiration for nodules smaller than 1 cm. Most children tolerate this procedure well. Malignant nodules are more likely to be solid in nature and larger in size. The presence of calcification and abnormal lymph nodes in the central compartment or in the lateral neck also predicts for

malignancy but has limited sensitivity due to low incidence of these features. The Bethesda System for Reporting Thyroid Cytopathology is commonly utilized for classifying the nodules. Patients with benign cytology can be safely followed unless the nodule is >4 cm in size as the predictive accuracy of a benign result in this group has been shown to be lower.[198] Those with malignant cytopathology will typically require a near total thyroidectomy. A diagnostic lobectomy is generally recommended in patients with indeterminate cytology. Although molecular profiling tests have recently been used with acceptable accuracy in adults to predict malignancy in nodules with indeterminate cytology, their use in the pediatric population has not been adequately studied.

More detailed anatomic imaging with MRI may be indicated in children presenting with symptoms and signs of airway invasion or compression for the purpose of preoperative planning.

Due to higher rates of lymphatic and distant metastasis at presentation, and a higher rate of recurrence in children with thyroid cancer, the threshold for performing a total thyroidectomy as opposed to a lobectomy should be lower with regard to the size of the primary tumor within the thyroid gland. Elective lateral neck dissection is not recommended, but clearance of the central compartment even in the absence of gross lymphadenopathy has been favored due to a high incidence of microscopic metastatic disease. However, such an operation is associated with a higher likelihood of recurrent laryngeal nerve injury as well as permanent hypoparathyroidism both of which are complications whose morbidity may be worse than the benign course of differentiated thyroid cancer itself and therefore must be performed only by experts. Presence of gross lymphadenopathy in the paratracheal region necessitates a central compartment clearance. A neck dissection of levels II through V best addresses any gross disease present in the jugular chain or the posterior triangle of the neck.

Most children will require postoperative treatment with radioactive iodine for ablation of residual thyroid tissue and any lymphatic or systemic metastasis. Both lymphatic spread and pulmonary metastasis are more common in children. The majority of these lung metastases are micrometastases that are not easily seen on chest radiographs or even CT scans but become apparent on radioactive iodine scans that are performed after thyroidectomy. Children who are treated with a lobectomy are more

likely to have recurrence compared to those that undergo a subtotal or total thyroidectomy. Differentiated thyroid cancer in children is more prone to recur. Long-term follow-up in children may be more challenging and medical compliance in adolescence and young adults may be suboptimal. Radioactive iodine given postoperatively can reduce the likelihood of recurrence.[195]

The dose of radioactive iodine depends on the initial extent of disease. Adjustments can be made for body size or be based on dosimetry. Generally, a dose of 100 mCi for low-risk patients, 150 to 175 mCi for those with lymph node metastasis, and up to 200 mCi for those with very high-risk disease including large tumors, capsular invasion, extrathyroidal spread of disease, extensive nodal disease, or distant metastasis has been recommended.[199]

Thyroid hormone replacement must be withdrawn for 2 to 3 weeks before radioactive iodine treatment and a low-iodine diet must be adhered to. TSH levels >30 mU/L must be reached prior to the treatment. Alternatively, recombinant TSH can be administered on 2 consecutive days followed 24 to 48 hours later with radioactive iodine.

Adverse effects of radioactive iodine include gastritis presenting as nausea and vomiting, neck pain from soft tissue swelling, and sialadenitis. In the long term, concerns for second primary malignancy, diminished fertility, and pulmonary fibrosis have been raised. A comprehensive analysis recently showed a 25% higher risk than the general population of second primary malignancy in patients with differentiated thyroid cancer whether or not they were treated with radioactive iodine. Radioactive iodine-related second primary malignancy risk was seen only with cumulative doses exceeding 200 mCi.[195] No excess of malformations or cancer have been reported in the offspring of individuals who have been treated with radioactive iodine. There is a higher rate of miscarriage within 1 year of treatment for women receiving more than 100 mCi. Hence, pregnancy should be avoided for 6 to 12 months after radioactive iodine therapy. In males, gonadal damage may occur with multiple administrations, and it has been suggested that sperm banking should be considered in patients who are likely to receive a cumulative dose >370 mCi.[200]

Treatment with radioactive iodine must be repeated in 6 to 12 months if there is remaining residual thyroid or tumor tissue. Suppression of TSH levels with exogenous thyroid hormone levels below 0.1 mU/L although

recommended in adults with nodal or distant metastatic disease must be used with caution in the pediatric age group due to possible adverse effects of prolonged subclinical hyperthyroidism.

Patients must be followed up every 6 months with measurement of basal and stimulated thyroglobulin levels and ultrasound of the neck. A diagnostic whole-body radioactive iodine scan is indicated for patients with lymph node or distant metastasis. Being in remission is defined as having undetectable thyroglobulin levels (<1.0 mcg/L) in the absence of thyroglobulin antibody, no evidence of neck disease by ultrasound and negative diagnostic radioactive iodine scan.

Prognosis with carcinoma of the thyroid is excellent. In a SEER study of patients with thyroid carcinoma <20 years of age diagnosed between 1973 and 2004, survival for papillary carcinoma was found to be 98%, 97%, and 91% at 5, 15, and 30 years, respectively. The figures for follicular carcinoma were similar (96%, 95%, and 92%).[192]

Medullary thyroid carcinoma arises from the parafollicular or C cells within the thyroid gland. It is a rare tumor in the pediatric age group. It results from an activating mutation in the RET proto-oncogene that is dominantly inherited as part of the multiple endocrine neoplasia type 2 syndrome. The sporadic variety of medullary thyroid carcinoma that is common in adults is exceedingly rare in children. MEN2A, consisting of medullary thyroid carcinoma, parathyroid hyperplasia, and pheochromocytoma, is by far the more common, occurring in 90% to 95% of the childhood MEN2 cases. Familial MTC is thought to be a variant of MEN2A and is diagnosed when medullary thyroid carcinoma occurs in multiple generations without any parathyroid hyperplasia or pheochromocytoma. MEN2B is the rarer form and is characterized by early development and an aggressive course of medullary thyroid carcinoma. The syndrome includes pheochromocytoma, Marfanoid habitus, pectus excavatum, hypotonia, mucosal neuromas of the lips and tongue, and ganglioneuromatosis of the intestine and urinary tract.[201,202]

In childhood, medullary thyroid carcinoma occurs with equal frequency in boys and girls. It is the most common thyroid malignancy in children younger than 5 years of age. In the era of genetic testing, it is uncommon for a child to present with clinical disease. Presymptomatic identification of RET mutation is the predominant mode of presentation. Mutations in the RET

proto-oncogene have been categorized into American Thyroid Association risk levels A through D according to an increasing risk of aggressive medullary thyroid carcinoma (see Table 5 in Kloos et al.[201]). MEN2A is most frequently caused by mutations in RET exons 10 (codons 609, 611, 618, and 620) and 11 (codon 634). MEN2B is almost always caused by mutation in exon 16 (codon 918).

Surgery is the mainstay of treatment of medullary thyroid carcinoma. The best hope of cure is before any metastasis has occurred. Patients with medullary thyroid carcinoma must have a baseline calcitonin level measured. If calcitonin is <100 pg/mL, the size of the primary thyroid nodule will be less than a centimeter in 98% of the patients. Systemic metastases are strongly associated with a markedly elevated calcitonin level (>5,000 pg/mL) but have been detected in patients with levels as low as 150 pg/mL. CEA levels are also associated with disease status.[203]

Prophylactic thyroidectomy is recommended in children with a known germline mutation in the RET proto-oncogene. Timing of prophylactic thyroidectomy is best guided by the ATA risk level of the RET mutation (see Table 6 in Kloos et al.[201]). Infants with ATA-D (codon 918) mutation must undergo a total thyroidectomy as soon as possible within the first year of life, whereas those with ATA-C (codon 634) mutation must have this surgery before 5 years of age. For children with ATA-A and ATA-B mutations, surgery may be delayed beyond 5 years of age in the setting of normal annual serum calcitonin level, normal ultrasound of the neck, family history of a less aggressive medullary thyroid carcinoma, and family preference.[201] All prophylactic thyroidectomy surgery should be performed in expert hands at experienced tertiary care centers.

In patients with biopsy-proven medullary thyroid carcinoma, calcitonin levels must be obtained prior to surgery. For patients with levels below 400 pg/mL, ultrasound imaging of the neck must be performed to rule out metastatic disease in the lymph nodes. For those with levels higher than 400 pg/mL, imaging must include CT scan of the chest and abdomen as well as a contrast-enhanced MRI of the liver to rule out systemic metastasis.[203]

A total thyroidectomy with central compartment neck dissection is required for patients whose disease is limited to the thyroid gland. No added value has been demonstrated for elective lateral neck dissection in the

absence of discernible disease outside the central compartment. However, a lateral neck dissection must be performed if metastatic disease can be demonstrated in the lymph nodes of the jugular chain or in the posterior triangle of the neck by imaging or confirmed by biopsy. Patients with spread of disease in the mediastinal lymph nodes may benefit from surgical clearance for palliation or prevention of tracheal compression but will rarely achieve biochemical remission.

Although there are some retrospective case series that showed benefit, there are no strong data in support of the use of radiation therapy postoperatively in high-risk disease. Cytotoxic chemotherapy has generally not been found to be of benefit with medullary thyroid carcinoma. Recently, vandetanib, a RET kinase inhibitor, was approved for use after it showed prolongation of progression-free survival in a randomized study.[204]

The prognosis of patients diagnosed with medullary thyroid carcinoma is dependent on the extent of disease at the time of presentation. When the initial disease is limited to the thyroid gland, survival at 10 years is ~95%. With lymph node involvement at presentation, the 10-year survival is closer to 75%, whereas in cases with distant metastatic disease, it drops to 40%.[203] The mean duration of survival for those treated for medullary thyroid carcinoma diagnosed in childhood was 28.3 years in one study of SEER data.[203]

Calcitonin levels are measured initially at 6 months after surgery and then every 6 months for the first 2 to 3 years. More frequent measurements may be necessary if calcitonin level starts to rise. Frequency of estimation then depends on the estimated calcitonin doubling time.

Parathyroid Carcinoma

Although exceedingly rare, parathyroid carcinomas have been reported in the pediatric literature. It requires upfront en bloc resection for cure with avoidance of rupture of the tumor capsule, rather than a simple parathyroidectomy as one would pursue for a benign adenoma. As diffuse metastatic progression renders patients incurable with refractory hypercalcemia and chronic hyperparathyroidism, early consideration and management by specialist teams is mandatory, particularly for cases with significant elevation of calcium and parathyroid hormone or with atypical

adherence of tumor to surrounding structures.[205,206]

Melanoma

Although melanoma is rare in children, accounting for only 1% to 4% of all melanomas, it is still the most common solid tumor in the 15- to 29-year age group. Approximately 450 new cases are diagnosed in individuals younger than 20 years of age in the United States each year.[207,208] The incidence of melanoma is increasing in the United States in children and adolescents. Most children with the disease are at least 10 years of age.[209]

The disease is more common in the Caucasian race but children with melanoma who are younger than 10 years of age are ethnically more diverse.[209] The risk of melanoma increases with an increased number of benign melanocytic nevi and atypical nevi. Giant congenital nevi are associated with a greatly increased risk of melanoma.[208] A positive family history of melanoma also increases the risk of developing this cancer. Mutation in the MITF gene predisposes to both familial and sporadic melanoma. Individuals with dysplastic nevus syndrome have a cumulative lifetime risk of up to 100%. Mutations in BAP-1 as well as germline mutations in CDKN2A and CDK4 have been found in familial melanoma. Gain of KIT and loss of INK4A have been frequently noted in pediatric melanoma.[210] Extrinsic UV radiation exposure with indoor tanning is an important risk factor for melanoma in adolescents, and many states are developing legislation banning the use of tanning salons by minors.

Melanomas in children do not always follow the established criteria of asymmetry, border irregularity, color variegation, diameter larger than 6 mm, and evolution (ABCDE). It has been shown that many lesions are amelanotic and present with bleeding, bumps, and color uniformity. Hence, it is important to have a higher index of suspicion in children with skin lesions.[211] A full-thickness excisional biopsy is the procedure of choice for establishing the diagnosis. A higher proportion of children with melanoma have thicker tumors and positive lymph node metastasis at the time of presentation than is seen adults.[212]

Margins of excision of 1 cm around the primary lesion are adequate for treatment of thin (<1 mm) melanomas. Margins of 1 to 2 cm are recommended for treatment of melanomas that are 1 to 2 mm thick. For

melanomas thicker than 2 mm, margin of 2 cm is considered adequate.[213]

Children with melanoma can benefit from sentinel lymph node biopsy.[212,214] Routine use of sentinel lymph node biopsy is not recommended for thin (<1 mm) melanomas as the incidence of metastatic lymphadenopathy is low. However, a subgroup of patients with ulceration or mitosis (one or more per high-power field) may benefit from sentinel lymph node biopsy. Patients with intermediate-thickness melanoma (1 to 4 mm) stand to benefit the most from sentinel lymph node biopsy. The procedure helps identify patients with occult lymphatic metastasis whose outcome is improved significantly due to early identification and treatment with completion lymphadenectomy.[215] Because patients with thick melanomas (>4 mm) are at high risk for systemic metastasis, historically, sentinel lymph node biopsy has not been offered because of lack of a demonstrated survival benefit. However, if distant metastasis is not present, these patients can be managed similarly to those with intermediate-thickness disease and hence are frequently offered a sentinel node biopsy. Lymphoscintigraphy must be performed to identify sentinel nodes as well as any in-transit nodes both of which must be removed. Patients with sentinel lymph nodes demonstrating metastatic melanoma should undergo a completion lymphadenectomy.[213]

Fine needle aspiration cytology must be performed if regional lymphadenopathy is noted clinically or radiologically. Confirmed metastatic melanoma is best treated with a comprehensive neck dissection. For melanomas arising on the face and scalp, a superficial parotidectomy may be included with neck dissection for complete clearance of draining lymphatics.

The survival of patients with melanoma in the pediatric and adolescent age group is similar to that in adults and is associated with tumor thickness, ulceration, lymph node status, and overall stage. There is a trend toward increased survival in children younger than 10 years of age.[207] The 10-year overall survival was reported to be 94.1% for American Joint Committee stage I disease, 79.6% for stage II disease, and 77.1% for stage III disease in an analysis of 365 pediatric patients with melanoma in an international registry study.[207]

Patients with advanced disease can benefit from recent advances in therapy including vemurafenib and ipilimumab. However, the data regarding use of these agents in the pediatric age group are still lacking.

Nonmelanoma Skin Cancer

Nonmelanoma skin cancer is exceedingly rare in the pediatric age group. Xeroderma pigmentosum is a rare autosomal recessive disorder that appears in early childhood and is characterized by photosensitivity, hyperpigmentation, and premature skin aging.[216] Patients are at increased risk for both squamous cell carcinoma and basal cell carcinoma. Face, head, neck, scalp, and other sun-exposed areas are common locations.[217] Ionizing radiation for treatment of previous childhood malignancy is also a known risk factor although cancers most commonly develop in early adulthood.[218]

Nevoid basal cell carcinoma syndrome is an autosomal dominant disorder that is characterized by multiple jaw keratocysts and basal cell carcinomas. Many patients have a recognizable appearance with macrocephaly, forehead bossing, and coarse facial features. Basal cell cancers develop more commonly from the third decade onward.[219] The primary underlying disorder is a defect in hedgehog signaling. Vismodegib, a hedgehog pathway inhibitor, has been shown to reduce the basal cell carcinoma tumor burden and block the growth of new basal cell carcinomas in patients with this condition. However, adverse events associated with treatment, including loss of taste, muscle cramps, hair loss, and weight loss, have led to discontinuation in over half of treated patients.[220]

Squamous Cell Carcinoma of the Upper Aerodigestive Tract

Squamous cell carcinoma of the oral cavity and other mucosal locations in the upper aerodigestive tract is an uncommon condition in children and adolescents. A literature review documented 55 cases in the period from 1894 to 2011 in the United States.[221] Predisposing conditions include xeroderma pigmentosum, Fanconi anemia, epidermolysis bullosa, and juvenile respiratory papillomatosis.

Fanconi anemia is a rare recessive DNA repair disorder that causes progressive bone marrow failure and is associated with a high incidence of malignancies including acute myeloid leukemia and squamous cell carcinoma of the head and neck.[222] Head and neck squamous cancers occur at an incidence several hundred to thousand folds higher than the normal

population. Cancers can develop anywhere in the upper aerodigestive tract and are characterized by a more aggressive behavior including a higher likelihood of soft tissue invasion and lymphatic metastasis. The most frequent birth defects in Fanconi anemia include skin hyperpigmentation, café au lait spots, short stature, and abnormalities of the head, eyes, kidneys, and ears. Because many patients with Fanconi anemia may be phenotypically normal, any patient who is diagnosed with a squamous cell carcinoma of the head and neck in the pediatric age group should be considered for testing for this condition with a chromosomal breakage test.[223] The mainstay of therapy is surgery because these patients are unusually sensitive to the toxic effects of radiation and chemotherapy. Severe mucositis and pancytopenia commonly occur and can lead to further complications including bleeding and infection.[224]

Malignant Germ Cell Tumor

Malignant germ cell tumors arise from primordial germ cells and afflict ~300 children annually in the United States.[225] The etiology of these tumors remains to be fully elucidated, although aberrant embryonal primordial germ cell migration is one of several hypotheses for the origin of these tumors (Brown 1976). The combination of platinum-based chemotherapy and surgery is most frequently employed, and current survivorship approaches 80% to 90% at 3 years, particularly when high-dose chemotherapy regimens are used.[226,227] Unfortunately, the intensification of chemotherapy agents, although lifesaving, also induces a variety of toxicities.[228]

Teratoma is a nongerminomatous germ cell tumor found particularly in neonates. Most teratomas are benign, with an overall malignancy rate of 20%, varying greatly depending on the primary site.[229] Mature or immature teratoma of children frequently demonstrates a benign long-term outcome.[230] Approximately 5% of head and neck teratomas contain malignant elements; these are rare in neonates and occur primarily in adults.[231] Other malignant germ cell tumors include embryonal carcinoma, endodermal sinus tumor/yolk sac tumor, choriocarcinoma, polyembryoma, and gonadoblastoma. Mixed tumors combine various components of the array of germinomatous and nongerminomatous germ cell tumors, but the natural history is driven by the more malignant component(s), as is the therapy.

Lesions in the head and neck region account for ~5% of all benign and malignant germ cell neoplasms[232]; common sites include the neck, oropharynx, nasopharynx, orbit, and paranasal sinuses.[233,234] Oropharyngeal and nasopharyngeal teratomas occur almost exclusively in neonates and young infants. Teratomas have a predilection for the oropharynx.[234] Orbital teratomas also typically present at birth with proptosis. The ovaries, testes, anterior mediastinum, retroperitoneum, and sacrococcygeal region are the most common primary sites outside the head and neck.

Even though the vast majority of pediatric cervical teratomas are histologically benign, the morbidity and mortality associated with these tumors can be significant.[235] Infants with large cervical teratomas have an increased incidence of polyhydramnios, prematurity, and stillbirth.

Histologically, teratomas are composed of ectodermal, mesodermal, and endodermal components. Depending on the degree of differentiation of the components, teratomas are classified as mature or immature. A predominance of immature elements portends a poorer prognosis and may suggest malignancy.[236] This, however, is not true in the neonatal age group. Teratoma secretion of alpha-fetoprotein and beta-human chorionic gonadotropin has implications regarding postoperative monitoring.

The treatment of teratomas is surgical extirpation, frequently in conjunction with chemotherapy. Because malignant degeneration in teratomas of the head and neck among children is so rare, much of the experience in the therapy of pediatric germ cell malignancies has been achieved in treating these lesions in gonadal and other extragonadal locations. These cases are primarily managed with resection. For those with unresectable or metastatic disease, chemotherapy is effective, thereby obviating maximal resection upfront when intervention risks damage to vital normal tissues. Patients with unresectable or residual disease may also receive radiation to the primary site; however, this is rarely advisable for infants.[237] Metastasis from childhood teratomas is rare, although it has been reported. When systemic metastases are present, multiagent chemotherapy and surgical resection are suggested. Salvage chemotherapy is used in the setting of recurrent disease.[236]

Almost all patients demonstrate an initial response to therapy. After surgical resection of immature teratomas, the 3-year survival is 93%.[236]

Orbital teratomas have an excellent prognosis after orbital exenteration.[235] The 4-year disease-free survival of malignant and mixed teratoma is ~70%.[238]

Regardless of the histopathology of the tumor, all patients should be followed for possible recurrence. Oropharyngeal and nasopharyngeal teratomas may require follow-up endoscopic examinations. Radiologic follow-up by means of CT or MRI is typically appropriate (April 1998). The tumor-secreted products alpha-fetoprotein and beta-human chorionic gonadotropin should also be monitored.

Paraganglioma

Paragangliomas and pheochromocytomas are rare, morphologically identical neuroendocrine tumors, with pheochromocytoma designating those that arise from the adrenal medulla, whereas paragangliomas are those that arise in various locations extra-adrenally along the parasympathetic and sympathetic chain. Most paragangliomas of the head and neck are nonsecreting (nonfunctional) tumors from parasympathetic tissues.[151] Approximately a quarter of paragangliomas are associated with a hereditary predisposition syndrome, with key genetic syndromes including multiple endocrine neoplasia, von Hippel-Lindau, neurofibromatosis type 1, hereditary paraganglioma syndrome, and Carney triad.[12,151] Due to the general potential for spontaneous or induced paroxysmal excess catecholamine release in turn leading to sequelae such as hypertensive crises, appropriate biochemical evaluation and multidisciplinary preoperative management with consideration for preprocedural blockade are mandatory. Biochemical diagnosis may be typically made with plasma and urine fractionated metanephrines. Different succinate dehydrogenase (SDH) mutations are implicated in different typical clinical manifestations, with paraganglioma of the head and neck often associated with SDHB, SDHD, and SDHC, with the latter particularly associated with multiple tumors of the head and neck.[11,12,239,240] Young patients with SDHB mutations may have an associated higher rate of metastatic presentation.[151,239] Special functional imaging techniques, such as FDOPA (18F-fluorodopa) PET, may allow increased sensitivity for head and neck paragangliomas that may at times be missed on conventional octreotide scintigraphy.[12] All pediatric patients with paragangliomas of the head and neck should be considered for genetic counseling and evaluation, with

engagement of the family and the multidisciplinary team in management decision-making.[239–242]

Tracheal and Endobronchial Tumors

Very rarely, pediatric tracheal and intrabronchial tumors may be identified, with diagnoses including well-differentiated neuroendocrine tumors (“carcinoid tumors”) and mucoepidermoid carcinoma.[243–245] Endobronchial presentation of the tumors highlighted above, including inflammatory myofibroblastic tumor and non-Hodgkin lymphoma, have also been reported.[244,246]

NUT Midline Carcinoma

NUT midline carcinoma represents a very rare malignancy, characterized by rearrangement of the NUT gene on chromosome 15q14.[151] First described in pediatric patients but affecting patients of all ages, these aggressive tumors characteristically occur in midline epithelial sites, including the mediastinum and upper aerodigestive tract. Despite aggressive multimodality therapy including surgical resection and radiation therapy, current fatality rates remain high, and ongoing studies are warranted to improve the course of this malignancy.[247,248] An international NUT midline carcinoma registry[249] has been established in an effort to promote advances.

SPECIAL CONSIDERATIONS

Genetic Considerations

Family history should be carefully reviewed in all children with cancers of the head and neck. Decision-making regarding genetic testing should be considered carefully with families as well as pediatric patients as developmentally appropriate, in the context of pre- and posttesting counseling, as recommended by the American Society of Clinical Oncology.[250] A number of cancer predisposition syndromes with potential manifestations in the head and neck in children have testing protocols or guidance considerations to help implement individualized decision-making, including retinoblastoma, von Hippel-Lindau syndrome, multiple endocrine

neoplasia, familial paraganglioma syndrome, PTEN hamartoma tumor syndrome, and Li-Fraumeni syndrome.[241,251–253]

Pediatric Cancers in Resource-Limited Settings

The epidemiology of cancers of the head and neck in the pediatric population is quite distinct in many resource-limited settings globally, compared to that in North America and other developed areas. In equatorial Africa, for instance, 50% of pediatric cancers are lymphomas, due to the predominance of endemic Burkitt lymphoma.[142,254] In contrast to sporadic Burkitt lymphoma, endemic cases most often present with jaw swelling or periorbital swelling.[254] Although Kaposi sarcoma represents 78% of oral cavity sarcomas in adults in the United States,[4] it is not typically a diagnosis encountered in children in North America, but is a dominant concern in settings with endemic HIV, including in Africa. Children with Kaposi sarcoma may present with manifestations in the head and neck such as brawny and disseminated lymphadenopathy, multifocal oral, facial, scalp, or tracheal lesions and nodules.[255]

Masses in the neck in children typically present late and with more advanced disease in resource-limited settings.[254,256] Local health beliefs are among potential factors for delayed presentations or alternative therapy choices, including those involving African traditional healers.[256] Tuberculous adenopathy, particularly in regions with endemic tuberculosis, needs to be considered as a potential comorbid or primary condition for a mass in the neck in a chronically ill child.

Although the survival of children with cancer has dramatically improved in recent decades, unfortunately, for the 80% of children in the world with cancer who live in low- and middle-income settings, outcomes are significantly poorer.[35,257] Apart from potentially distinct disease epidemiology and infectious comorbidities such as HIV and endemic tuberculosis, physicians working in many resource-limited settings are confronted with shared concerns regarding access to quality diagnosis, treatment, and care, with health system and service delivery challenges, human resource and technology gaps, and sociocultural factors. Thus, effective diagnosis and management of a mass in the head and neck warrant considerations of an effective chain of care, from preoperative management

of infections through to safe anesthesia and intensive care, alongside appropriate handling of tissue specimens and care coordination among trained team members, feasibility of local control including access to complex surgery and radiotherapy, and timely delivery of multimodality therapy.[258,259]

Compounding late and advanced presentations, children in these resource-limited environments often have less functional reserve to tolerate treatment owing to poor nutrition or health status and less access to essential diagnostic tools, medications, and interventions due to prohibitive costs and/or regulatory barriers. Outcomes in resource-limited settings even for typically curable cancers are thus limited by high rates of progressive disease, treatment- and infection-related morbidity and mortality, as well as treatment refusal and treatment abandonment (the failure to complete curative therapy).[254,259,260] As an example, whereas almost all children with retinoblastoma diagnosed in high-income settings survive, children with retinoblastoma diagnosed in many resource-limited settings have cure rates much below 50%, warranting sustained partnered approaches that are sensitive to contextual health systems needs and social determinants of health.[261,262]

Context-sensitive, locally relevant evidence and best practices should be sought and applied wherever possible, extending clinical studies as well as interval consensus recommendations for specific cancers as well as supportive care, via networks such as the Pediatric Oncology in Developing Countries working groups of the International Society of Paediatric Oncology (SIOP).[254,255,260,263–266] Consensus publications for pediatric cancer care in resource-limited settings have included adapted treatment regimens and recommendations for diagnoses such as retinoblastoma[266] and Kaposi sarcoma,[254] as well as position statements on core needs including supportive care,[265] nursing care,[264] and addressing treatment abandonment.[260] Through extended partnerships and sustained on-site interdisciplinary efforts, continued progress is being made so that children with cancers of the head and neck the world over may benefit from diagnostic and therapeutic advances.[261,267,268]

OPTIMIZING LONG-TERM

OUTCOMES

Reconstruction of Defects in the Head and Neck

The idea of using flaps of local tissue to reconstruct adjacent defects led to significant advances in reconstructive surgery. Initially, flaps were selected randomly based on criteria such as proximity to a soft tissue defect and geometry rather than on specific knowledge of the pattern or reliability of the blood supply.[269] Subsequently, axial flaps such as the deltopectoral flap and the groin flap were described, based on an incorporated known axial blood supply. Myocutaneous flaps were added to the list of available flaps in the 1970s, and this improved the facility with which immediate reconstructions were reliably performed. Free microvascular tissue transfer is now routinely used in reconstructive surgery.

Reconstructive microsurgery has become an integral part of head and neck reconstruction, allowing the completion of complex resections with predictable outcomes. Common flaps and their reconstructive applications include (but are not limited to) ones listed in **Table 24.10**.

Table 24.10 Recontructive Options for Surgical Defects in the Head and Neck

Flap	Defect
Anterolateral thigh	Floor of mouth, tongue, face, skull base, maxilla, mandible (soft tissue only)
Radial forearm	Floor of mouth, tongue, face, palate
Scapula	Face, maxilla, mandible
Fibula	Mandible, maxilla, calvarium
Rectus abdominis	Skull base, maxilla
Latissimus dorsi	Scalp

Surgery for cancer of the head and neck is rare in the pediatric age group,

and there are limited reports in the literature regarding reconstruction of these defects. Despite these limitations, some general observations with regard to indications for free flap reconstruction, needed for surgical planning to incorporate future facial growth and dental rehabilitation, have been made. Future advances with newer alloplasts, virtual surgical planning, and distraction osteogenesis will no doubt improve treatment of these patients. In general, pediatric patients lack the numerous comorbid conditions of adult head and neck cancer patients (e.g., tobacco use, vascular disease), thus making reconstruction more successful. Given the pediatric patient's improved capacity for nerve healing, current and future research is focused on improving outcomes using innervated free flaps to improve sensibility and function.

General discussions about principles of head and neck reconstruction and techniques can be found elsewhere in this text. Thus, the following discussion is focused on issues specifically relevant to pediatric head and neck cancer reconstruction in the pediatric age group.

Mandible

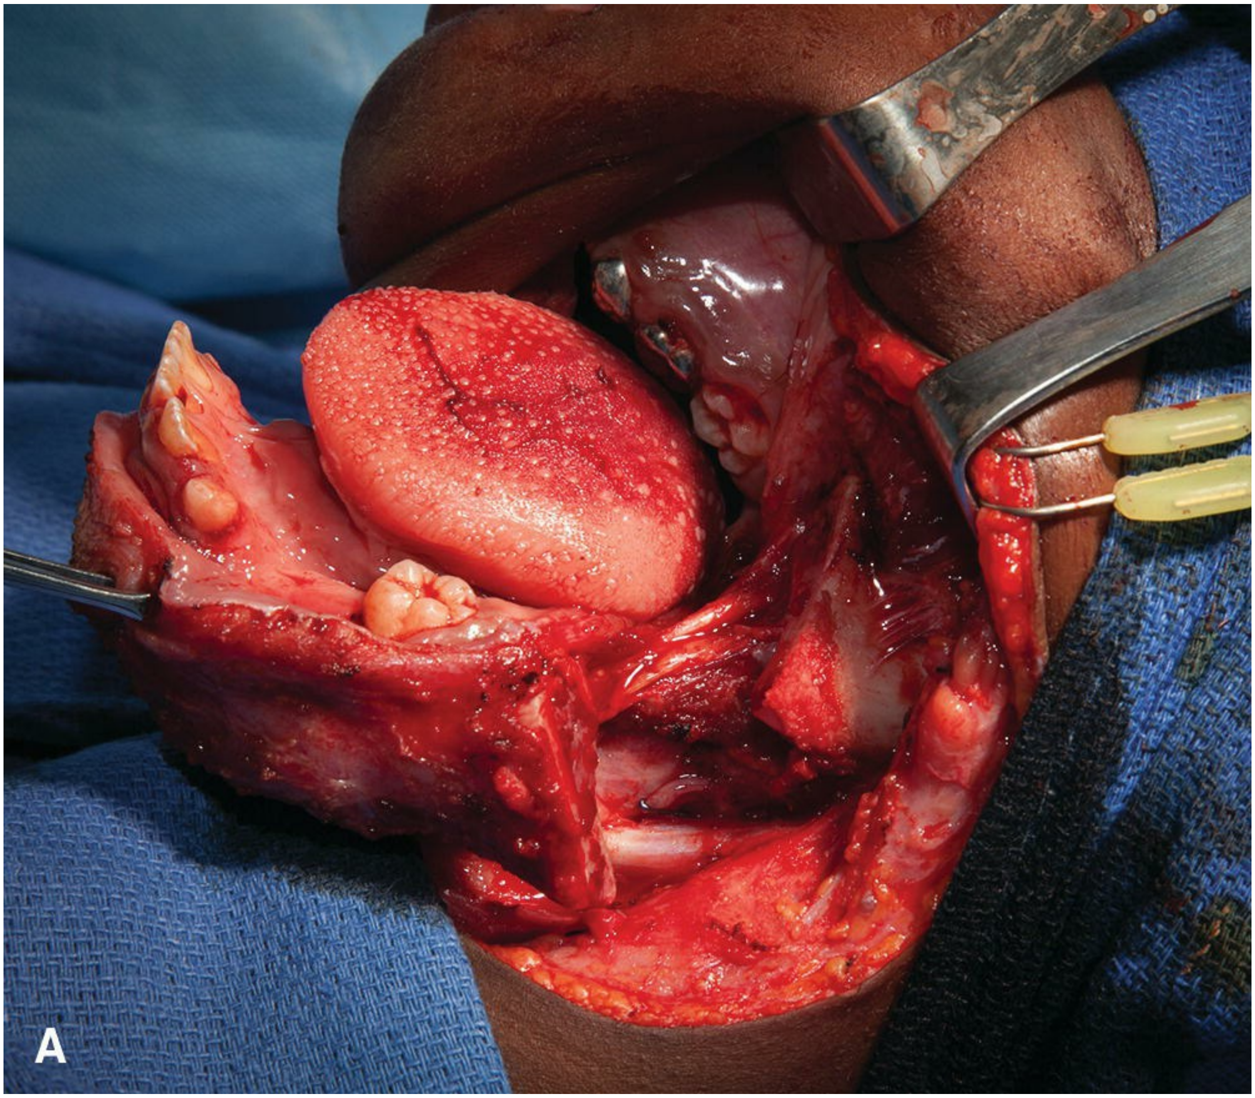
Many techniques have been used in reconstructing the mandible, including those associated with nonvascularized bone grafts, sterilized autogenous bone, and alloplasts of different types. Although there may be specific indications to use some of these techniques, the goal of reconstruction must include control of the malignant process and reconstitution of form, function, and cosmesis. The issue of whether or not reconstruction with bone is always required in reconstructing mandible is particularly challenging in pediatric patients.[270] In many situations, posterior and lateral mandibular defects can be reconstructed with a soft tissue flap only, without the use of a plate or bone. Although short- and midterm outcomes, with regard to function and cosmesis, are acceptable, the greatest disadvantage is that, over time, progressive mandibular crossbite and malocclusion develops and dental restoration is either impossible or severely compromised. The consensus would appear to be that this is a reasonable option for lateral mandibular defects in patients with multiple comorbidities and/or a poor prognosis.

The criterion standard for reconstruction of the mandible using the fibular osseocutaneous flap, originally introduced by Hidalgo in 1989.[271] It provides good bone stock for fashioning a mandible, and the option of a reliable skin

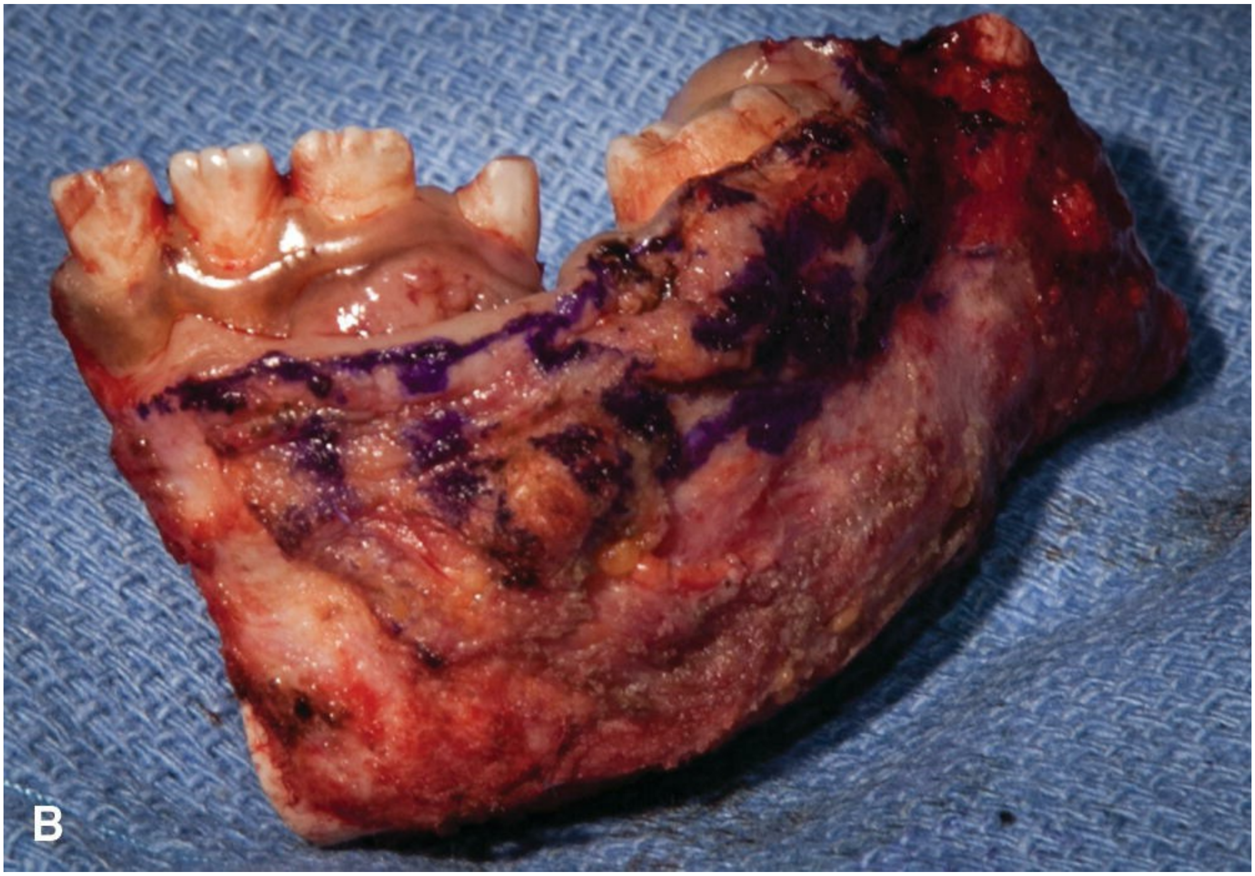
paddle that can be used either for oral lining or external cover with the potential for reinnervation. Among the several advantages of the fibular osseocutaneous flap is the fact that the bone stock it supplies is adequate for insertion of osseointegrated implants for dental rehabilitation. This is important for restoring oral function although, because of cost issues, many patients, particularly in North America, are not in a position to benefit from this final step in their reconstruction. A modification of the fibular flap that provides a greater mandibular height and optimizes dental rehabilitation is to double barrel the fibula.[272,273]

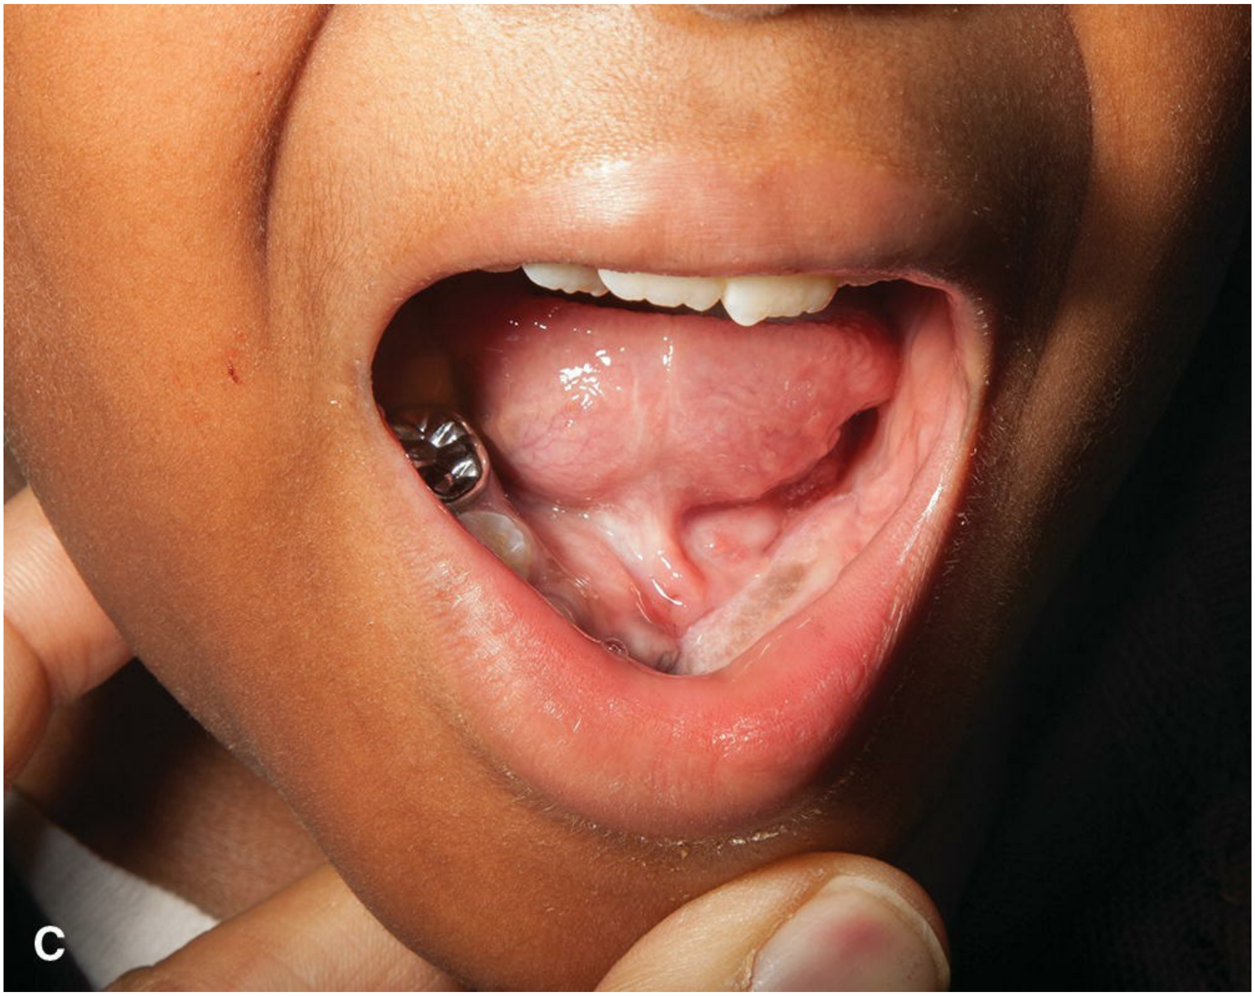
With regard to pediatric patients, there are a number of unique concerns with regard to mandibular reconstruction. When reconstruction is performed in a skeletally immature patient, it is important to attempt to avoid the mandibular growth centers in the condyle and symphysis; otherwise, growth retardation will ultimately necessitate surgical revision, as with bone reconstruction in the extremities.[274] Similarly, hardware (i.e., plates and screws) must avoid these areas.

Reconstruction with a free flap is a challenging but reliable option in pediatric patients (**Fig. 24.13**). Preoperative planning should involve oral maxillofacial surgeons and take into consideration the timing of tooth development and maxillary and mandibular growth as part of the long-term strategy.[275] Growth of the vascularized fibula without epiphyseal transfer has not been identified. Therefore, there are often needs for additional osteotomies to readvance the fibula or for additional vascularized or nonvascularized bone grafts. Also, to ultimately have enough bone stock for implants, double-barrel fibular flaps or secondary bone grafts are often necessary. Many of these patients need more than one free tissue transfer of bone and soft tissue before their reconstruction is completed at the time of skeletal maturity.



A





C

Figure 24.13. A: A 6-year-old boy with an invasive gingival squamous

carcinoma undergoing segmental mandibulectomy. **B:** Mandibulectomy specimen. **C:** Intraoral appearance after fibula reconstruction. **D:** Appearance after reconstruction.

It should be noted that in extremely young (i.e., <2 years) or small patients, prosthetic-only reconstructions (e.g., reconstruction plate; alloplastic stainless steel mandible prosthesis) are viable options, provided that there is ultimately a plan for bone grafting. Similarly, traditional nonvascularized bone graft mandibular reconstruction has been successful in the pediatric population, but is not as reliable as free flap reconstruction.

Although dental rehabilitation is a necessary part of recovery after cancer of the oral cavity, there is no consensus regarding the type or timing of dental rehabilitation in the pediatric patient. Options include no reconstruction, denture or fixed prosthesis reconstruction, or placement of osseointegrated dental implants. Dental implants have the advantage of permanent fixation for a dental prosthesis and help to prevent long-term osteolytic changes of the native mandible and fibular flap by transferring loading directly to the bone. However, owing to growth changes in the pediatric native mandible and maxilla, it is not a feasible option in many children. Dentures and/or a fixed prosthesis (bridge) may be a viable option in these patients, but they do not provide an adequate stress response to the mandible and thus can ultimately result in significant bone loss with the need for future bone grafting and/or flap reconstruction.

Scalp

Although there are many situations in which local flaps can be used to reconstruct the scalp, for larger defects, free flaps are commonly used. Unfortunately, there is no flap available that can replicate the hair-bearing characteristics of the scalp. Also, the surface area of the reconstruction frequently demands a large flap. For these reasons, the general consensus for reconstruction of the scalp is the latissimus dorsi muscle flap, covered with an unmeshed split-thickness skin graft.[276,277] Although the muscle may be bulky initially, the flap generally thins owing to muscle atrophy and ultimately replicates a normal hairless scalp within a matter of months. Of particular importance to the pediatric population, long-term reconstruction of hear-bearing skin requires the use of follicular micrografting, serial excision,

or tissue expansion of hair-bearing residual scalp.

Midface

An area of ongoing development is the management of the maxillectomy defect. With respect to palatal reconstruction, functional outcomes are oftentimes equivocal between microvascular reconstruction and an obturator.[278] The need for adjuvant radiation therapy may preclude the use of metallic implants used for rigid reconstruction. Unfortunately, without some type of rigid reconstruction, soft tissue contracture results to extremely difficult or impossible correction of secondary deformities. Definitive dental rehabilitation frequently needs to wait until skeletal maturity, thus placing a premium on the use of removable prosthetics. Fortunately, it may not be necessary to reconstruct all mucosal surfaces with multipaddled skin flaps, as raw muscle surfaces often mucosalize, and sinus cavities can be obliterated. Finally, even for external facial defects, prosthetics can provide a viable option. Where possible, it is imperative to preserve function unless this compromises the ablative procedure. The diversity of flaps used to reconstruct these defects bears testament to the fact that there is no criterion standard in maxillary reconstruction.

The fibula is used extensively and has the advantage of a long pedicle, versatile bone, and soft tissues and is amenable to placement of an implant.[279] However, the fibula can be bulky, and this can have an impact on flap inset. Anastomosis can be performed to the superficial temporal vessels or to the facial vessels, although often a vein graft is required. The scapular flap is a very versatile flap, as it allows the transfer of excellent bone stock with the option of incorporating muscle for soft tissue reconstruction. It also has the advantage of a long pedicle.

A number of factors particular to pediatric reconstruction merit note. Although reconstruction with soft tissue flaps has been the norm in the past, the major disadvantage of soft tissue–only flaps is that they do not address the structural defect that results from bony resection and progressive soft tissue contracture results, which is extremely difficult to address secondarily, particularly in the pediatric patient.[280,281] These reconstructions ultimately contract, and the patient tends to lose facial height and facial projection, with effects on the nose, lips, and orbits. It is not only intuitive but has been shown in the craniofacial literature that if the bony framework is restored, the soft

tissues cannot contract and the long-term aesthetic results are superior.

As with reconstruction of the mandible, bone flaps do not grow with the native maxilla. Thus, there is often a need for bone regrafting as patients mature.[282] Distraction osteogenesis (DO) is an excellent option, in properly selected patients. Historically, adjuvant radiation therapy has been considered a contraindication to DO. However, there is a growing literature to suggest that DO is a viable option in properly selected patients. Our group has had a favorable experience with this technique, when it is coupled with use of preoperative and postoperative hyperbaric oxygen therapy. Such patients have even successfully tolerated placement of osseointegrated dental implants and bone grafting.

In summary, need for major reconstruction for cancer of the head and neck in the pediatric age group is relatively uncommon, and there are limited reports in the literature regarding reconstruction of these defects. For many reconstructions, no perfect donor tissue is available. In some cases, a patient's ideal donor site has been compromised by trauma, radiation, or progressive comorbid disease. In any event, reconstructive ingenuity is critically important to achieve success in this patient population. Despite these limitations, some general observations with regard to indications for free flap reconstruction, need for surgical planning to incorporate future facial growth, and dental rehabilitation have been made. Future advances with newer alloplasts, tissue engineering, composite tissue allotransplantation, virtual surgical planning, and DO will no doubt improve our treatment of these patients.

Late Effects of Therapy

When discussing late effects of head and neck cancer therapy, the major subcategories include structural or functional abnormalities of normal tissues and secondary malignancies. Although progressive primary tumor remains the overall leading cause of mortality in the majority of these patients, as cure rates improve, growing attention is being focused upon late effects and other causes of morbidity and mortality.[283] Bone growth abnormalities of the craniofacial structures are another manifestation of intensive, multimodality therapy.[284–287] These frequently lead to functional deficits and cosmetic defects; mortality can result in severe clinical scenarios.

The use of surgery to extirpate lesions and/or reconstruct pediatric craniofacial anatomy is not without long-term sequelae. Particularly, when combined with the use of chemoradiotherapy, the late effects can be associated with considerable morbidity. This knowledge continues to drive an extensive array of research into the molecular biology of craniofacial development and surgical reconstruction with the objective of minimization of morbidities.[288–290]

Chemotherapeutic effects cannot be discounted when used as part of a multimodality regimen. The sensitizing potential to enhance toxicity in both tumor and normal tissue is well known.[291] Molecularly targeted agents have sought to selectively enhance tumor cell kill and thereby widen the therapeutic window; however, much remains to be done in bringing effective therapy into the mainstream.[292]

Likewise, a growing body of evidence suggests a small but notable risk of secondary malignancy associated with chemotherapy.[293] The predominant form of these complications arise in the spectrum of myelogenous disorders (myelodysplasia or myelogenous leukemia). There may be a small contribution to the development of solid tumors; however, this has largely been attributed to the frequent concurrent or sequential use of radiotherapy.[294] Still, occasional solid tumor secondary malignancies will develop remotely from the irradiated fields.[295,296]

The increased risk of secondary cancers due to radiotherapy has been well documented, partly due to the longer history of use relative to chemotherapy.[134] Radiotherapy dose reduction may lead to a lower incidence of some secondary solid cancers.[135,297–299] However, at least some data for secondary thyroid malignancy suggest that there may be a threshold effect, beyond which cell-killing effect may predominate over carcinogenesis.[300] The cumulative risk of developing a mesenchymal carcinoma of the soft tissues, thyroid, or head in radiotherapy fields increases over time.[127,296,301] The cumulative risk of developing a secondary malignancy correlates with age of the child, radiotherapy field size, as well as dose; reduction of risks associated with each of these parameters is countenanced while optimizing the chance for cure.

Vascular abnormalities can also be caused as a result of high-dose radiotherapy, and these sequelae may be severe as well.[302,303] The morbidity

and mortality of these late effects remain poorly studied, although initial reports demonstrate the need for improved targeting/selectivity of therapy. The growing array of documented comorbidities associated with therapy is helpful in providing a thorough understanding for the families of pediatric patients, for whom informed consent is a critical process.

25 Head and Neck Cancer in Developing Countries

Johan Fagan Clare Stannard

INTRODUCTION

Cancer in developing countries is a public health crisis. Developing countries constitute the majority of the world's landmass (**Fig. 25.1**) and are home to more than 50% of its people. Farmer et al.[1] reported in 2010 that developing countries accounted for more than 50% of newly diagnosed cancers and projected that this would increase to 70% by 2030 (**Fig. 25.2**); this increase can be attributed to population growth, reduced mortality from infectious diseases, and an aging society. The same authors report a wide disparity in cancer-related case mortality, which is aligned with income levels of countries, ranging from 75% in low-income countries to 46% in high-income countries (**Fig. 25.3**).[1] Even though developing countries account for 67% of cancer-related deaths, they account for only 5% of cancer-related spending.[1] For all the aforesaid reasons, a discussion about head and neck cancer would be incomplete were it not to include a developing world perspective. It is also apparent that, in order to improve head and neck cancer outcomes globally, it is essential that innovation, expertise, resources, teaching, and research also be directed at addressing cancer in the developing world.

Figure 25.1. Developing (*dark*) versus developed world (*light*).

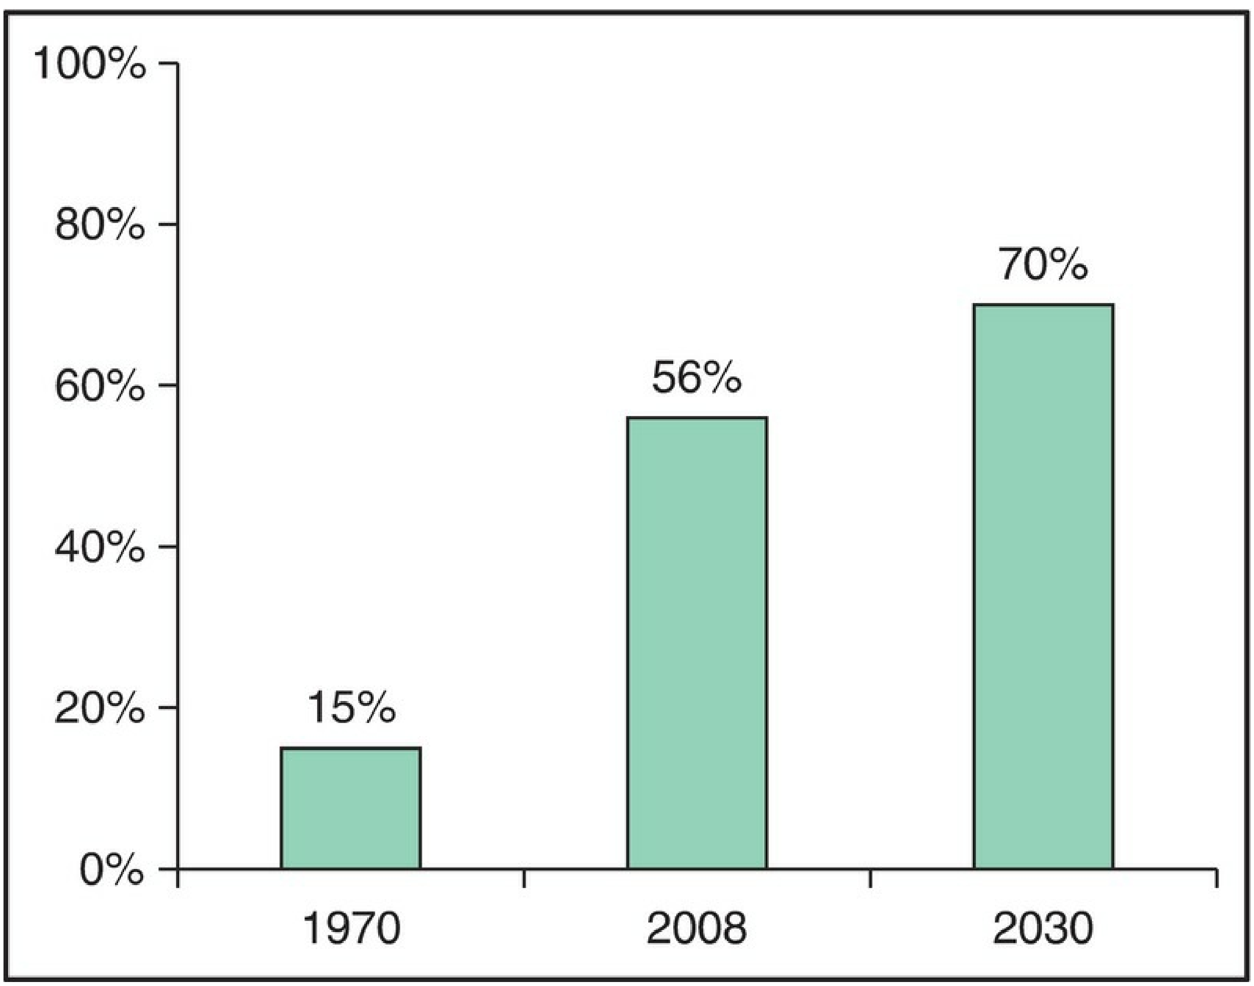

Figure 25.2. Increasing percentage of global burden of cancer in the developing countries. (From Farmer P, Frenk J, Knaul FM, et al. Expansion of cancer care and control in countries of low and middle income: a call to action. *Lancet.* 2010;376(9747):1186–9113.)

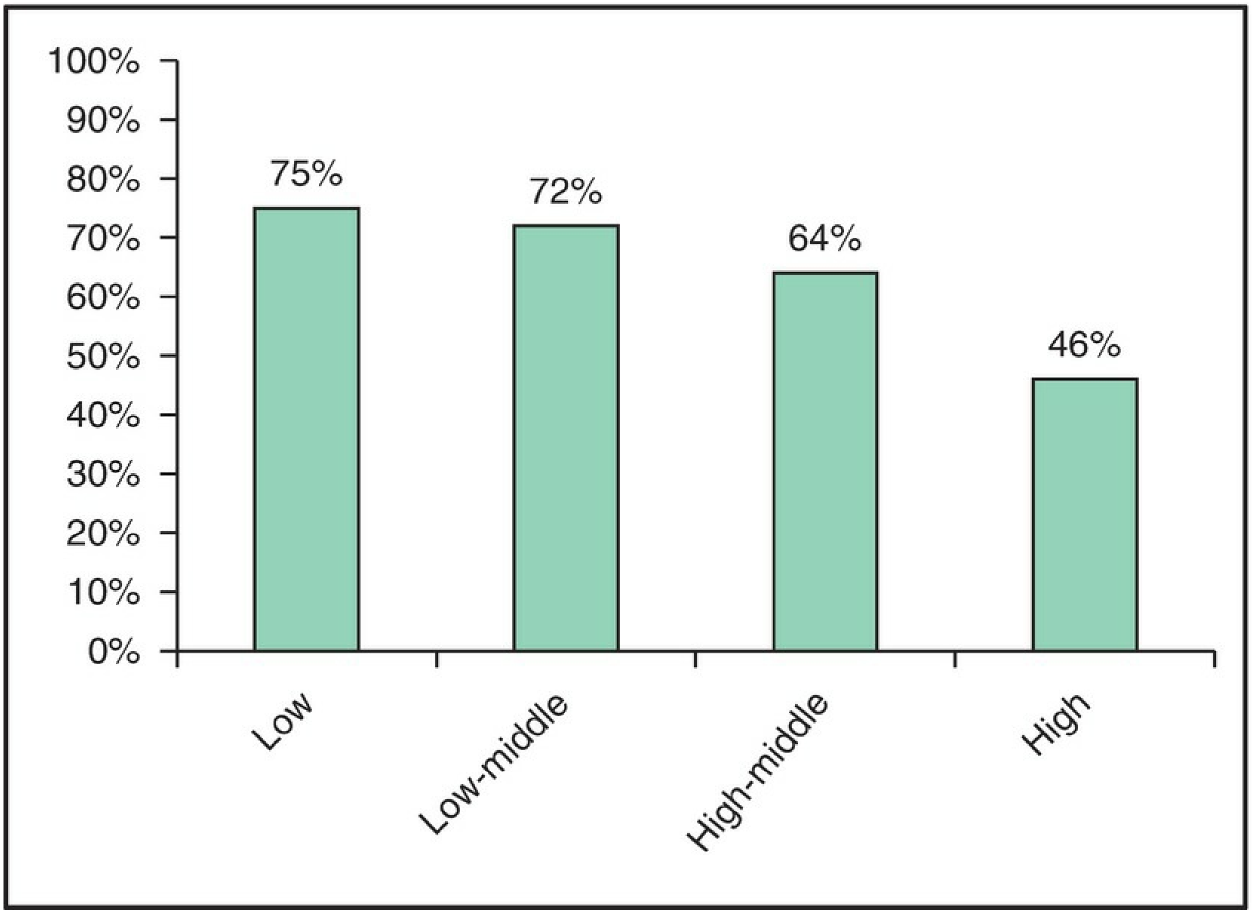

Figure 25.3. Case mortality from cancer according to income levels of countries. (From Farmer P, Frenk J, Knaul FM, et al. Expansion of cancer care and control in countries of low and middle income: a call to action. *Lancet.* 2010;376(9747):1186–9113.)

EPIDEMIOLOGY

The developing world is undergoing rapid economic growth; this is accompanied by lifestyle changes such as increased rates of smoking and alcohol consumption. These changes coupled with increased longevity are associated with global changes in the epidemiology of squamous cell cancer of the head and neck. Two-thirds of oral and pharyngeal cancers (excluding

nasopharynx) occur in developing countries.[2] **Figure 25.4** illustrates the significant geographical variation that exists for the incidence of oral cancer; it is the most common cancer in males in high-risk areas such as Sri Lanka, India, Pakistan, and Bangladesh and accounts for up to 25% of all new cancers.[2] The principal causes of oral cancer are tobacco (smoked or chewed) and betel quid.[2] Buccal cancer is common in Asia due to its association with betel quid and tobacco chewing; 40% of oral cancers in Sri Lanka are buccal carcinomas.[2]

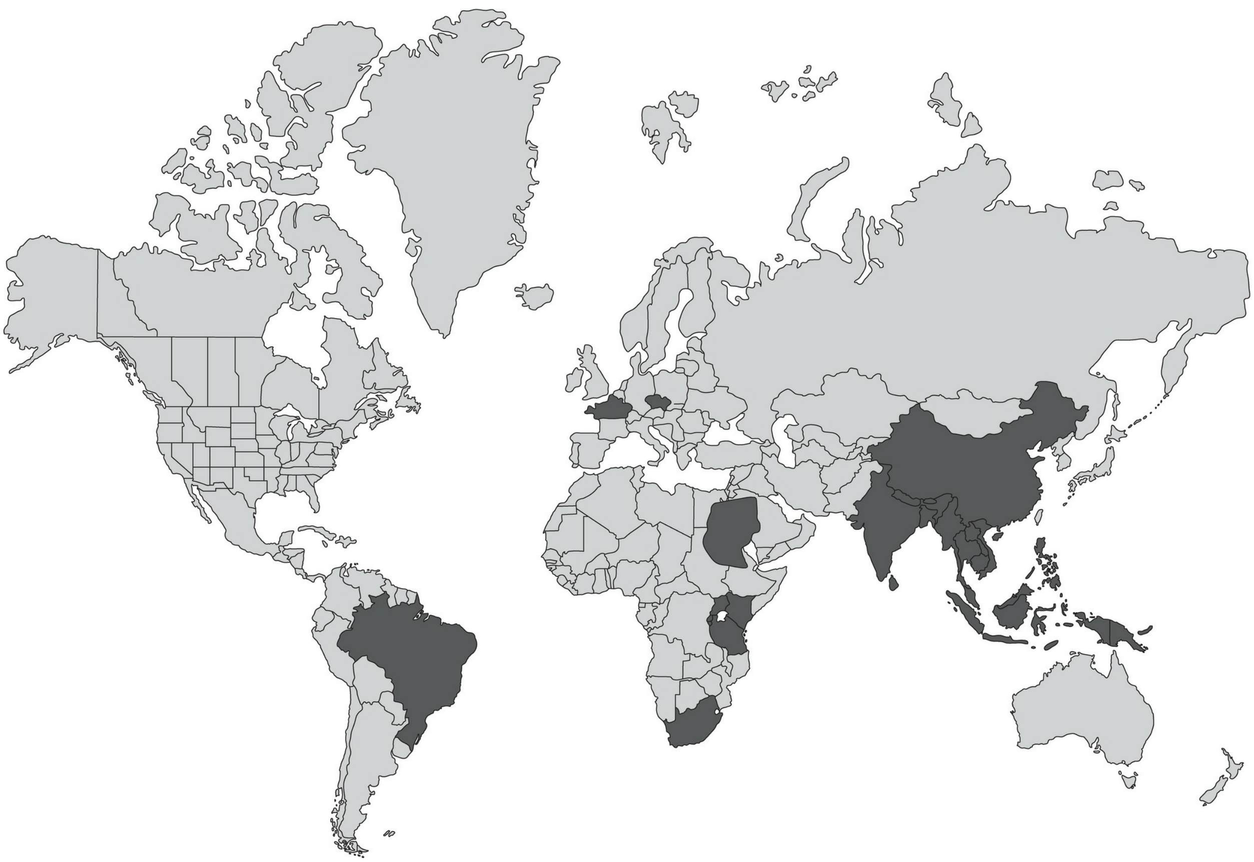

Figure 25.4. Countries with high incidence and mortality from oral cancer. (From Warnakulasuriya S. Global epidemiology of oral and oropharyngeal cancer. *Oral Oncol.* 2009;45:309–316.)

Cancer of the nasopharynx is also principally a developing world problem (**Fig. 25.5**).[3] It is associated with the Epstein-Barr virus (EBV) in China, Southeast Asia, northern Africa, and the Inuits of Alaska[4] where nonkeratinizing squamous cell carcinoma and undifferentiated carcinoma are more common. Human papillomavirus (HPV) may be an etiologic factor in

the EBV-negative Caucasian population.[5]

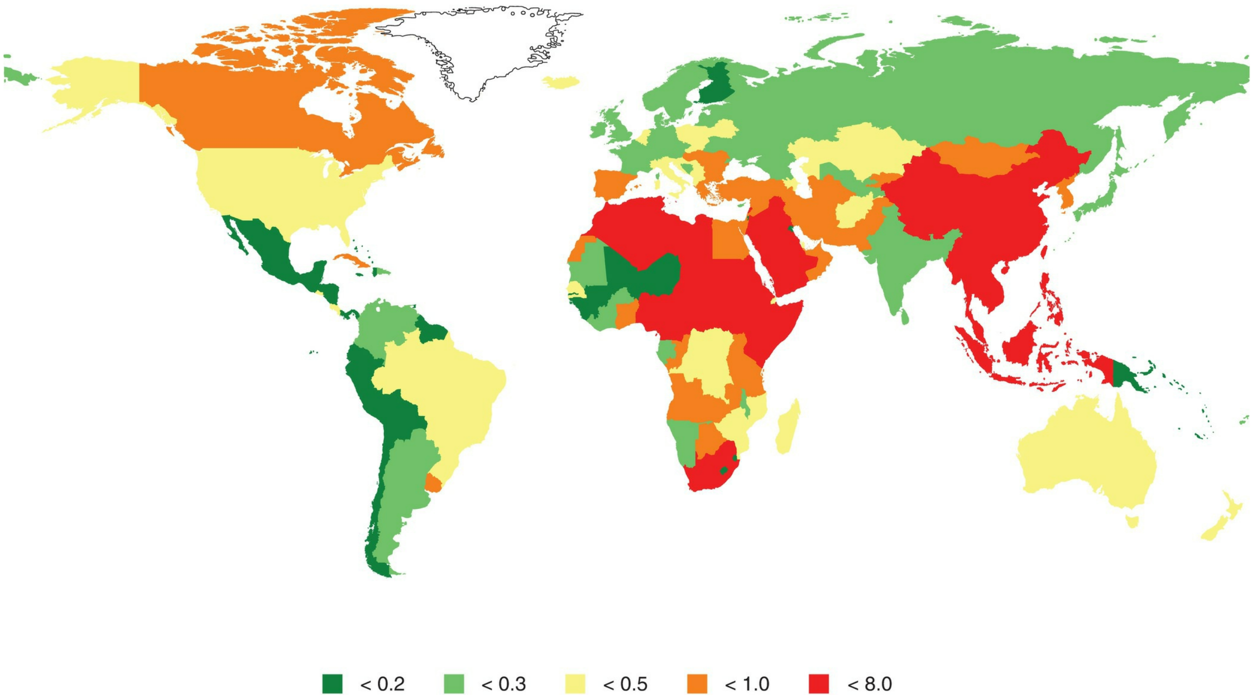

Figure 25.5. Nasopharyngeal carcinoma: Estimated age-standardized incidence rate/100,000; GLOBOCAN 2008 (IARC).
(From GLOBOCAN 2008: International Agency for Research on Cancer (IARC), 2013.)

Human immunodeficiency virus (HIV) is associated with malignancies of the head and neck. The prevalence of HIV is highest in developing countries; two-thirds of HIV-positive people live in sub-Saharan Africa and the prevalence of HIV in South Africa is 18%.[6] Engsing et al.[7] reported in a Danish study that even though HIV status was associated with a higher risk of developing squamous cell carcinoma of the head and neck, it appeared to be a marker of family-related risk factors associated with head and neck carcinoma rather than immunosuppression or HIV infection causing carcinoma per se. HIV is associated with Kaposi sarcoma and non-Hodgkin (and Hodgkin) lymphoma. In a study of a cancer population, those with squamous cell carcinoma of the conjunctiva were 10 times more likely to be HIV positive than those with other cancers.[8]

Although the association of HPV infection with squamous cell carcinoma of the oropharynx is now well established, few studies exist of HPV and cancer of the oropharynx in developing countries.

IMPORTANT CONSIDERATIONS WHEN TREATING HEAD AND NECK CANCER IN DEVELOPING COUNTRIES

It is generally not possible to simply apply treatment protocols suited to developed world centers of excellence to head and neck patients in a developing world setting. Important considerations when making treatment decisions are next discussed.

Advanced Cancer

Patients in developing countries are more likely to present with advanced cancer[9,10]; consequently, treatment is primarily palliative.[11] Onyango[9] reported that 58% of laryngeal cancer patients required emergency tracheostomy in Kenya. Even South Africa, a middle-income country, 52% of patients undergoing total laryngectomy in Cape Town required emergency tracheostomy.[12] Late presentation may be attributed to ignorance, poverty, poor access to specialized health services, and patients turning initially to traditional healers and traditional remedies.

The adverse consequences of delayed presentation are compounded by long waiting lists for surgery and irradiation. Frequently, patients become inoperable while awaiting surgery or radiation therapy; this complicates initial patient selection and treatment planning. In a study of patients awaiting treatment for head and neck cancer, Jensen et al.[13] reported that 1 month's delay was associated with 62% increase in tumor size and 20% in new nodal metastases and that cancers were upstaged (TNM) in 16% of patients studied; mean tumor volume doubling time was 3 months. Some institutions administer "holding chemotherapy" (methotrexate or platinum-based drugs) to slow tumor progression while patients await definitive treatment, even though there is no published evidence that this practice improves the outcome.

HIV Status

When managing HIV-positive patients with squamous cell carcinoma of the head and neck, especially when resources are limited, an oncology team may

need to consider the following:

- *Is radiotherapy in HIV-positive patients accompanied by the potential for increased mucosal and cutaneous toxicity?* Although many reports exist of radiotherapy-induced skin and mucosal toxicity with Kaposi sarcoma, the few reports of toxicity with other head and neck malignancies indicate good tolerance to radiation ± chemotherapy.[14–16]
- *Should antiretroviral therapy be initiated in immunocompromised patients to boost CD4 counts prior to initiating (chemo)radiation therapy?* Radiation therapy can suppress CD4 counts; therefore, even though it may seem reasonable to commence antiretroviral therapy to boost depressed CD4 counts prior to initiating radiation, there are no controlled studies to address this. Although interactions between antiretroviral therapy and radiation have not been well documented in the literature, there is a theoretical concern about the additive myelosuppressive effects of certain antiretroviral agents and myelosuppressive chemotherapeutic agents used with head and neck cancers, for example, platinum alkylators such as cisplatin and carboplatin.[16]
- *What is the anticipated life expectancy of an HIV-positive patient?* Adults that commence antiretroviral therapy before CD4 counts drop to <200 cells/mm3 have about 80% of normal life expectancy; even the most severely ill HIV patients treated with antiretroviral therapy have at least an 80% chance of surviving 2 years.[17]
- *How do CD4 count and HIV status affect surgery?* Even major surgery does not depress CD4 counts,[18] and HIV status per se does not affect the incidence of early surgical complications.[19] A low CD4 count (<100 cells/mm3) has however been reported to be a predictor of postoperative sepsis.[20,21] Instituting antiretroviral therapy prior to surgery has the benefits of reducing viral load (viral exposure to the surgical team) and increases patients' CD4 counts.

In view of the above, there is inadequate evidence to modify treatment in generally healthy HIV-positive patients (CD4 count >350 cells/mm3) with head and neck cancer.[16] There is also little reason to routinely determine the HIV status of an otherwise healthy-looking head and neck cancer patient from an oncologic perspective alone; only when HIV infection causes general

ill health and immunosuppression may HIV status preclude patients from undergoing major surgery or chemoradiation.

Patient Prioritization

Deciding who or who not to treat when the burden of head and neck cancer exceeds available treatment resources is perhaps the most difficult task oncologists and surgeons in developing countries have to face. It involves ethical and practical considerations such as tumor stage, prognosis, palliation versus cure, comorbidities, nutritional status, age, socioeconomic status, social support structure, distance from the closest treatment center, likelihood of regular follow-up, parental status, employment, and the ethical dilemma of whether to deny publicly funded treatment to patients originating from a foreign country without adequate treatment facilities. As access to surgery and radiotherapy are the principal bottlenecks in many developing countries, it is reasonable to prioritize patients with the most curable (early-stage) malignancies, especially when adjuvant radiation is not available or will be significantly delayed following resection of advanced malignancies.

TREATMENT MODALITIES

Surgery

Surgery is often the principal or only treatment available to a patient with cancer of the head and neck in developing countries. Yet, surgeons lack head and neck surgical training in many developing countries, and modern surgical technology (bipolar cautery, laser, transoral robotic surgery, endoscopic surgery), frozen section, blood products, adequate operating time, good anesthesia, and intensive care support are often lacking.[22] Surgeons in developing countries need to keep abreast of and adapt modern surgical principles and techniques to a lower technology practice, for example, substitute transoral microsurgery for early laryngeal cancer with laryngofissure and other open partial laryngectomy procedures, ensure wider tumor resection margins in the absence of frozen section control and postoperative radiation therapy, liberally employ elective neck dissection in the absence of sophisticated imaging, and rely on a range of pedicled rather than microvascular free tissue transfer flaps to reconstruct surgical defects.

Radiotherapy

Radiotherapy is central to the treatment of head and neck cancer but is unavailable in much of the developing world. Abdel-Wahab et al.[11] reported that only 23/52 African countries had radiotherapy facilities and that facilities were concentrated in the southern and northern parts of the continent (**Fig. 25.6**), that brachytherapy resources were available in only 20 countries, and that because only 2% of African countries have modern imaging equipment, treatment planning systems and curative treatment is generally based on two-dimensional imaging and treatment planning. Tatsuzaki and Levin[23] reported significant unavailability of radiation facilities in Asia and the Pacific regions[23]; and Zubizarreta et al.[24] reported a major restriction to access to radiotherapy services in 16/18 South American countries due to insufficient numbers of specialists.[24]

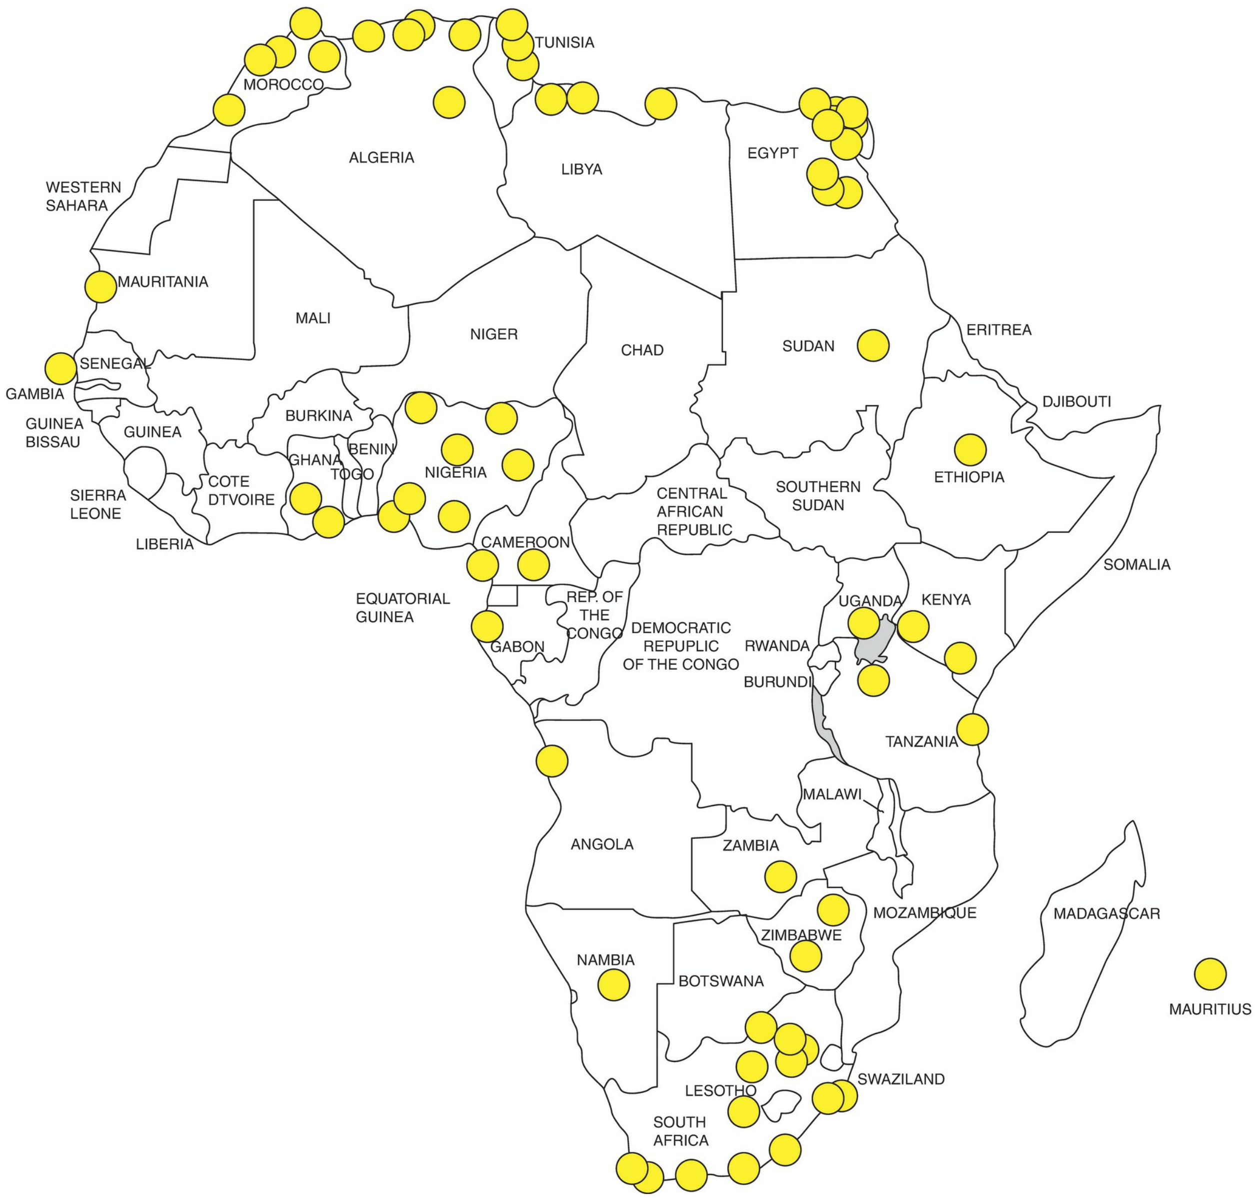

Figure 25.6. Radiation therapy services in Africa. (From Abdel-Wahab M, Bourque J-M, Pynda Y, et al. Status of radiotherapy resources in Africa: an International Atomic Energy Agency analysis. *Lancet Oncol.* 2013;14(4):e168–e175.)

Therefore, most radiation services in Africa and elsewhere in the developing world are fairly basic and deliver mainly palliative care.[11] Radiation therapists in such centers need to be cautious about extrapolating favorable results emanating from modern radiation therapy centers of excellence to situations where reliance is placed on older technology. Patients that undergo radiation to the head and neck require long-term follow-up to

detect and manage delayed radiotherapy-related morbidity. For example, because hypothyroidism increases over time and is present in 25% of patients at 5 years, patients require long-term monitoring of thyroid function.[25] Yet as many patients in developing countries do not return for regular follow-up, the ability to monitor thyroid function and treat hypothyroidism has to be considered when selecting patients for radiation to the head and neck.

Chemoradiation

Concurrent chemoradiation (CCRT) is widely employed for organ sparing in patients with squamous cell carcinoma of the oro-, hypo-, and nasopharynx and larynx in developed countries. It also has an 8% advantage in terms of locoregional control (LRC) and survival rates compared to radiotherapy alone.[26] However, to achieve such favorable outcomes, the "package of care" must include sophisticated imaging (CT, MRI, PET) for both treatment planning and follow-up, medical and intensive care support for chemotoxicity, short- and long-term PEG feeding, complex salvage surgery for persistent cancer or disease recurrence, as well as dental, speech, swallowing, and audiologic rehabilitation facilities. Salvage surgery requires high levels of surgical expertise that include proficiency with free tissue transfer flaps.

Because chemoradiation is an expensive, toxic,[26] and complex treatment and requires a "package of care" not available in many developing world centers, it has to be employed with great circumspection in a developing world setting. Kumar et al.[27] reported a 14% mortality rate during and within 30 days of treatment in patients with advanced head and neck cancer treated with concomitant boost radiotherapy with concurrent weekly cisplatin at a tertiary hospital in India; the authors attribute this high mortality to poor support to deal with acute morbidity, poverty, malnutrition, illiteracy, and poor hygiene and conclude that "on present evidence in the setting of a developing country, CCRT with concurrent cisplatin cannot be recommended as primary therapy in advanced head and neck cancers without formal comparison with other treatment modalities" (**Fig. 25.7**). Therefore, if chemoradiation is to be considered, patients must be carefully selected to predict favorable functional outcomes by considering factors such as age, general health, social support, immune (HIV) status, and tuberculosis, and the "package of care" mentioned above should be available.

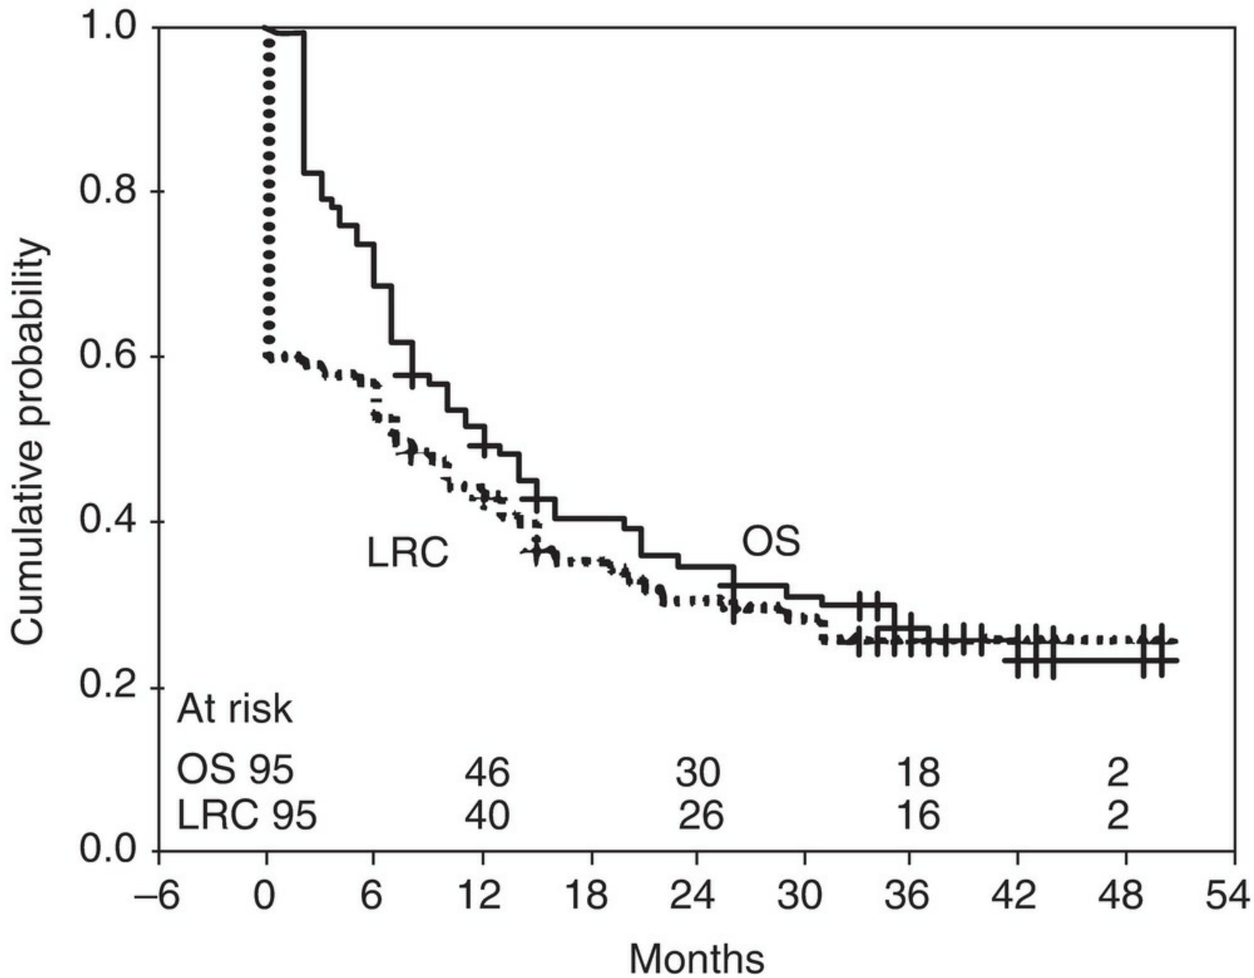

Figure 25.7. LRC and overall survival (OS). (From Kumar S, Pandey M, Lal P, et al. Concomitant boost radiotherapy with concurrent weekly cisplatin in advanced head and neck cancers: a phase II trial. *Radiother Oncol.* 2005;75(2):186–192.)

Altered Fractionation

A variety of altered fractionation schedules, including hyperfractionation, accelerated radiotherapy, or a combination of the two, provide improved local control and survival compared with conventional radiotherapy. *Accelerated radiotherapy* is perhaps better suited to a developing world setting than chemoradiation as it is cheaper and better tolerated. Overgaard et al.[28] reported in a multicenter study of squamous cell carcinoma of the larynx, pharynx, and oral cavity that a six-fraction-per-week radiation schedule resulted in significantly improved LRC at 5 years compared to conventional schedules of five treatments per week. Despite increased acute morbidity,

accelerated radiotherapy did not cause increased late morbidity and had the benefit of reducing overall treatment by 1 week. *Concomitant boost radiotherapy* with a second daily fraction to the gross tumor volume in the final 10 to 12 days of treatment also reduces the overall treatment time, thus reducing the chance of repopulation and improving local control.[29] However, both these schedules would require some reorganization to accommodate the second daily fraction unless in the former case, a radiation therapy department already treats patients 6 days per week.

MANAGEMENT ALGORITHMS

Selecting appropriate management algorithms for head and neck cancer patients in developing countries is particularly challenging and involves making complex, individualized decisions generally without the benefit of special investigations such as FNAC, CT, MRI, PET–CT, and HPV status. Unlike the situation in well-resourced health systems, it may not always be possible for treatment to be protocol driven as the majority of patients are dependent on state run medical services characterized by inadequate health infrastructure and resources. For the same reasons, management algorithms designed for developed world settings are not always relevant, for example, because tuberculosis mimics metastases on PET scan, its utility as a staging tool is limited in societies where tuberculosis is endemic. Reliance therefore frequently has to be placed on clinical acumen, experience, intuition, and institutional bias, often in the absence of scientific evidence to support clinical decisions. Investigations and treatment have to be tailored to the individual patient taking into account resource constraints, for example, availability of CT, MRI, operating rooms, ICU, radiation facilities, and blood transfusions; treatment delays (often many months); likelihood of regular follow-up; access to drugs, for example, thyroid and calcium replacement; nutritional status; social support; poverty; comorbidities (often poorly treated or neglected) including HIV; cultural bias; and the availability of surgical expertise, radiation therapy, and chemotherapy. Certain principles will now be touched on that may be considered when designing management algorithms in resource-constrained settings.

History

Be cognizant of cultural and religious values of patients as this may affect how one manages cancers of the head and neck. Inquire about risk factors including betel nut, areca nut, reverse smoking, chewing tobacco, and comorbidities, for example, tuberculosis.

Metastatic Workup

When access to operating time and adjuvant radiotherapy is limited, one could argue for employing CT scan (even if it is a limited and expensive resource) to rule out pulmonary metastases before inappropriately committing scarce surgical resources to more advanced T and N stage cancers that have metastases not evident on CXR.

N0 Neck

It is reasonable to advocate a lower threshold to electively treat the N_0 neck with selective neck dissection in cases of unreliable follow-up; lack of imaging, for example, ultrasound, CT, or MRI, both initially and at follow-up; and lack of timely adjuvant radiation. In the absence of frozen section, surgeons should have a low threshold to convert a selective to a modified neck dissection when enlarged lymph nodes are encountered, especially in the absence of postoperative irradiation facilities.

N+ Neck

Even though lymphadenopathy in patients from poorer communities may be a result of untreated dental and pharyngeal infections, HIV, or tuberculosis, palpable nodes within the lymphatic drainage area of a primary cancer should be treated with modified or radical neck dissection to avoid undertreating a neck that harbors metastases. Even though the presence of ≥2 cervical nodal metastases is generally considered to be an indication for adjuvant radiation, the evidence to support this threshold is tenuous; hence, centers that lack capacity to provide postoperative radiation to all deserving patients could argue that this threshold for adjuvant radiation be adjusted upward so that patients most likely to benefit, for example, with positive margins, extracapsular spread, and large tumor volumes are not deprived of adjuvant radiation.[30]

Reconstruction

Excellent functional results with microvascular free tissue transfer flaps can be achieved in a developing world setting[31]; however, such surgery is time consuming and requires specialized training. In the absence of reconstructive expertise with microvascular free tissue transfer flaps, surgeons should become proficient at using a range of pedicled flaps, for example, buccinator, buccal fat pad, temporalis, nasolabial, pectoralis major, forehead, deltopectoral, and latissimus dorsi flaps.

Oral Cavity

When postoperative radiation is unavailable, surgery for T1 and T2 cancers should be prioritized, including cancers that are staged T4 due to limited bony invasion that can be resected by marginal or segmental mandibulectomy or partial maxillectomy. Cancers of the tongue and floor of mouth that are digitally palpable (likely to be >4 mm thick) or are staged ≥T2 should undergo elective neck dissection due to the significant likelihood of occult cervical metastases. Preserving oral function is crucial; other than microvascular free tissue transfer flaps, surgeons can use pedicled flaps, for example, buccinator, buccal fat pad, temporalis, nasolabial, and pectoralis major flaps; with inferior or total maxillectomy, one must separate the oral cavity from the nose; if prosthetic expertise is not available, this can be achieved with temporalis muscle flaps. Without the facility to reconstruct bone (e.g., free fibula flap), mandibular resection should not be extended beyond the midline to avoid the crippling and unsightly *Andy Gump* deformity.

Oropharynx

Management of cancers of the oropharynx has undergone a paradigm shift in recent years following the realization that HPV infection is both an etiologic and prognostic factor for a subset of oropharyngeal squamous cell carcinomas, the introduction of transoral robotic surgery to resect oropharyngeal tumors, as well as attempts to reduce the morbidity of chemoradiation by accepting smaller resection margins when combined with postoperative radiation. However, HPV testing, transoral robotic surgery, and chemoradiation are generally not available in developing world centers;

neither is the ability to deal with adverse consequences of chemoradiation. Surgery and radiation therefore remain the mainstay of treatment. Pedicled flaps used to reconstruct soft palate, lateral pharyngeal wall, or base of tongue may include buccinator, buccal fat pad, temporalis, and pectoralis major flaps.

Larynx and Hypopharynx

Early cancers are commonly excised with CO_2 laser in developed world centers. Advanced cancers (dysfunctional larynx, cartilage invasion, tracheostomy for stridor) are treated with total laryngectomy. The remainder are offered chemoradiation with surgery reserved for salvage. However, CO_2 laser is generally not available in developing world centers; chemoradiation is expensive and the package of care required to manage both acute and late consequences and complications of chemoradiation (dysphagia, PEG feeds, cancer surveillance with MRI and PET scans, complex salvage surgery, hypothyroidism, hypocalcemia) is lacking. Therefore, such centers have to rely on open approaches such as laryngofissure; vertical partial, supraglottic, supracricoid, and near-total laryngectomy for smaller cancers; and total laryngectomy for advanced cancers. When performing a total laryngectomy, the surgeon should attempt to preserve both thyroid lobes and the parathyroids to minimize the risks of hypothyroidism and hypoparathyroidism, particularly in settings where thyroid and calcium replacement and monitoring are difficult or unavailable. With a dedicated speech therapy service, postlaryngectomy tracheoesophageal fistula speech results can be achieved that match those of developed world centers even in poor, illiterate patients living long distances from treatment centers.[32] Voice prostheses are however expensive; this has led to strategies such as using removable prostheses as indwelling prostheses to reduce expense.[32] HME devices are unaffordable in developing countries; yet cheap, homemade cloth stoma covers (bibs) are as effective for maintaining the tracheal climate.[32] Although esophageal speech is inexpensive, only 27% of patients in a Brazilian study mastered esophageal speech.[33] Another option is to use mucosal shunts; however, the surgery is technically difficult and can be used only in highly selected patients with good pulmonary function who can cope with aspiration.[33] Because of a severe shortage of speech therapists in many developing world countries,[22,33] an electrolarynx is a reasonable alternative

to achieve postlaryngectomy speech.

Nasopharynx

Cancers of the nasopharynx are principally a developing world problem (Fig. 25.5). Chemoradiation is the mainstay of treatment and the meta-analysis of chemotherapy in nasopharynx carcinoma (MAC-NPC) meta-analysis showed that the 5-year survival improved by 6%, from 56% to 62%, with the addition of concurrent chemotherapy to the radiotherapy.[34] However, the supportive care required for the extreme chemotoxicity is not always available in developing countries. Patients generally present with advanced disease; in an unpublished study conducted in Cape Town, South Africa, 50% of patients presented with stage 4B disease of which 28% did not complete treatment for socioeconomic reasons (Dalvie et al., unpublished data). Hence, it may be prudent to accept the lower survival rate with radiotherapy alone than try to improve it with CCRT with its attendant morbidity. Intensity-modulated radiotherapy (IMRT/complex 3-D conformal radiotherapy) increases local control by allowing dose escalation to the tumor and can improve the quality of life by reducing xerostomia.[4] Although it is now regarded as the standard of care for nasopharyngeal cancer, it is not generally available in developing countries.

Thyroid

Most thyroidectomies in developing countries are done by surgeons not specializing in endocrine surgery. Bilateral recurrent laryngeal nerve injury causing airway compromise or hypoparathyroidism causing hypocalcemia in situations where monitoring serum calcium and treating hypocalcemia with calcium and vitamin D are not possible may have fatal consequences. Regardless of surgical expertise, complication rates rise with the extent of resection. Subtotal thyroidectomy preserves the blood supply to the ipsilateral parathyroid glands and reduces the risk of hypocalcemia. Thyroid lobectomy almost never causes significant hypoparathyroidism. Total thyroidectomy is however associated with both increased short- and long-term morbidity relating to recurrent laryngeal nerve paralysis and hypocalcemia, particularly in an occasional thyroid surgeon’s hands. In the absence of convincing evidence that total thyroidectomy confers survival benefit for favorable, differentiated thyroid cancer[35,36] (especially when I131 therapy is not

available), coupled with the morbidity and mortality of total thyroidectomy in a setting where calcium monitoring and replacement are suboptimal, the occasional thyroid surgeon practicing in a developing world center may be wise to perform only thyroid lobectomy or subtotal thyroidectomy for favorable differentiated thyroid cancer.

OPPORTUNITIES TO IMPROVE HEAD AND NECK CANCER CARE IN DEVELOPING COUNTRIES

It should be apparent to clinicians, researchers, and health planners that the developing world presents great opportunities to make a substantial difference in terms of “lives saved” of head and neck cancer patients. The developing world does not have the human, infrastructural, or financial resources to address its enormous cancer burden without global assistance. A multifaceted approach is required including lobbying international organizations, governments, and aid organizations to support infrastructure development and research and for industry to provide appropriate and affordable technology. A global effort is required to educate and train oncologists and surgeons to manage head and neck cancer in developing countries.

Both developed and developing world clinicians and medical centers can contribute in many ways *inter alia:*

Prevention and Screening

Public awareness campaigns and educating primary health care workers about the risks of nicotine, alcohol, and HPV, as well as the need for albinos to avoid sun exposure, are required. Despite the survival benefit of earlier detection of cancer, a Cochrane review reported that visual screening for oral cancer did not have any survival benefit, although there was some evidence that it might be effective in high-risk patients.[37,38] Techniques using toluidine blue staining, brush biopsy or cytology, or fluorescence imaging as primary screening tool or as adjunct for screening have also not been shown to have any benefit.[35] Consequently, it would appear that, based on current evidence,

there are more important interventions that will improve head and neck cancer outcomes in a developing world setting than diverting scarce human and financial resources to screening.

Education and Training

Oncologists and surgeons need to be trained to manage head and neck cancer through residency programs, clinical fellowships, *in loco* training, and international support.

Educational Resources

Clinicians in developing countries often cannot access textbooks and journals, both of which are generally unaffordable. Hence, open access to journals, textbooks, and educational resources should be encouraged. Examples include the *HINARI Programme*, a collaboration between the WHO and major publishers to enable low- and middle-income countries to gain access to health literature (http://www.who.int/hinari/en/), textbooks such as the *Open Access Atlas of Otolaryngology, Head and Neck Operative Surgery* (http://www.entdev.uct.ac.za/guides), and a variety of open-access journals.

Outreach

Many outreach projects exist whereby clinicians visit and work in developing countries. However, for such outreach projects to be effective, they need to focus on developing sustainable head and neck cancer programs. This requires that outreach projects be integrated with existing local services and that the focus should be on the teaching and training of local clinicians and clinical teachers.

Research

Research should be encouraged in fields such as epidemiology, preventative strategies, and designing and validating resource-appropriate management algorithms for head and neck cancers in poorly resourced developing world contexts.

26 Lymphomas Presenting in the Head and Neck: Current Issues in Diagnosis and Management

Chan Yoon Cheah Fredrick B. Hagemeister

Lymphoma is the fifth most common cancer in Western countries, with 80,000 new cases estimated in the United States in 2014.[1] Up to a quarter of extranodal lymphomas present in the head and neck, and 8% of supraclavicular node fine needle aspiration (FNA) are lymphoma.[2] The 2008 World Health Organization (WHO) classification recognizes 54 distinct subtypes of lymphoma, which can be broadly classified as Hodgkin lymphoma (HL) or non-Hodgkin lymphoma (NHL) with the latter category further divided according to their postulated normal cell of origin being of B- or T-cell lineage.[3] Although lymphoma typically presents with lymphadenopathy, extranodal involvement is common with the most frequently involved extranodal site in the head and neck area being the tonsil, followed by the nasopharynx, oral cavity, salivary glands, paranasal sinuses, and base of the tongue. HL rarely presents with extranodal disease; however, in NHL, extranodal sites of involvement may be the primary (or exclusive) disease manifestation. Lymphomas are typically both chemo- and radiosensitive tumors and may be cured in a significant proportion of patients, even when presenting with disseminated disease. Therefore, the distinction of lymphomas from carcinomas and other malignancies is critical. The purpose of this chapter is to review the clinical presentation, diagnosis, staging, and treatment of this group of diseases with emphasis on patient treatment when presentation includes localized nodal or extranodal disease in the head and neck region.

CLINICAL PRESENTATION

The clinical presentation of lymphoma varies considerably depending on the anatomic site and underlying subtype; however, painless nodal enlargement is typical. Aggressive lymphomas with rapid proliferation may result in painful nodes due to central necrosis. Constitutional or “B” symptoms (unintentional weight loss, night sweats, unexplained fevers) are usually associated with aggressive lymphomas with advanced stage and are uncommon in patients with indolent or localized disease. An overview of typical presentations of lymphomas in the head and neck is presented in **Table 26.1**. In addition to standard evaluation for other lymphadenopathy and enlargement of the liver and spleen, physical examination should also specifically focus on evidence of superior vena cava obstruction, which may indicate a large mediastinal mass.

Table 26.1 Anatomic Sites, Common Histologic Subtypes, and Clinical Manifestations of Lymphoma of the Head and Neck

Anatomic Location	Common Histologic Subtypes	Clinical Presentation
Cervical and supraclavicular nodes	Hodgkin lymphoma Diffuse large B-cell lymphoma Follicular lymphoma	With a rubbery/nodal enlargement Alcohol-induced node pain (<5% HL only)
Tonsils	Diffuse large B-cell lymphoma Follicular lymphoma Lymphoplasmacytic lymphoma Mantle cell lymphoma	Fleshy, nonulcerated unilateral tonsillar mass, odynophagia, globus sensation, dysphagia, and hearing loss secondary to otitis media
Salivary glands	Marginal zone lymphoma	Asymmetric swelling
Nasopharynx and paranasal sinuses	Extranodal NK-cell lymphoma Diffuse large B-cell lymphoma	Nasal obstruction, epistaxis, sinusitis, bloody drainage, or pain
Orbits, ocular adnexal tissue	Extranodal marginal zone lymphoma Diffuse large B-cell lymphoma	Facial swelling, ocular discomfort, diplopia, proptosis, conjunctival lesions, lacrimal duct blockage
Thyroid	Diffuse large B-cell lymphoma Marginal zone lymphoma	Swelling of the neck, dysphagia, dysphonia or hoarseness, or facial edema
Base of the skull, leptomeninges, brain	Diffuse large B-cell lymphoma Mantle cell lymphoma Burkitt lymphoma Lymphoblastic lymphoma Double-hit lymphomas Intravascular large B-cell lymphoma	Cranial nerve palsies, headache, pyramidal weakness, dysphasia, ataxia, vertigo

CLASSIFICATION

The classification of lymphoid neoplasms has evolved over time from a morphologic classification system (Rappaport, Kiel) into the current WHO classification, which incorporates molecular, immunophenotypic,

cytogenetic, morphologic, and clinical features.[3] Lymphomas can broadly be classified according to their normal hematopoietic counterpart (B-cell malignancies, T- and NK-cell malignancies, or HL) and the point of maturation of the cells (precursor or mature). Generally speaking, there is an inverse correlation between degree of maturation and proliferation rate. For example, the most immature (lymphoblastic lymphoma) is considered a nodal variant of acute lymphoblastic leukemia and is rapidly fatal if untreated. At the other end of the spectrum, indolent subtypes such as follicular lymphoma (FL) may sometimes be observed safely without treatment for more than 10 years. It is important to note that even within histologic subtypes, there exists considerable heterogeneity in disease biology, clinical behavior, and outcome. **Tables 26.2** and **26.3** list the current (2008) WHO classification of B-cell and T- and NK-cell lymphomas, respectively.

Table 26.2 WHO Classification of Mature B-Cell Lymphomas

Mature B-Cell Lymphomas

Diffuse large B-cell lymphoma (DLBCL), not otherwise specified

- T-cell/histiocyte-rich large B-cell lymphoma
- DLBCL associated with chronic inflammation
- EBV + DLBCL of the elderly
- Primary mediastinal B-cell lymphoma
- Intravascular large B-cell lymphoma
- Primary cutaneous DLBCL, leg type
- ALK+ large B-cell lymphoma
- Plasmablastic lymphoma
- Primary effusion lymphoma
- Large B-cell lymphoma arising in HHV-8–associated multicentric Castleman disease

Follicular lymphoma

Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma)

Chronic lymphocytic leukemia/small lymphocytic lymphoma

- Splenic marginal zone lymphoma
- Lymphoplasmacytic lymphoma
- Nodal marginal zone B-cell lymphoma (MZL)
- Primary cutaneous follicle center lymphoma
- Mantle cell lymphoma
- Lymphomatoid granulomatosis
- Burkitt lymphoma
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and Burkitt lymphoma
- B-cell lymphoma, unclassifiable, with features intermediate between DLBCL and classical HL

Hodgkin Lymphoma

Nodular lymphocyte-predominant HL

Classical HL

- Nodular sclerosis classical HL
- Lymphocyte-rich classical HL
- Mixed cellularity classical HL
- Lymphocyte-depleted classical HL

Bold text denotes entities commonly presenting in the head and neck.

Table 26.3 WHO Classification of Mature T- and NK-Cell Neoplasms

Mature T- and NK-Cell Lymphomas
Extranodal NK-/T-cell lymphoma, nasal type
Anaplastic large cell lymphoma (ALCL), ALK+
Anaplastic large cell lymphoma (ALCL), ALK–
Peripheral T-cell lymphoma, not otherwise specified
Angioimmunoblastic T-cell lymphoma
Systemic EBV$^+$ T-cell lymphoproliferative disease of childhood (associated with chronic active EBV infection)
Hydroa vacciniforme-like lymphoma
Adult T-cell leukemia/lymphoma
Enteropathy-associated T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis–like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30$^+$ T-cell lymphoproliferative disorder
Lymphomatoid papulosis Primary cutaneous anaplastic large-cell lymphoma
Primary cutaneous aggressive epidermotropic CD8$^+$ cytotoxic T-cell lymphoma
Primary cutaneous gamma-delta T-cell lymphoma
Primary cutaneous small/medium CD4$^+$ T-cell lymphoma

Bold text denotes entities commonly presenting in the head and neck.

ETIOLOGY

For any given individual patient with lymphoma, the precise etiology is usually unknown. However, risk factors for developing lymphoma have been identified. There is evidence for genetic susceptibility in lymphoma. Siblings of younger patients (<40) with HL have a 7-fold increased risk, and identical twins have a 100-fold risk.[4–6] Relatives of patients with NHL also appear to be at 4- to 10-fold increased risk of developing NHL.[5] Exposure to various substances including phenytoin, phenoxy herbicides (Agent Orange), hair dyes, dioxin, and benzenes has been found to have some correlation with an increased incidence of lymphoma.[7–10] Occupations in which exposure to these agents may occur are associated with a higher-than-normal risk for lymphoma; these include woodworking industries, agriculture, rubber and petrochemical industries, and dry-cleaning occupations. In contrast, exposure to ultraviolet sunlight (but not dietary vitamin D intake) and diets rich in fruits and vegetables have found to be associated with a reduction in the risk of developing lymphoma.[11–13] Exposure to prior radiation is also associated with increased risks of lymphoma, although the risk appears to be mainly in men.[14]

In addition to environmental factors, a variety of infectious agents have been associated with lymphomagenesis. In particular, chronic antigenic stimulation is thought to play an important role in the pathogenesis of extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma).[15] Of particular relevance to the head and neck setting, *Chlamydophila psittaci* DNA has been found in 47% to 80% of patients with ocular adnexal MALT lymphoma,[15] and eradication with doxycycline has been shown to be effective in some patients.[16] Other infectious agents associated with MALT lymphoma include hepatitis C (splenic), *Helicobacter pylori* (gastric), and *Borrelia burgdorferi* (cutaneous). Patients with chronic hepatitis B also appear to carry an approximately threefold increased risk of development of NHL.[17] Other viruses associated with lymphoma include human T-cell leukemia/lymphoma virus (HTLV)-1, Epstein-Barr virus (EBV), human herpes virus (HHV) 8, and HIV.[18,19] Immunosuppression, whether acquired (HIV infection, 11-fold),[20] congenital (combined variable immunodeficiency, 12-fold),[21] or iatrogenic (organ transplant recipients, up to 240-fold),[22] is probably among the most potent risk factors for the

development of lymphoma. Finally, other disorders characterized by dysregulation of the immune system have been associated with development of lymphoma. An increased incidence of NHL has been noted in patients with rheumatoid arthritis, celiac disease, Sjögren syndrome, dermatitis herpetiformis, inflammatory bowel disease, and acquired angioedema.[23,24] Lymphoma of the thyroid has been associated with either antecedent diagnosis or concomitant histologic finding of Hashimoto thyroiditis in more than 90% of cases, although <1% of patients with Hashimoto thyroiditis will develop lymphoma.[25]

EPIDEMIOLOGY

The incidence of lymphoma has been increasing, and lymphomas account for 3% to 4% of cancers worldwide.[26] Lymphoma is the leading cause of cancer death in adolescents and young adults.[1] HL has a bimodal incidence curve, the first peak occurring in teenagers to young adults and the second peak in older adults (>55 years).[27] There is a higher frequency among males than females. The incidence of NHL varies by histologic subtype: highly aggressive histologic subtypes (e.g., lymphoblastic and Burkitt lymphoma) are more common in children and adolescents, but most other forms of NHL are diseases of older adults, in particular, elderly adults (>60 years). NHL is more common in men than women, though the size of the discrepancy varies between subtypes.[3] HL accounts for around 10% of lymphoma diagnoses; in developed countries, 70% are nodular sclerosing, 20% are mixed cellularity, 5% are lymphocyte rich, and 1% are lymphocyte depleted, a group of diseases known collectively as classical HL, and 5% are nodular lymphocyte predominant, a disease that has a morphologic appearance that is distinct from the classical variants.[3] Among NHL, B-cell lymphomas are vastly more common and constitute 85% to 90% of NHL with T- and NK-cell lymphoma constituting the remainder.[3]

DIAGNOSTIC EVALUATION

Fine Needle Aspiration

When a patient presents with lymphadenopathy in the head and neck region,

FNA is helpful only as a minimally invasive test that can distinguish carcinoma or some other malignant process from lymphoma. If a diagnosis of lymphoma is favored by FNA findings, either excisional biopsy or image-guided core biopsy (if excisional biopsy is considered unfeasible) is needed, as the classification of lymphomas relies heavily on the histologic pattern of the malignancy in the lymph node. FNA may also result in both false negatives (e.g., concurrent reactive hyperplasia may occur as a response to the lymphoma in the lymph node) and false positives (e.g., infectious mononucleosis in which individual cells may appear aberrant). Therefore, a patient with a negative FNA but a clinically enlarging lymph node should undergo definitive excisional biopsy before a final diagnosis can be verified.

Biopsy

Biopsy of a representative lymph node is still the optimal procedure for establishing the diagnosis and subclassification of lymphomas. The selection of node for biopsy depends on the safety and accessibility of lymph nodes and the availability of baseline PET–CT imaging. The latter is valuable as the standardized uptake value (SUV) has some correlation with proliferation index in NHL,[28,29] and thus, the targeted biopsy of a node with SUV significantly higher than other involved nodal areas can be used to establish the presence of histologic transformation of an indolent lymphoma.[30] A prospective study of 38 patients with indolent lymphoma undergoing PET-CT–directed biopsy used ROC analysis to identify an optimum SUV cutoff of 14, which resulted in a positive predictive value of 93.9% and specificity and negative predictive value of 95.3% for detecting histologic transformation.[31] As the presence of histologic transformation may have significant treatment and prognostic implications, in cases where there is heterogeneous nodal ^{18}F-flurodeoxyglucose (FDG) avidity present, the area with highest SUV should be biopsied if feasible. Excisional biopsy is preferred; however, in cases where excisional biopsy is not feasible, CT-guided core biopsy is an acceptable alternative. Rebiopsy is usually necessary in patients who have residual FDG-avid masses at the completion of therapy, particularly if escalation of therapy is planned as the finding of nonmalignant pathologies, such as necrosis, foamy macrophages, or sarcoidosis, is not unusual in this setting.[32,33] Rebiopsy is also needed at time of relapse as it is possible for indolent lymphomas to undergo transformation to aggressive lymphomas

such as diffuse large B-cell lymphoma (DLBCL) and vice versa.[34,35] The entire lymph node should be removed in one piece and its capsule maintained intact. The lymph node must be handled gently during surgery to minimize crush artifact, and the tissue should be placed fresh in saline and transported to the laboratory immediately to minimize deterioration of the sample. Biopsies of the tonsil, base of the tongue, and nasopharynx are done in the same manner as biopsy in diagnosis of squamous cell carcinoma.

Pathologic Studies

Histology

Histologic evaluation of a lymph node involved by lymphoma should include an assessment of tumor cell morphology, growth pattern of the lymphoma (diffuse or follicular), and the presence of composite lymphomas (where two histologically distinct lymphomas exist in a single lymph node or in different nodes contemporaneously in the same patient). Immunohistochemistry can confirm hematopoietic origin of the tumor (CD45 or LCA), distinguish tumor cells from normal or reactive lymphoid tissue, determine B-cell (CD20, PAX5) or T-cell (CD3, CD5) lineage and proliferation index (Ki 67), assist in the determination of specific subtype (e.g., cyclin D1 expression in mantle cell lymphoma or CD10, BCL6, and MUM1 to determine cell of origin in DLBCL),[36] and give prognostic information (coexpression of MYC and BCL2 or BCL6 in the highly aggressive double-hit lymphoma).[37] Additional surface marker studies such as keratin, mucin stain, or S100 may also be useful in excluding squamous cell carcinoma, adenocarcinoma, and melanoma, respectively.

Flow Cytometry

Flow cytometric analysis is a useful complementary tool in the diagnosis of lymphomas as it allows for the detection of two or more markers simultaneously (e.g., concurrent expression of CD19 and CD5 in small lymphocytic and mantle cell lymphoma), has rapid turnaround, and can provide a more quantitative assessment of the intensity of antigen expression than immunohistochemistry. However, it gives no information about cellular morphology and is not useful in the diagnosis of HL as the neoplastic Reed-

Sternberg cells constitute <1% of the cellular population in involved lymph nodes. In the setting of NHL, when performed on FNA specimens, it can distinguish B-cell or T-cell lineage, although in most cases accurate subtyping is still contingent on evaluation of an adequate biopsy sample. It is also more sensitive than cytology alone in detecting lymphoma cells in cerebrospinal fluid (CSF) in patients with leptomeningeal disease and should always be requested in addition whenever lumbar puncture is performed.[38–40]

Cytogenetic Analysis

Cytogenetic analysis by conventional karyotype or fluorescence in situ hybridization (FISH) may be required in specific lymphoma subtypes or clinical presentations. These studies can be performed on both fresh and formalin-fixed paraffin-embedded tissue and will usually be requested as needed by the reporting pathologist or treating hemato-oncologist. FISH can identify a range of chromosomal abnormalities including deletions, gains, translocations, and duplications and can be used to provide both diagnostic and prognostic information. **Table 26.4** summarizes clinically relevant chromosomal abnormalities in lymphoma.

Table 26.4 Important Chromosomal Translocations in Lymphoma

Histologic Subtype	Gene	Cytogenetic Abnormalities	Utility
Diffuse large B-cell lymphoma	*MYC*	MYC/8q24	*MYC* and *BCL2* and/or *BCL6* = double- or triple-hit lymphoma, adverse prognosis
	BCL2	BCL2/18q21	
	BCL6	BCL6/3q27	
Burkitt lymphoma	*MYC-IGH*	t(8;14) (q24q32)	Diagnosis
	MYC-IGK	t(2;8)(p12q24)	
	MYC-IGL	t(8;22)(q24q11)	
Follicular lymphomas; some large-cell lymphomas	*IGH-BCL2*	t(14;18) (q32q21)	Diagnosis
Mantle cell lymphoma	*CCND1-IGH*	t(11;14) (q13q32)	Diagnosis
Marginal zone lymphomas	*FOXP1-IGH*	t(1;14) (p22q32)	BIRC3-MALT resistant to antibiotic therapy
	IGH-MALT1	t(3;14)(p14.1q32)	
	BIRC3-MALT1	t(11;18)(q12q21)	
Anaplastic large-cell lymphoma, ALK+	*NPM1-ALK*	t(2;5) (p23q35)	Diagnosis, prognosis (ALK+ better than ALK−)
Extranodal NK-cell lymphoma, nasal type		del(6)(q21q25)	Uncertain

Molecular Analysis

In some cases, the distinction of malignant lymphoma from a reactive

lymphoid proliferation can be difficult, and molecular analysis for polymerase chain reaction for immunoglobulin gene rearrangements (in B-cell NHL) or T-cell receptor gene rearrangements (in T-cell NHL) to demonstrate clonality can be helpful in some cases.[41] Perhaps the defining milestone in medicine in the last decade has been the advent of high-throughput whole-exome sequencing. The increasing availability and decreasing cost of this technology have resulted in definition of the mutational landscape of many lymphoma subtypes.[42–45] These advances will fundamentally change the way lymphomas (and for that matter, all cancers) are classified, diagnosed, and treated. However, at the present time, technologies such as next-generation sequencing, nanostring, and whole-exome sequencing remain largely research tools and are not widely available in diagnostic pathology laboratories.

Staging

For the last 40 years, the Ann Arbor classification system has remained the most widely used staging system for lymphomas (**Table 26.5**).[46] Originally designed for HL (which spreads in a pattern of anatomic contiguity), the system classifies patients as having limited (I/II) or advanced (III/IV) stage—a division that remains critically important for prognostic and therapeutic purposes for many (but not all) types of lymphoma. Although widely used in NHL, it is not ideally suited to describe disease extent due to frequent involvement of extranodal sites. Furthermore, in both HL and many subtypes of NHL, specific prognostic indices have been developed, which may incorporate stage as only one of several factors (**Table 26.6**).

Table 26.5 Ann Arbor Staging Classification

Stage I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (I_E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site (II_E)
Stage III	Involvement of lymph node regions on both sides of the diaphragm (III) or localized involvement of an extralymphatic organ or site (III_E) or spleen (III_S) or both (III_{SE})
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement
A	Absence of B symptoms
B	Unexplained fever (>38°C), night sweats, unintentional weight loss >10% of body weight

From Carbone PP, Kaplan HS, Musshoff K, et al. Report of the Committee on Hodgkin's Disease Staging Classification. *Cancer Res.* 1971;31:1860–1861.

Table 26.6 Prognostic Scoring Systems in Selected Lymphoma Subtypes

Histologic Subtype	Prognostic Index	Components (Points)	Risk Groups	Outcome
Diffuse large B-cell lymphoma	NCCN-IPI[47]	Age, normalized serum LDH		5-y OS
		Involvement of marrow, GIT/liver, lung, or CNS, stage III/IV, ECOG ≥2	Low Low intermediate High intermediate High	96% 77% 56% 38%
Follicular lymphoma	FLIPI-2[48]	Age, elevated serum LDH, hemoglobin <12 g/dL, marrow involvement, longest diameter of largest involved node 6 cm	 Low Intermediate High	5-y PFS 80 51 19
Mantle cell lymphoma	MIPI[49]	Age, ECOG, normalized LDH, WBC	 Low Intermediate High	5-y OS 60 35 20
Classical Hodgkin lymphoma (stage III/IV only)	IPS[50]	Albumin <4 g/dL, hemoglobin <10.5 g/dL, male, age >45, stage IV, white-cell count >15 × 10⁹/L, lymphocyte <8% of total WBC	Number of factors 0 1 2 3 4 5+	5-y FFP 84% 77% 67% 60% 51% 42%
Nodular lymphocyte-predominant Hodgkin lymphoma	NLPHL score[51]	Variant histology, albumin, gender	 Low Intermediate High	5-y PFS 95% 87% 69%
NK-/T-cell lymphoma	NKPI[52]	B symptoms, stage III/IV, elevated LDH, regional nodal involvement	Number of factors 0 1 2 3–4	5-y OS 81 64 34 7

NCCN, National Comprehensive Cancer Network; IPI, International prognostic index; FL, follicular lymphoma; M, mantle cell lymphoma; NK, natural killer cell; IPS, international prognostic score; NLPHL, nodular lymphocyte-predominant Hodgkin lymphoma; LDH, lactate dehydrogenase; GIT, gastrointestinal tract; CNS, central nervous system; ECOG, eastern cooperative oncology group; WBC, white blood cell count; OS, overall survival; PFS, progression-free survival; FFP, freedom from progression.

History and Examination

For a patient with lymphoma, it is important to document the presence or absence of lymphoma-related constitutional symptoms (unexplained fevers of >38°C, drenching night sweats, or the unintentional loss of more than 10% of body weight over 6 months), which are more commonly associated with advanced-stage disease. Thorough physical examination, with particular attention to peripheral lymph node stations (cervical, supraclavicular, infraclavicular, axillary, epitrochlear, inguinal, and femoral) and abdomen for detection of hepatomegaly and splenomegaly, should be performed. A detailed examination of the head and neck should be performed, and if

clinical features suggestive of nasopharyngeal involvement are present, an otolaryngologist should directly visualize the region using nasal endoscopy and perform biopsies if necessary. A complete neurologic examination should also be performed, especially in cases of aggressive lymphomas, which can invade the base of skull and other cranial structures and can be sites of involvement at the time of relapse of the disease.

Laboratory Investigations

Laboratory evaluation should include complete blood count and smear, electrolytes, serum lactate dehydrogenase (LDH), β2-microglobulin, uric acid, liver function tests, serum electrophoresis and immunoglobulin levels, hepatitis B and C and HIV serology, and, in HL, erythrocyte sedimentation rate. Patients with elevated lymphocyte counts or atypical lymphocytes on peripheral blood smear should have flow cytometric analysis to determine whether peripheral blood involvement is present. In line with recently published Lugano consensus recommendations, bone marrow biopsy (BMB) can be omitted in patients with HL who undergo staging with PET-CT,[53] particularly if the intended treatment for advanced-stage patients is not influenced by the International Prognostic Score (IPS). In a study of 454 patients, no patients classified as limited stage by PET–CT were reclassified as having advanced stage by positive BMB, and only 5 (1%) were upstaged from stage III to IV.[54] This would result in a one-point increase in the IPS,[50] which could have therapeutic consequences in centers where intensified consolidation chemotherapy is given to patients with high IPS. However, in contrast to recommendations from the Lugano meeting, some believe that patients with DLBCL should still undergo BMB, because the finding of low-grade lymphoma in the marrow would influence subsequent treatment strategy.[55] In all other types of lymphomas, BMB is still recommended: a unilateral trephine biopsy of >20 mm in length, analysis of multiple levels, and appropriate immunohistochemistry make bilateral biopsies unnecessary.[56] Patients with clinical features suggestive of CNS involvement (headache, confusion, radicular pain, sensory loss, or focal neurologic lesions) should undergo lumbar puncture with detailed CSF analysis by cell count, cytology, flow cytometry, biochemistry, and microbiology.

Imaging

PET-CT is the imaging modality of choice for FDG-avid tumors, with contrast-enhanced CT scan from the head and neck to the pelvis for non–FDG-avid lymphomas. Aggressive histologies such as HL, DLBCL, Burkitt, lymphoblastic, and mantle cell lymphoma are typically FDG avid.[57] Among indolent lymphomas, FL is usually avid; however, small lymphocytic, marginal zone, and cutaneous lymphomas are less routinely avid.[58] In FDG-avid lymphomas, PET–CT changes CT-defined stage in 10% to 30% of patients, largely due to greater ability to detect extranodal disease involvement.[59,60] To evaluate suspected CNS involvement, dedicated magnetic resonance imaging (MRI) with gadolinium enhancement should be performed, with regions evaluated determined according to clinical presentation.

Treatment

The initial therapy of lymphomas in the head and neck depends on a number of factors including histologic subtype, disease stage, age, comorbidities, and performance status of the patient. In this chapter, we describe general treatment approaches for the histologies most commonly encountered in the head and neck, followed by a brief discussion of rare entities that require a specific management approach.

Classical Hodgkin Lymphoma

The current approach to initial therapy of HL considers different stages of the disease: favorable risk early-stage (I/II) disease, unfavorable risk early-stage disease, and advanced-stage disease. The precise definition of unfavorable risk early-stage disease varies slightly between study groups. For example, the National Comprehensive Cancer Network (2014) uses the presence of any one of four factors to indicate unfavorable risk: a large mass occupying more than one-third of the mediastinal width or more than 10 cm in maximal diameter, B symptoms, ESR >50 mm/hour, and more than three sites of disease. The German Hodgkin Lymphoma Study Group (GHSG) criteria are similar, but also include extranodal involvement as an adverse feature. The absence of any of these features defines favorable risk early-stage HL.

Favorable Risk Early-Stage Disease.

Favorable risk early-stage HL defines a group of patients who have an

excellent prognosis with an expected 5-year overall survival (OS) of more than 95%. The focus of therapy for these patients has been the minimization of toxicity while retaining efficacy of treatment. In patients who fulfill the GHSG criteria for favorable risk early disease, the HD10 study found that reduced intensity treatment with two (compared with four) cycles of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) followed by 20 Gy (compared with 30 Gy) involved field radiotherapy (IFRT) did not compromise outcomes. The estimated 8-year freedom from treatment failure (FFTF) and OS were 88% and 98%, respectively.[61] In selected cases, an acceptable alternative radiation-sparing approach is four to six cycles of ABVD.[62]

Unfavorable Risk Early-Stage Disease.

Patients with unfavorable risk early-stage HL generally require four cycles of ABVD plus 30 Gy IFRT; attempts to improve outcomes by intensifying chemotherapy using bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisolone (BEACOPP) in either standard or escalated doses have resulted in increased toxicity without improvement in progression-free survival (PFS).[63,64] Patients with nonbulky disease who decline radiation or in whom the radiation fields are deemed unacceptably toxic may receive ABVD alone for four to six cycles.[65] However, there are insufficient data on the omission of radiation in a patient with early unfavorable risk HL with a bulky mass combined modality therapy recommended in such cases.

Advanced-Stage Disease.

Patients with advanced-stage HL require prolonged induction chemotherapy, with choices including ABVD, $\text{BEACOPP}_{\text{baseline}}$, and $\text{BEACOPP}_{\text{escalated}}$. The only study to date that has directly compared the two regimens randomized patients to receive six cycles of ABVD or eight cycles of BEACOPP (four escalated, four baseline).[66] They found superior 7-year freedom from progression (FFP) in the BEACOPP arm (85% vs. 73%, $p = 0.004$), but OS was not significantly different (89% vs. 84%, $p = 0.39$). The lack of difference in OS was attributed to both ability to successfully salvage patients experiencing disease relapse after ABVD and the increased acute and long-term toxicity in patients treated with BEACOPP. Although a recent network

meta-analysis of 14 studies reported that $\mathrm{BEACOPP}_{escalated}$ × 6 cycles was associated with a 10% OS advantage over ABVD,[67] expert opinion remains divided. However, until direct comparisons demonstrate a survival benefit for $\mathrm{BEACOPP}_{escalated}$ over ABVD, both regimens remain reasonable choices for treatment of this group; however, because BEACOPP induces more toxicity than does ABVD, without clearly defined survival advantage, most clinicians at major centers in the United States still administer ABVD to patients with advanced presentations of HL.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) carries a better prognosis than does classical HL. Patients with NLPHL constituted 4.8% of all patients treated on the GHSG HD4 to HD12 studies.[68] Compared with classical HL, patients with NLPHL were more likely to achieve CR, were less likely to experience disease progression, and had lower treatment-related mortality than did patients with classical HL. Due to the relative rarity of these patients, data supporting treatment decisions are based largely on prospective phase II and retrospective studies.

Limited-Stage Disease.

Most patients (70% to 80%) with NLPHL have limited-stage disease at diagnosis, and enlarged lymph nodes in the head and neck area are frequently the only involved site at disease presentation. Patients with stage IA NLPHL have excellent outcomes using radiation therapy alone, with an estimated 15-year FFP of 85%.[69] A recent retrospective analysis from the British Columbia Cancer Agency (BCCA) suggested that combined modality with two cycles of ABVD followed by IFRT resulted in improved PFS and OS compared to results from a group of patients who received only radiation therapy.[70] Patients with stage IB or II disease are generally treated with chemotherapy in addition to radiation; however, direct comparisons between regimens have been precluded by the rarity of the disease. Strategies vary from center to center, although the BCCA approach (two ABVD followed by IFRT) is reasonable.

Advanced-Stage Disease.

Patients with NLPHL and classical HL with advanced-stage disease treated with identical regimens on GHSG HD4 to HD12 studies had similar FFTF results (77% vs. 75%, p = 0.46) with median observation of 50 months.[68] However, given that rituximab has activity in this entity,[71] an alternative approach would be to administer rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP), the same regimen used to treat other types of B-cell lymphomas that express CD20 on the tumor cell surface. In a retrospective analysis of 63 patients with NLPHL conducted at MD Anderson Cancer Center, 24 had advanced-stage disease, and 12 received R-CHOP. All patients had a response (90% CR) and no progressions have occurred, with a median observation of 42 months.[72] No prospective, randomized comparisons are possible, but the regimen appears at least as effective as regimens used in classical HL and requires validation in a larger cohort of patients.

Diffuse Large B-Cell Lymphoma

This histologic subtype describes a group of tumors with diverse molecular and clinical features. CHOP constituted the backbone of therapy in this disease for many years[73] until the anti-CD20 monoclonal antibody rituximab was established as a highly effective agent in patients with CD20-positive lymphomas.[74] Subsequent phase III studies demonstrated that the addition of rituximab to CHOP (R-CHOP) improved CR, PFS, and OS rates compared to results obtained with CHOP alone, establishing R-CHOP as a standard of care.[75,76] For older patients (>65 years of age) with DLBCL, R-CHOP remains the standard of care, given every 2 (R-CHOP14) or 3 weeks (R-CHOP21). No significant difference in outcome has been demonstrated between these two schedules, as two large, randomized studies have found no significant differences in outcomes with treatment consisting of six cycles of R-CHOP14 (with 8 doses of rituximab) or eight cycles of R-CHOP21.[77,78]

In younger patients (<65 years of age), most attempts to improve outcomes using more intensive chemotherapy have met with increased toxicity without improvements in efficacy.[76,79] A notable exception to this rule was a French randomized study comparing rituximab, doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisolone (R-ACVBP) and R-CHOP21 for patients aged 18 to 59 with an IPI score of at least 1.[80]

Patients randomized to R-ACVBP had superior 3-year PFS (91% vs. 67%, $p = 0.0035$) and OS (92% vs. 84%, $p = 0.007$). However, the toxicity was considerably higher: febrile neutropenia was seen in 38% of those receiving the more intensive regimen versus 9% with standard R-CHOP. This fact, as well as difficulty accessing vindesine outside Europe, has limited widespread adoption of this regimen in Western countries. Furthermore, physician familiarity, outpatient deliverability, and predictability of adverse events with R-CHOP all contribute to its durability in practice. Dose-adjusted rituximab, etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (R-EPOCH) has been effective in phase II studies although patients with activated B-cell DLBCL still have inferior outcomes.[81,82] A phase III randomized study conducted by Cancer and Leukemia Group B (CALGB) comparing R-CHOP with R-EPOCH in patients with previously untreated DLBCL, with a primary endpoint of 5-year EFS (NCT00118209) with molecular correlative analysis will clarify the best use of these regimens.

Special Cases of Diffuse Large B-Cell Lymphoma

Limited-stage (I/II) disease.

Patients with limited-stage disease constitute 30% to 40% of patients with DLBCL. Patients with bulky (>10 cm) or stage IIB disease should be treated as having advanced-stage disease (see above). Nonbulky limited-stage patients can be treated with three cycles of R-CHOP21 plus IFRT or six to eight cycles of R-CHOP21 without radiation as outcomes using either approach are excellent, with 3-year PFS results of ~90%.[76,83] Therefore, the choice between these approaches is made with the intention of minimizing treatment-related toxicity. Factors that should be considered include the location of the radiation field, age and comorbidities of the patient, and patient and physician preference. Radiation alone is not recommended, as outcomes are inferior compared with combined modality therapy.[84–86]

Double-hit lymphoma.

Patients with “double-hit” lymphomas (whether defined by gene rearrangements or immunohistochemistry of both *MYC* and *BCL2* or *BCL6*) have particularly aggressive clinical behaviors with poor outcomes with R-CHOP chemotherapy.[87,88] CNS involvement appears to be higher in these patients compared to those without “double-hit” disease, though the

magnitude of this risk varies widely between studies.[37,89–94] Nonetheless, such patients should undergo baseline evaluation for CNS involvement. Given the rarity of the disease, prospective data are lacking; however, a retrospective analysis of 129 cases from MD Anderson Cancer Center provides some insights.[93] The 2-year EFS rates in patients treated with R-CHOP (n = 57), R-Hyper-CVAD (n = 34), and R-EPOCH (n = 28) were 25%, 32%, and 67%, respectively. Among those patients who achieved CR, there was no apparent difference in 2-year EFS (68% vs. 53%, p = 0.13) or OS (70% vs. 70%, p = 0.563) for patients who received ASCT consolidation following induction of remission compared to those who did not. However, at the present time, the approach at MD Anderson Cancer Center is to administer induction therapy with R-EPOCH with the addition of CNS-directed prophylaxis followed by consolidation with stem cell transplant in the majority of cases.

Primary mediastinal B-cell lymphoma.

Patients with primary mediastinal B-cell lymphoma (PMBL) are typically young and female and may present with supraclavicular lymphadenopathy and evidence of superior vena cava obstruction. Although R-CHOP is an acceptable treatment provided radiation is also used,[95] a phase II trial of 51 patients using R-EPOCH (largely without radiotherapy) achieved excellent EFS of 93% and OS of 97% after a median observation period of 5 years.[96] Because this approach avoids the risk of radiation-induced cardiac morbidity and second malignancies, this currently is considered the preferred approach for therapy of PMBL.

Marginal Zone/MALT Lymphoma.

Extranodal marginal zone or MALT lymphomas frequently involve sites in the head and neck including ocular adnexal structures, salivary glands, and thyroid. Patients with this disease have excellent outcomes regardless of therapy: a retrospective International Extranodal Lymphoma Study Group (IELSG) series of nongastric MALT reported a 5-year OS of 90% irrespective of treatment.[97] There is no clear standard of care, with treatment options including radiation alone, chemotherapy, or rituximab and eradication with antibiotics. Surgery alone is not the treatment of choice, although the diagnosis may only become apparent after resection has been performed. If there is no evidence of recurrent disease, observation is

sufficient; however, patients with positive resection margins may be offered radiation to minimize the risks of recurrence. MALT lymphoma is exquisitely radiosensitive, and radiotherapy at doses of 24 to 32 Gy results in excellent response rates and long-term disease control.[98] Due to the frequent presence of *C. psittaci* infection in orbital and ocular adnexal MALT lymphomas, the IELSG conducted a phase II study of doxycycline alone as therapy for this disease, administering 100 mg oral twice weekly for 3 weeks.[16] The treatment was safe and effective with an OS of 65%, but responses took some time to achieve, with best responses attained at 6 months. The 5-year PFS rate for patients treated in this study was 55%. Chemotherapy with alkylating agents such as cyclophosphamide or chlorambucil either alone or in combinations (e.g., cyclophosphamide, vincristine, prednisolone [CVP]) is well tolerated and effective.[99] Single-agent rituximab provides a response rate of 70% in this entity and when added to chlorambucil improves CR and EFS rates (but not OS) compared to chlorambucil alone.[100]

Follicular Lymphoma.

For therapeutic purposes, patients with FL are considered in three main groups: limited stage (I/II) and advanced stage with either low or high tumor burden.

Limited-stage disease.

Only 15% to 30% of patients have limited-stage disease at diagnosis. The standard of care for limited-stage disease is radiotherapy, which results in excellent local tumor control and 10-year PFS of ~50%, suggesting that a proportion of these patients are potentially cured of their disease.[101,102] However, much of the published data are retrospective, and there is some evidence that adding combined modality therapy may improve outcomes. Seymour et al.[103] treated 85 patients with limited-stage indolent NHL (mostly FL) with CHOP/CVP + bleomycin followed by 30 to 40 Gy IFRT and observed 10-year FFS and OS rates of 72% and 80%. An ongoing cooperative group study by the Australasian Leukemia and Lymphoma Group and Trans-Tasman Radiation Oncology Group comparing IFRT ± CVP is ongoing (NCT00115700). Three small retrospective series have described long-term outcomes (collectively around 100 patients) with asymptomatic localized FL who have undergone observation alone.[104–106] A

retrospective analysis from Stanford reported a 10-year OS rate of 85%, with 63% of patients not having required any therapy after a median follow-up of 7.2 years. These data lend qualified support that this approach is reasonable.

Low-tumor burden, advanced-stage disease.

Patients with advanced-stage disease (stage III/IV) constitute the majority of patients with FL. The decision on when to initiate treatment was established in the prerituximab era in two studies that randomized patients to observation or treatment and found no difference in OS for early treatment.[107,108] These criteria remain widely used in both practice and clinical trials today (Table 26.6). A recent international phase III study of 379 patients recently compared observation only (n = 187) with rituximab induction only (n = 84, arm closed early) or rituximab induction followed by maintenance for 2 years (n = 192).[109] The number of patients not needing treatment at 3 years was 46%, 78%, and 88% in observation, rituximab induction, and maintenance arms, respectively ($p < 0.0001$), although there was no difference in OS rates, probably because patients with FL usually have chemosensitive disease at first relapse. Patients randomized to maintenance reported improvements in patient-reported outcomes. Finally, the ECOG E4402 (RESORT) study compared two schedules of rituximab in asymptomatic low–tumor burden patients.[110] They treated 289 patients using 4 doses of weekly rituximab as induction; patients were then randomized to re-treatment at progression or maintenance rituximab given every 3 months, with both strategies continued until treatment failure. There was no difference in time to treatment failure (TTF) between the two strategies, suggesting that the re-treatment approach was as effective while using less rituximab. Although these two studies demonstrate that rituximab is a reasonable treatment option in patients with asymptomatic low–tumor burden FL, there remains no evidence of a benefit in OS using this approach, and observation of the asymptomatic patient with advanced disease still remains a viable option of management (**Table 26.7**).

Table 26.7 Criteria for the Initiation of Treatment in Patients with Advanced-Stage Follicular Lymphoma

GELF Criteria[108]	BNLI Criteria[107]
ALL of the following: ■ Maximum diameter of disease <7 cm ■ Fewer than three nodal sites ■ No systemic symptoms ■ Spleen <16 cm on CT ■ No significant effusions ■ No risk of local compressive symptoms ■ No circulating lymphoma cells ■ No bone marrow compromise (Hb < 10 g/dL, WBC count < 1.5 × 10^9/L, platelet count < 100 × 10^9/L)	NONE of the following: ■ B symptoms or pruritus ■ Rapid generalized progression of disease ■ Bone marrow compromise (Hb ≤ 10 g/dL, WBC count < 3.0 × 10^9/L, or platelet count < 100 × 10^9/L) ■ Life-threatening organ involvement ■ Renal infiltration ■ Bone lesions

GELF, Groupe pour L'Etude de Lymphome Folliculaire; BNLI, British National Lymphoma Investigation; CT, computed tomography; Hb, hemoglobin; WBC, white blood cell.

High-tumor burden, advanced-stage disease.

Rituximab-based chemoimmunotherapy is considered the standard of care for symptomatic patients with FL. Common chemotherapy backbones include CHOP, CVP, bendamustine, and fludarabine-based regimens. The Italian FOLL05 study randomized 534 untreated patients with FL to eight cycles of R-CVP, six cycles R-CHOP, or six cycles of R-FM (fludarabine and mitoxantrone).[111] Three-year TTF results were 46%, 62%, and 59% in the R-CVP, R-CHOP, and R-FM arms, respectively. Although both R-CHOP and R-FM were superior to R-CVP in terms of disease control, R-FM resulted in higher rates of grade III/IV neutropenia and a higher number of second malignancies. Two large studies with a noninferiority design have compared bendamustine–rituximab (BR) with R-CHOP. Rummel and colleagues randomized 549 patients with untreated indolent lymphoma (54% FL) to BR or R-CHOP.[112] Among patients with FL, the median PFS was not reached for the BR arm, compared with 40.9 months for patients who received R-CHOP (hazard ratio 0.61; 95% CI 0.42 to 0.87; p = 0.0072). The BRIGHT study randomized 447 patients with indolent NHL to BR or R-CHOP/CVP.[113] BR was noninferior to R-CHOP/CVP in terms of response rates; however, the more clinically relevant secondary endpoints of PFS and OS were not mature at the time of initial report. Therefore, we consider either BR or R-CHOP as appropriate induction therapy for patients with high–tumor burden FL. BR has some advantages because it appears at least as effective as R-CHOP and less toxic; however, if there is clinical or pathologic uncertainty about whether a large-cell component may be present (such as a rapidly enlarged discordant lymph node growth, serum LDH >2 × upper limit of normal,

$SUV_{max} > 15$), R-CHOP is preferred, as the outcome is poor in patients with DLBCL treated with BR.[114]

Maintenance rituximab.

Treatment with maintenance rituximab following induction with chemoimmunotherapy is supported by two large studies. In the ECOG E1496 study, investigators treated patients who had stage III/IV indolent B-cell NHL (73% FL) with CVP; responders were randomized to receive either maintenance rituximab or observation.[115] Maintenance improved the depth of response and PFS rates, with a nonsignificant trend toward benefit in OS [HR 0.6 (0.4 to 1.1, $p = 0.05$)]. In the PRIMA study, patients received R-chemoimmunotherapy as induction [R-CVP (23%), R-CHOP (74%), or R-FCM (4%)] and then received either rituximab maintenance or observation.[116] Patients receiving maintenance had better PFS results than those who did not, and at a recent update, with a median follow-up of 73 months from randomization, the 6-year PFS rate was 42.7% for the observation arm and 59.2% for the maintenance arm ($p < 0.001$), with consistent benefits regardless of FLIPI risk groups, age, sex, induction chemotherapy, and type of response to induction.[117] Similar to outcome in the ECOG study, there was no benefit yet reported in OS. The RESORT study has shown that rituximab retreatment results in similar TTF with much less rituximab use than a maintenance strategy after single-agent rituximab induction in low–tumor burden patients: whether the same is true in symptomatic patients with high tumor burden treated with chemoimmunotherapy induction remains to be seen. Until then, such patients should receive maintenance rituximab if improved PFS is the goal of treatment.

Extranodal NK-/T-Cell Lymphoma, Nasal Type.

Previously described as “lethal midline granuloma,” this is an aggressive EBV-positive extranodal NK-/T-cell neoplasm characterized by relentless ulcerative destruction of the nose and deep midfacial structures and angioinvasion. Extranodal NK-/T-cell lymphoma (ENKTL), nasal type, is most common in Asia and Central and South America.[118] An EBV-driven hemophagocytic syndrome is reported in <5% of cases, but it is important to recognize as it can be rapidly fatal if unrecognized and untreated. The clinical

features include high fevers, pancytopenia, hepatosplenomegaly, and very high serum ferritin levels.[119] Treatment requires the use of an etoposide containing chemotherapy regimen plus high-dose steroids or intravenous immunoglobulin. Histologically, necrosis is common and hampers diagnosis; therefore, surgeons should take as large and representative a biopsy as safely possible, with material sent fresh to the laboratory. The NK-/T-cell lymphoma prognostic index (NKPI) was derived from a large series of Korean patients (see Table 26.1).[52] Higher pretreatment plasma EBV DNA level number predicts inferior outcome,[120] and levels can be used to monitor response to therapy and predict recurrence.[118]

Around 70% to 80% of patients have localized (IE/IIE) disease, and chemoradiotherapy is the preferred approach. NK cells have high levels of P-glycoprotein; thus, ENKTL are frequently highly resistant to drugs amenable to cellular export using this mechanism.[121] Responses to CHOP are suboptimal, and many patients actually experience kinetic failure between cycles.[122] A combination of dexamethasone, etoposide, and ifosfamide with carboplatin (DeVIC) with concurrent radiotherapy developed by the Japanese cooperative group has produced encouraging results, with CR rates of 77% to 80% and a 70% 5-year OS rate.[123] A Korean protocol that uses dexamethasone, etoposide, and ifosfamide cisplatin (VIPD) achieved similar results.[124] L-asparaginase-based regimens such as GELOX (gemcitabine, L-asparaginase, and oxaliplatin) and the more intensive SMILE (dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide) both sandwiched with IFRT have resulted in high response rates and durable remissions. SMILE in particular is associated with considerable hematologic toxicity and a toxic death rate of 7%.[125] In advanced-stage patients, multiagent chemotherapy using L-asparaginase-based regimens such as SMILE and L-asparaginase, methotrexate, and dexamethasone is the treatment of choice.[126,127]

SUMMARY

The lymphomas are a group of malignancies with widely heterogeneous biologic and clinical manifestations. The incidence of lymphomas in the United States is rising, and their effects on mortality in the young and in productive adults are important. The prognosis varies widely according to the

histology, tumor burden, age, and performance status of the patient. Specific prognostic indices have been developed and validated in many histologic subtypes. Because correct diagnosis is critical for appropriate management, effort should be made to obtain an optimum pathologic specimen by surgical excision. The success of the pathologist in appropriately diagnosing the disease rests in part on the technical skill of the surgeon in removing and handling the surgical specimen. A rapid increase in information regarding the genetic and molecular pathogenesis of various lymphoma subtypes has resulted in greater precision and refinement of diagnostic and management strategies.

27 Sarcomas and Soft Tissue Tumors of the Head and Neck

Marcus M. Monroe Beverly A. Guadagnolo Vinod Ravi Wei-Lien Wang Erich M. Sturgis

Sarcomas of the head and neck are a varied group of malignancies with widely differing clinical courses and clinical outcomes. Head and neck sarcomas arise from mesenchymal elements within the head and neck, including deep soft tissues, bone, and cartilage. Approximately 15% of all sarcomas arise within the head and neck, yet only 1% of all head and neck malignancies are sarcomas.[1,2]

Sarcomas are frequently categorized by their cell of origin and are generally broadly grouped into soft tissue sarcomas and bone/cartilaginous. More than 50 subtypes of sarcomas defined on the basis of histologic are recognized by the World Health Organization (WHO) (**Table 27.1**).[3] Alternatively, sarcomas may be categorized according to their histologic grade, which may inform treatment decisions more directly than cell of origin does. For example, high-grade sarcomas are more likely to require complex multidisciplinary treatment plans.

Table 27.1 Etiologic Factors for Head and Neck Sarcomas

Genetic Predisposition	Gene(s)	Sarcoma(s)
Li-Fraumeni syndrome	TP53	Bony and soft tissue sarcomas
Hereditary retinoblastoma	Rb	Osteosarcoma
DMS-MFH	LOH at 9p21-22	Malignant fibrous histiocytoma (MFH)
Werner syndrome	WMN	Bony and soft tissue sarcomas
Gardner syndrome	APC	Desmoid tumors
Neurofibromatosis type 1	NF1	MPNST
Costello syndrome	HRAS	Rhabdomyosarcoma
Beckwith-Wiedemann syndrome	CDKN1, IGF2, H19, KCNQ1OT1	Rhabdomyosarcoma
Rothmund-Thompson syndrome	RECQL4	Osteosarcoma
Paget disease	Unknown	Osteosarcoma
Ollier and Maffucci syndromes	IDH1, IDH2	Chondrosarcoma
Environmental Exposures		**Sarcoma(s)**
Ionizing radiation		Bony and soft tissue sarcomas
HIV, HHV-8		Kaposi Sarcoma
Industrial waste		Bony and soft tissue sarcomas
Herbicides and chlorophenols		Bony and soft tissue sarcomas

DMS-MFH, diaphyseal medullary stenosis with malignant fibrous histiocytoma; HLRCC, hereditary leiomyomatosis and renal cell cancer; MPNST, malignant peripheral nerve sheath tumors.

For the vast majority of sarcomas, the etiology of the tumor is not known. Some genetic and environmental factors have been associated with development of sarcomas. For example, although very rare, several inherited syndromes are well known to increase the risk of specific types of sarcomas (**Table 27.2**). Germline mutations in the tumor suppressor gene *TP53*, such as those occurring in Li-Fraumeni syndrome, have been linked to an increased risk of both soft tissue and osteosarcomas.[4,5] Diamond-Blackfan syndrome, a hereditary anemia linked to mutations in genes encoding ribosomal proteins, has been associated with osteosarcoma.[6,7] Malignant fibrous histiocytoma (MFH) arising in bone occurs in up to 35% of patients with the rare cancer syndrome, diaphyseal medullary stenosis with MFH, and is characterized by loss of heterozygosity at the chromosomal band 9p21-22.[8] Werner syndrome, characterized by rapid aging and mutations in the WMN gene, is well known to be associated with an increased incidence of multiple sarcoma types.[9] Gardner syndrome, characterized by *APC* mutations and hereditary colon polyposis and cancer, is associated with an increased incidence of desmoid fibromatoses.[10]

Table 27.2 Histologic Subtypes of Head and Neck Sarcomas with

Known Genetic Alterations

WHO Sarcoma Histologic Subtypes	Cytogenic Alterations	Altered Gene(s)
Adipocytic Tumors		
Dedifferentiated liposarcoma	Supernumerary ring and giant marker chromosomes, amplification 12q13-15	MDM2, CDK4, HMGA2, SAS, GL1
Myxoid/round cell liposarcoma	t(12;16)(q13;p11), t(12;22)(q13;q12)	FUS-DD1T3, EWSR1-DD1T3
Pleomorphic liposarcoma	Complex alterations	
Fibroblastic, Myofibroblastic, and Fibrohistiocytic Tumors		
HPC/SFTs	Complex alterations	NAB2–STAT6
Fibrosarcoma	Complex alterations	
Myxofibrosarcoma	Complex alterations	
Low-grade fibromyxoid sarcoma	t(7;16)(q33;p11), t(11;16)(p11;p11)	FUS-CREB3L2, FUS-CREB3L1
Sclerosing epithelioid fibrosarcoma		EWSR1-CREB3L1
Undifferentiated pleomorphic sarcoma/MFH		
Desmoid fibromatosis	Trisomy 8 or 20; Loss of 5q21	CTNNB1 or APC mutations
DFSPs	t(17;22)(q21;q13) and derivative ring chromosomes	COL1A1-PDGFB
Smooth Muscle Tumors		
Leiomyosarcoma	Complex alterations	
Skeletal Muscle Tumors		
Embryonal rhabdomyosarcoma	LOH at 11p15	
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14), t(1;13)(p36;q14), t(X;2)(q13;q35)	PAX3-FKHR and PAX7-FKHR
Pleomorphic rhabdomyosarcoma	Complex alterations	
Vascular Tumors		
Epithelioid hemangioendothelioma	t(1;3)(p36.3;q25)	
Angiosarcoma	Complex alterations	PTPRB and PLCG1 mutations
Tumors of Peripheral Nerves		
Malignant peripheral nerve sheath tumors	Complex alterations	
Tumors of Uncertain Differentiation		
Synovial sarcoma	t(X;18)(p11;q11)	SS18-SSX1, SS18-SSX2, SS18-SSX4
Alveolar soft-part sarcoma	der(17)t(X;17)(p11;q25)	ASPL-TFE3
Sarcomas of Cartilage and Bone		
Chondrosarcoma	Complex alterations	
Osteosarcoma	Complex alterations	
PNET/Ewing sarcoma	t(11;22)(q24;q12), t(21;22)(q22;q12), t(2;22)(q33;q12), t(7;22)(p22;q12), inv(22)(q12;q12), t(16;21)(p11;q22)	EWS-ETS

The best characterized environmental risk factors linked to sarcoma development include the link between HIV infection and HHV8-induced Kaposi sarcoma (KS). Rarely, sarcoma can arise in the setting of prior exposure to ionizing radiation. Less well-established associations have been documented between increased sarcoma risk and environmental exposure to chlorophenols, herbicides, and certain chemicals in industrial waste products.[11]

PRINCIPLES OF SARCOMA MANAGEMENT

Patient Evaluation

Symptoms and clinical presentations in patients with sarcoma vary widely according to the histologic subtype and tumor location, but several sarcoma types have characteristic presentations. For instance, angiosarcomas typically present as a violaceous plaque on the scalps of elderly white males, whereas a chondrosarcoma often presents as a destructive bony lesion centered on the cricoid. The majority of types of sarcoma, however, lack a specific characteristic presentation and frequently present with an asymptomatic mass.[11] In a review of over 2,000 patients presenting to MD Anderson Cancer Center over the past 44 years (**Tables 27.3 and 27.4**), the most frequent locations for sarcomas arising in the head and neck of adults (Table 27.3) included the scalp/face (30% of cases), followed by the sinonasal cavity/anterior skull base (23%) and the upper aerodigestive tract and the parotid/neck (each accounting for 19%). Sarcomas arising in the ear/lateral or posterior skull base were quite rare (<8%). In the pediatric and adolescent population (Table 27.4), the distribution of sites is somewhat different with the sinonasal cavity/anterior skull base accounting for 28% of cases and the upper aerodigestive tract for 27% followed by the scalp/face (22%), the parotid/neck (14%), and the ear/lateral or posterior skull base (9%).

Table 27.3 Adult Head and Neck Sarcomas at the University of Texas MD Anderson Cancer Center (Age ≥ 18, 1970–2013)

Histologic Type	No.	%	Site of Origin				
			Scalp and Face	Sinonasal Tract Anterior/Medial Skull Base	Ear Lateral/ Posterior Skull Base	Upper Aerodigestive Tract	Parotid and Neck
Bone and Cartilage							
Osteosarcoma	288	14.8	3	108	48	125	4
Ewing sarcoma/PNET	35	1.8	5	10	9	5	6
Chondrosarcoma	153	7.9	2	45	52	46	8
Fibrous							
Undifferentiated pleomorphic sarcoma/MFH	159	8.2	59	27	10	17	46
Fibrosarcoma	49	2.5	10	16	0	11	12
Fibromyxoid sarcoma	4	0.2	1	0	0	0	3
DFSP	110	5.7	89	0	1	0	20
Muscular							
Rhabdomyosarcoma	199	10.3	22	112	1	52	12

The physical examination in a patient with a known or suspected sarcoma should entail a careful assessment of the extent of the disease, the degree of fixation to surrounding structures, and the presence or absence of regional adenopathy. Cross-sectional imaging should be performed to further delineate the extent of the primary lesion and to assess for regional and distant spread of disease. For most head and neck sarcomas, distant metastases are most likely to present in the lungs, and chest imaging with computed tomography should be obtained routinely. For sarcomas with a higher risk of intracranial metastases, such as alveolar soft part sarcoma (ASPS) and angiosarcoma, the staging workup should include imaging of the brain.[12]

Although fine needle biopsy is the initial biopsy of choice for many head and neck masses, biopsy for head and neck sarcomas often entails either a core needle or incisional biopsy as the limited amount of tissue and lack of tissue architecture provided by fine needle aspiration makes diagnosis of

sarcomas particularly difficult. Biopsy sites should be planned such that they can be easily excised during subsequent surgical resection. Pathologic assessment of the biopsy specimen should be undertaken by a pathologist with experience in sarcomas[13] with the goal of providing information on the histologic subtype as well as tumor grade at a minimum. Standard morphologic assessment remains the standard for diagnosis, although the use of cytogenetics to augment standard morphologic assessment is accelerating (Table 27.1). For consistency and communication among providers, pathologic reports should use the nomenclature for sarcomas standardized by the WHO.[3] Approximately one-quarter of head and neck sarcomas arising in adults are unclassified and undifferentiated, high-grade, pleomorphic sarcomas, with osteosarcomas, angiosarcomas, and rhabdomyosarcomas accounting for another one-third (Table 27.3). However, in children and adolescents, the majority are rhabdomyosarcomas (Table 27.4).

Staging and Prognostic Factors in Head and Neck Sarcomas

The American Joint Committee on Cancer staging system for soft tissue sarcomas incorporates measures of tumor size (> or ≤5 cm), location with respect to deep fascial planes, the presence of regional or distant metastatic spread, and tumor grade. For sarcomas located in the head and neck, the usefulness of this staging system has been questioned, as such tumors are typically smaller than 5 cm at the time of presentation and have high rates of deep fascial involvement.[1,14]

For most histologic subtypes of sarcoma, studies have shown that location within the head and neck portends a worse prognosis than location in other anatomic regions.[15] Tumor grade and margin status remain the most consistently identified prognostic factors in multiple case series of head and neck sarcomas.[1,16–18] Unfortunately, the proximity to vital structures frequently precludes wide resection margins for head and neck sarcomas, a factor that has been linked to their poor prognosis. In addition to grade and margin status, tumor size, age, and smoking status have been associated with reduced survival.[15–19] The prognostic significance of regional metastatic spread for head and neck sarcomas is debated.[14,20]

Principles of Surgery

The traditional cornerstone of therapy for head and neck soft tissue and bony sarcomas without evidence of distant metastatic disease on presentation is surgical excision with histologically negative margins. Given the propensity for microscopic spread beyond the clinically apparent tumor, margins of 2 cm and inclusion of an adjacent normal-appearing tissue plane beyond the mass should be attempted. Surgical resections should be planned to include excision of the biopsy site. Within the head and neck, proximity of critical structures frequently precludes obtaining wide margins. If close or histologically positive surgical margins are anticipated on the basis of preoperative clinical and radiologic evaluation, neoadjuvant chemotherapy and/or preoperative radiation therapy should be considered.[12] Standard terms used to describe surgical margins for sarcomas are *R0* for microscopically negative margins, *R1* for microscopically positive margins, and *R2* for grossly positive margins.

Head and neck sarcomas should be managed by experienced multidisciplinary teams with experience in treating sarcomas. Surgical management of head and neck sarcomas frequently involves multispecialty surgical teams including thoracic, vascular, reconstructive, ophthalmologic, and neurosurgical services, but regardless of which other specialists are involved, an experienced head and neck surgeon is essential. Given the frequent need for adjuvant chemotherapy and radiation therapy either before or after surgery, close coordination with medical and radiation oncologists with experience treating sarcomas is critical.

Principles of Radiation Therapy

For head and neck sarcomas, preoperative or postoperative adjuvant radiation therapy is typically given as part of combined modality primary local therapy for nonmetastatic presentations. Multiple case series have demonstrated improved local control with the use of adjuvant radiation therapy in cases of positive margins or high-grade tumors.[21,22] Unfortunately, negative margins can be difficult to achieve in head and neck sarcoma surgery; in some series, up to half of patients have R1 or R2 resections.[11] Low-grade sarcomas with wide negative margins may be considered for single-modality treatment with surgery alone.

Although the benefits of adjuvant radiation therapy for sarcomas in the head and neck are widely accepted, the optimal timing of radiation therapy remains controversial. Both preoperative and postoperative radiation therapies have potential advantages. Tumor margins and the regions that need to be targeted with radiation are more easily defined before surgical resection, when the sarcoma mass is present during simulation. Consequently, preoperative radiation therapy has the advantages of a lower dose (50 Gy vs. 60 to 66 Gy for postoperative radiation therapy) and a smaller, precisely defined radiation field, translating into a lower risk of late radiation-related side effects, including fibrosis and edema, and the potential to minimize the radiation dose to critical structures.[23] However, preoperative radiation therapy has been reported to be associated with increased wound complications following surgery. In a randomized trial that attempted to address this issue, 190 patients with soft tissue sarcoma of the extremities were randomized to preoperative or postoperative adjuvant radiation therapy.[24] Similar rates of local control, disease-free survival, disease-specific survival, and overall survival were noted between the groups. Among patients with lower extremity sarcomas, wound complications were more common in patients undergoing preoperative radiation therapy. While late side effects of radiation therapy are presumed to be lower with lower doses used preoperatively then with postoperative doses, long-term side effects have not been reported for this trial. In a separate analysis of 40 consecutive patients with head and neck soft tissue sarcomas treated with preoperative radiation therapy, the rate of wound complications was lower than that reported previously for soft tissue sarcomas of the extremities,[25] suggesting that the improved blood supply of the head and neck may reduce the risk of some of the wound complications associated with preoperative radiation therapy at other sites. The use of preoperative radiation therapy should be considered in all cases of sarcoma of the head and neck where radiation will be used and the complication risk for surgery in an irradiated field does not preclude it.[26] This requires treatment plan coordination and discussion between the treating radiation oncologist and the head and neck surgeon.

Principles of Chemotherapy

For sarcomas that display evidence of distant metastatic spread,

chemotherapy is generally indicated and is individualized on the basis of specific tumor histologic features.[26] For localized resectable sarcomas in adults, the role of chemotherapy remains less well defined. The Sarcoma Meta-analysis Collaboration analyzed results from 14 trials evaluating doxorubicin-based therapy in resectable soft tissue sarcomas. Local, distant, and overall recurrence-free survival times were significantly improved with doxorubicin-based adjuvant chemotherapy, although the absolute improvement in overall recurrence-free survival was only 6% to 10% at 10 years.[27] Other trials have demonstrated histologic subtype–specific responses to different chemotherapeutic agents and are discussed below. Authors increasingly describe the use of chemotherapy to treat sarcomas, particularly the use of neoadjuvant chemotherapy for high-risk tumors.

SOFT TISSUE SARCOMAS

Soft Tissue Tumors of Endothelial Origin

Angiosarcoma

Angiosarcomas are rare soft tissue sarcomas arising from endothelial cells. They classically present as a violaceous macule or papule on the scalp in elderly white males, although they can present in people of any age, gender, or ethnicity and in any anatomic location. Most angiosarcomas in the head and neck arise spontaneously in the elderly, although several well-known risk factors are associated with the development of angiosarcomas at other sites in the body. These risk factors include chronic lymphedema following treatment for breast cancer (Stewart-Treves syndrome), prior radiation exposure, and prior exposure to environmental toxins such as vinyl chloride, thorium dioxide, anabolic steroids, arsenic, and radium.[28] Susceptibility to angiosarcoma has been proposed to be increased in people with mutations in *BRCA1* and *BRCA2*, neurofibromatosis, Maffucci syndrome, and Klippel-Trenaunay syndrome. Up to 38% of cases of angiosarcoma harbor mutations in *PTPRB* or *PLCG1*.[29]

Frequent delays in diagnosis are common for head and neck angiosarcomas given their propensity to mimic benign conditions, including bruises and benign vascular lesions, typically of the scalp (**Fig. 27.1**, Table

27.3). Angiosarcomas, particularly those of the scalp, have a propensity for diffuse spread beyond the visible cutaneous abnormality, making underestimation of the true extent of disease commonplace. Satellite lesions occur in up to half of patients and portend a worse prognosis.[30] Regional nodal disease at presentation is relatively uncommon, occurring in 6% to 10% of patients,[31] although up to 16% of patients may experience delayed regional recurrence following treatment.[30] The development of distant metastatic disease occurs in 36% to 77% of patients,[30–32] and the most common site of metastasis is the lungs. Local relapse occurs in 35% to 53% of patients[30–32] and is more common with larger tumor size, tumor location on the scalp, and single-modality treatment.[30,33,34] Local relapse portends a poor prognosis.[30]

Figure 27.1. Angiosarcoma of the right temple **(A)** and scalp **(B)**. Early lesions may mimic that of benign conditions such as bruising, leading to delays in diagnosis.

Angiosarcomas arising in the head and neck have a worse prognosis than do those arising in other sites: the estimated 5-year survival rate for scalp and neck angiosarcomas is 34%, compared to 64% to 75% for those arising at other locations.[35] Among angiosarcomas of the head and neck, angiosarcoma of the scalp is associated with worse disease-specific survival than are tumors at other locations.[30]

The combination of surgery and radiation therapy appears to offer the best chance for local control as well as improved disease-specific and overall survival as compared to either surgery alone or radiation alone.[30,31,33,34] Achieving an R0 resection can be particularly difficult in angiosarcomas of the head and neck given the propensity for a diffuse and multifocal growth pattern.[30,33] Because of this, some have argued against extensive resections

necessitating complicated reconstructions that may delay postoperative radiation therapy.[30] Given the need for adjuvant radiation therapy in nearly all cases of angiosarcoma, repair of surgical defects should be robust enough to withstand radiation therapy. In particular, skin grafting for repair of scalp defects should be avoided when possible. Limited evidence exists to support the role of chemotherapy for localized angiosarcomas, although neoadjuvant taxane-based chemotherapy followed by radiation therapy and/or limited surgical excision has produced encouraging results.[30,36,37]

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma (EH) is an extremely rare vascular neoplasm with an angiocentric growth pattern and malignant behavior intermediate between that of benign hemangioma and high-grade angiosarcoma. EH occurs most commonly on the extremities but can also occur in the lung, liver, or head and neck.[38] Clinically, EH most commonly presents as a subcutaneous or deep painful nodule. Histologically, EH appears as cords or strands of epithelioid endothelial cells embedded in a matrix that varies from chondroid-like to hyaline-like.[3] Most tumors are low grade, although a small subset displays more aggressive features similar to those of angiosarcomas. There is a tendency for EHs to be misdiagnosed, frequently as metastatic carcinoma.[39,40] EH does have the potential for both regional and distant metastatic spread, which occurs in up to 20% to 30% of cases.[3] Primary treatment is typically surgical resection; adjuvant radiation therapy is used for cases of EH associated with adverse features.

Kaposi Sarcoma

KS is a locally aggressive endothelial cell neoplasm universally associated with human herpesvirus 8 infection. Multiple different subtypes of KS are recognized, including classic, endemic, iatrogenic (immunosuppression associated), and AIDS associated. Of these subtypes, the AIDS-associated subtype is the most frequently found within the head and neck.

KS typically presents with multiple dark brown to violaceous patches that progress to plaques and nodules. Ultimately, these lesions may coalesce and ulcerate. Although the skin is the classic site of involvement, the oral cavity, particularly the hard palate, and the oropharynx are common sites of

involvement in the head and neck.[41,42] Histologically, KS is characterized by irregular proliferation of small blood vessels with an accompanying inflammatory infiltrate and spindled cell proliferation.[3,41]

Treatment for KS differs according to the subtype of KS and extent of disease. Before any specific therapy is undertaken, a thorough evaluation should be performed to assess the full extent of disease. This evaluation should include a head and neck examination as well as ophthalmologic, dermatologic, genital, lymphatic, and radiographic assessments. Any patient in whom the HIV status is uncertain should undergo testing. Therapeutic strategies range from observation in patients with limited asymptomatic lesions to systemic chemotherapy for patients with widespread disease or the endemic subtype. For HIV-associated KS, standard treatment consists of initiation of antiretroviral therapy. In patients with iatrogenic KS, modification of immunosuppressive regimens, including a reduction in the degree of immunosuppression or a change in the drug regimen, may be efficacious. KS is particularly radiosensitive, with high rates of response reported. Patients with head and neck mucosal KS may be particularly susceptible to mucositis from radiation therapy, even at low doses. Radiation therapy is typically reserved for palliation. Surgical excision is typically reserved for symptomatic limited lesions as this therapy is ineffective in preventing the onset of new lesions.[43]

Soft Tissue Tumors of Myocyte Origin

Rhabdomyosarcoma

Rhabdomyosarcoma (RMS) is a soft tissue sarcoma arising from striated muscle. The majority of RMSs occur in children, in whom RMS is the most common soft tissue sarcoma (Table 27.4). However, up to one-third of cases of head and neck RMS are diagnosed in adults.[44] The orbit is involved in one-quarter of cases of RMS; most of the remaining cases arise in the nasopharynx, nasal cavity, and paranasal sinuses.[45] RMS of childhood has been associated with multiple syndromes, including Costello syndrome, Beckwith-Wiedemann syndrome, and Li-Fraumeni syndrome, as well as with neurofibromatosis type 1.[45]

Histologically, RMS appears as a small round blue cell tumor. Three

different histologic subtypes—embryonal, alveolar, and pleomorphic—are recognized and have important prognostic differences. Embryonal RMS is the most common subtype recognized in children and is genetically characterized by loss of heterozygosity at 11p15. Alveolar RMS accounts for ~20% of childhood RMS cases and has a significantly worse prognosis than does embryonal RMS. Two translocations have been well characterized in alveolar RMS: the t(2; 13) (q35; q14) and t(1; 13) (p36; q14) translocations, which result in the *PAX3-FOX01* and *PAX7-FOX01* fusion transcripts, respectively. Survival rates are significantly higher for patients with metastatic tumors harboring the *PAX7-FKHR* fusion transcript than for patients with metastatic tumors harboring the *PAX3-FKHR* fusion transcript; estimated 4-year survival rates are 75% and 8%, respectively.[45] Pleomorphic RMS is more commonly identified in adult-onset RMS than in childhood RMS.[46]

In childhood RMS, regional lymphatic spread is uncommon. Of 139 head and neck RMSs included in Intergroup Rhabdomyosarcoma Study I and II, only 8 (6%) were associated with regional lymphatic spread. For RMSs located within the orbit, there was no demonstrable lymphatic spread, whereas 8% of nonorbital head and neck RMSs demonstrated lymphatic spread.[46] This was considerably lower than the rates of lymphatic spread identified for RMSs of other sites. This low rate of lymphatic spread for head and neck RMSs was confirmed in an analysis of Intergroup RMS Study IV, in which only 9% of pediatric head and neck RMSs demonstrated regional lymphatic spread.[47] In adult RMS, the rate of regional lymphatic involvement is less well defined but appears to be higher than other adult soft tissue sarcomas. In a series of 43 adult patients with head and neck RMS, 18 (42%) had demonstrable involvement of regional lymphatics.[48] Up to 23% of patients with RMS have distant metastatic disease at presentation; therefore, imaging for distant metastases should be part of the workup for all patients with RMS.[2]

For childhood RMS, head and neck tumors are further subdivided into orbital, parameningeal, and nonparameningeal sites. Parameningeal sites include the middle ear, nasal cavity, paranasal sinuses, nasopharynx, pterygopalatine fossa, and infratemporal fossa. Parameningeal RMS accounts for ~40% of cases of pediatric head and neck RMS[45] and is associated with the worst prognosis among RMSs of the head and neck sites because of a

propensity for bony erosion and contiguous intracranial spread and anatomic constraints that limit the application of local therapy.

In general, pleomorphic RMS should be treated similarly to other high-grade soft tissue sarcomas. For embryonal and alveolar RMS, especially cases occurring in pediatric patients, treatment should be performed at a high-volume center.[26] Treatment regimens for nonpleomorphic RMS frequently differ from those for other soft tissue sarcomas. Surgical resection remains an important part of the treatment algorithm. However, given the frequent proximity to critical intracranial structures or extension, complete surgical excision is frequently not achievable without significant morbidity. The Intergroup RMS Study Group and subsequently the Children's Oncology Group Soft Tissue Sarcoma Committee are a tremendous example of the power of cooperative groups to define treatment standards.[49] As example, RMSs in pediatric patients are risk stratified based principally upon surgical and pathologic criteria, and treatment (various combinations of chemotherapy and radiation therapy) is determined by prognostic risk group. Long-term sequelae of radiation therapy in pediatric patients remain significant and can include asymmetric facial growth, cataracts, blindness, cognitive deficits, and radiation-induced secondary malignancies.[2,50]

Overall survival rates have improved significantly following the successes of the Intergroup RMS Studies. For children with head and neck RMS, the 5-year disease-free survival rate ranges from 58% to 74%.[2] Given the rarity of adult RMS, data regarding treatment outcomes are limited, but outcomes in adults are significantly worse than those in younger cohorts.

Leiomyosarcoma

Leiomyosarcoma is a rare soft tissue sarcoma arising from smooth muscle cells. Only a small percentage of leiomyosarcomas are located in the head and neck.[51] Leiomyosarcomas account for ~1% to 14% of head and neck sarcomas[1,17–19,22,52] (Table 27.3). Careful histologic review by an experienced sarcoma pathologist is critical to avoid misdiagnosis, a common occurrence for lesions initially diagnosed as leiomyosarcoma. Additionally, when leiomyosarcoma is suspected, a primary tumor at a more typical abdominal or pelvic site should always be considered and ruled out. The most common locations for leiomyosarcomas in the head and neck are the deep

soft tissues and the skin.[53] Smooth muscle associated with arrector pili muscles and smooth muscles surrounding the vasculature may give rise to leiomyosarcomas.

The mainstay of therapy for leiomyosarcoma is surgical resection with radiation therapy either preoperatively or postoperatively, unless the lesion is superficial. If the lesion is cutaneous and is <2 cm, radiation is typically omitted. Regional and distant spread of disease at presentation is rare, occurring in fewer than 2% of cases.[53] Data are lacking on long-term clinical outcomes of patients with regional or distant spread at presentation. Tumor grade has been identified as an important prognostic factor: 5-year disease-specific survival rates range from 86% to 88% for well and moderately differentiated tumors, compared to 53% for poorly differentiated tumors.[53] Location on the skin has been associated with an improved prognosis.[53]

Soft Tissue Tumors of Fibroblast, Myofibroblast, and So-Called Fibrohistiocytic Origin

Hemangiopericytoma and Solitary Fibrous Tumors

Hemangiopericytomas (HPCs) and solitary fibrous tumors (SFTs) are rare neoplasms thought to arise from pericytes of Zimmerman surrounding small capillaries and postcapillary venules. Historically, HPCs and SFTs were considered separate entities. Now, however, on the basis of overlapping histologic findings and shared molecular alterations, HPCs and SFTs are considered closely related if not synonymous lesions.[3] HPCs/SFTs are composed of varying proportions of fibroblastic spindled cells that stain positive for CD34 and have characteristic sinusoidal or staghorn vasculature, findings that can make differentiation of HPCs/SFTs from synovial sarcoma challenging on the basis of histologic findings alone. Recent advances in molecular characterization of these lesions through whole-genome sequencing have demonstrated that HPCs/SFTs harbor characteristic fusions of the *NAB2* and *STAT6* genes.[54,55]

HPCs/SFTs can occur anywhere in the body. Approximately one-quarter of cases occur within the head and neck, and the sinonasal tract is the most common subsite[2,56] (Table 27.3). HPCs/SFTs of the sinonasal tract most frequently present with epistaxis and nasal obstruction and typically are

located within the nasal cavity and ethmoid sinuses.[56] In other locations, HPCs/SFTs most commonly present as slowly enlarging painless masses.

HPCs/SFTs are locally aggressive. Surgical excision is the standard therapy. Local recurrence occurs in a significant proportion of patients, and the strongest predictor of recurrence is incomplete excision. In a review of more than 190 cases of sinonasal HPCs/SFTs, local recurrence occurred in ~20% of cases with gross total resection, compared to 71% to 100% of cases with incomplete excision.[57] Distant metastatic spread occurs in up to 15% of HPCs/SFTs occurring outside the central nervous system, although distant metastatic spread from tumors located within the head and neck is reported to occur in only 2% of cases.[57] The roles of radiation therapy and chemotherapy for HPCs/SFTs of the head and neck are not well characterized.

Desmoid Tumor/Desmoid Fibromatosis/Aggressive Fibromatosis

Desmoid tumors are monoclonal proliferations of histologically benign-appearing fibroblasts that can occur within deep soft tissues. Clinically, desmoid tumors are characterized by a locally infiltrative growth pattern with high rates of local recurrence but a highly variable clinical course and absence of metastatic potential. The median age at diagnosis has been reported to be in the early fourth decade of life, and the female-to-male ratio of patients with desmoid tumors is ~2:1.[58] Desmoid tumors occur infrequently in the general population; the estimated incidence is 2 to 4 cases per 1 million person-years. Approximately 85% of sporadic desmoid tumors harbor one of three different point mutations in *CTNNB1*, the gene encoding beta-catenin. The *CTNNB1* S45F mutation has been associated with lower recurrence-free survival rates than the *CTNNB1* T41A and S45P mutations.[59] In patients with familial adenomatous polyposis and germline *APC* mutations, desmoid tumors occur in up to 10% of patients.[60] An etiologic role for estrogen in desmoid tumors is suggested by the female preponderance of cases, increased incidence of desmoid tumors in females of reproductive age and during pregnancy, and consistent high expression of estrogen receptor beta in nonabdominal desmoid tumors.[61] A history of trauma at the site of tumor development is also frequently cited[61] but is more likely to have brought the lesion to the patient’s attention than actually to be its cause.

Head and neck desmoid tumors are estimated to account for 7% to 15% of all desmoid tumors.[61] The neck, in particular the supraclavicular fossa, is the most common site of involvement for desmoid tumors of the head and neck.[61] Desmoid tumors most commonly present as enlarging masses. Differentiation from fibrosarcoma, low-grade fibromyxoid sarcoma, and other benign fibrous lesions can be difficult on the basis of histologic findings alone; evaluation for *CTNNB1* mutations can be helpful in such cases.

Treatment for desmoid tumors is an area of controversy. The rarity of desmoid tumors, combined with their highly variable clinical course, which ranges from indolent to locally aggressive and can even include spontaneous resolution, makes evaluation of response to treatment difficult. Historically, surgical resection has been the mainstay of therapy. However, given the infiltrative growth pattern and lack of a well-defined tumor capsule, R0 resections are difficult, particularly in the head and neck, where proximity to critical structures frequently limits the width of surgical resection margins.[62,63] Given the variable clinical course and difficulty of achieving negative margins, most authors agree that mutilating surgery should be avoided. For patients without a history of rapid growth or proximity of tumor to critical structures, a period of observation may be considered. For desmoid tumors of the abdominal wall, high rates of spontaneous regression have been reported with a strategy of initial observation.[64] Radiation therapy can achieve disease stabilization and prevent progression[65] and in some cases shrinks the tumor. The potential benefits of radiation therapy should be balanced against long-term side effects on an individualized basis.[66,67] No standardized systemic therapy paradigm has emerged. Regimens used to date have included traditional cytotoxic therapies, nonsteroidal anti-inflammatories, tamoxifen, and imatinib.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a rare low-grade cutaneous sarcoma of fibroblast origin with little metastatic potential. DFSP accounts for 4% of soft tissue sarcomas and 4% to 10% of head and neck sarcomas.[2] The incidence is approximately four cases per million person-years, and the median age at diagnosis is in the fourth decade of life.[2]

DFSP is characterized by an indolent clinical course but an infiltrative growth pattern with irregular subclinical tumor extensions. The most common site of involvement is the scalp (Table 27.3), where DFSPs most commonly appear as painless raised nodules or plaques, a fact that may lead to delayed diagnosis. Surgical excision with histologically negative margins is the treatment of choice for DFSP when possible. High rates of local recurrence are noted with incomplete surgical excisions and with positive initial resection margins, so re-excision should be attempted in such cases when not prohibited by proximity of the tumor to critical structures.[26] When re-excision is not possible or when complete surgical excision would be associated with unacceptable adverse effects, adjuvant radiation therapy combined with conservative surgical excision affords high rates of local control.[68]

A characteristic chromosomal translocation—t(17;22), resulting in fusion of the *COL1A1* and *PDGFβ* genes—occurs in DFSP, resulting in activation of the platelet-derived growth factor receptor beta (PDGFβ) signaling pathway.[69] Imatinib, a tyrosine kinase inhibitor with activity against PDGFβ, has emerged as an alternative adjuvant therapy for patients with metastatic or inoperable DFSP, and complete and partial response rates to this day range from 36% to 57%.[70,71]

Local recurrence occurs in 1% to 60% of patients with DFSP and may be quite delayed.[72,73] Distant metastatic disease ultimately occurs in 2% to 4% of patients.[72,73] In patients who have surgical excision with negative margins, estimated 5-year overall survival rates are excellent, approaching 100%.[2]

MFH/Undifferentiated High-Grade Pleomorphic Sarcoma

Historically, MFH was considered a discrete soft tissue sarcoma with a suspected fibroblastic origin that displayed both fibrous and histiocytic differentiation. More recently, it has been recognized that the histologic pattern of MFH may be shared by a wide variety of poorly differentiated neoplasms. Consequently, the term *malignant fibrous histiocytoma* is now reserved for soft tissue malignancies for which no reliable line of differentiation may be established, and MFH is considered synonymous with undifferentiated high-grade pleomorphic soft tissue sarcoma. In historic

series, MFH represented the most common soft tissue sarcoma in adults and one of the most frequent soft tissue sarcomas of the head and neck.[1,11,74]

MFH typically occurs in the fourth to sixth decades of life and is rarely identified in young patients. The vast majority of MFH lesions arise spontaneously; however, in the rare patient who develops a radiation-associated sarcoma after previous radiation therapy, the histology is often MFH or undifferentiated pleomorphic sarcoma.[74] In a series of over 2,000 long-term survivors of nasopharyngeal carcinoma who were treated with radiation therapy, the prevalence of MFH was 0.4%, and the 15-year cumulative incidence was 2%.[75] MFH most commonly presents as a mass. The most common sites of involvement are the parotid and neck, followed by the scalp, face, and then the anterior skull base and orbit; less commonly involved are the aerodigestive tract and lateral skull base[75] (Tables 27.3 and 27.4). Specific symptoms depend on the tumor location. Involvement of regional lymphatics is infrequent, although distant spread, most frequently to the lungs, has been reported in up to 16% of patients.[74]

The management of MFH requires a true multidisciplinary approach. While the primary treatment modality remains surgical excision, high rates of positive margins and frequent local recurrence necessitate the use of adjuvant radiation therapy either before or after surgery in a majority of patients. However, if the patient has a radiation-associated sarcoma, reirradiation is not recommended due to morbidity concerns associated with reirradiation. Because patients with undifferentiated high-grade pleomorphic sarcomas are at increased risk for distant metastatic spread, the use of neoadjuvant or adjuvant chemotherapy should routinely be considered.

Although population-level data are not available for head and neck MFH, estimated survival rates are available from a large series of patients with MFH of the head and neck, in which 5-year overall, disease-specific, and disease-free survival rates were estimated to be in the range of 55%, 69%, and 44%, respectively.[74] Factors associated with a poor prognosis in patients with MFH include positive surgical margins, tumor size >5 cm, high grade, location other than in the parotid or neck, and tumor arising in a previously irradiated field.[74,76–78]

Fibrosarcoma

Fibrosarcomas are malignant neoplasms of fibroblastic or myofibroblastic origin. Historically, fibrosarcoma was one of the most frequent soft tissue sarcomas identified. However, with advances in immunohistochemistry and molecular diagnosis, many lesions previously classified as fibrosarcomas are now recognized to be of different histologic subtypes.[79,80] Reclassification of lesions in historic series of head and neck fibrosarcomas has demonstrated that the majority of lesions reported to be fibrosarcomas would now be classified as desmoid tumors, dermatofibrosarcomas, synovial sarcomas, and MFH/pleomorphic undifferentiated high-grade sarcomas.[79] Advances in immunohistochemistry and molecular diagnosis have also led to the recognition of multiple new subtypes of fibrosarcomas, including myxofibrosarcoma, low-grade fibromyxoid sarcoma, sclerosing epithelioid fibrosarcoma, and the classic adult fibrosarcoma, which is now a diagnosis of exclusion.[3]

Adult fibrosarcoma is a malignancy of fibroblast origin with variable collagen production. Classic adult fibrosarcoma appears as sweeping fascicles of spindle-shaped cells in a herringbone pattern.[3] Limited data are available on incidence rates, optimal treatment, or clinical outcomes for adult fibrosarcomas diagnosed using modern diagnostic criteria.

Myxofibrosarcomas are malignant neoplasms of fibroblast origin characterized histologically by myxoid stroma and a characteristic curvilinear vascular pattern.[3] They are most commonly located on the extremities but rarely occur in the head and neck. Myxofibrosarcomas have a high propensity for local recurrence regardless of tumor grade; recurrence rates of 50% or higher have been reported.[81,82] Regional lymph node spread occurs in ~8% of cases,[82] and distant metastasis, most commonly to the lungs, occurs in ~15% of cases.[81,82]

Low-grade fibromyxoid sarcoma and sclerosing epithelioid fibrosarcoma are very rare subtypes of fibrosarcoma, and only a few cases of these tumors occurring in the head and neck have been reported in the literature. Low-grade fibromyxoid sarcoma is characterized by bland-appearing spindled cells with rare mitoses admixed with heavily collagenized zones and a whorling growth pattern. Up to 40% of cases demonstrate poorly formed collagen rosettes.[3] It has been reported that 81% to 88% of low-grade fibromyxoid sarcomas harbor a characteristic translocation of either the *FUS*-

CREB3L2 or *FUS-CREB3L1* fusion.[83,84] Despite the bland histologic appearance, up to 64% of patients with low-grade fibromyxoid sarcoma develop local recurrence, and 21% to 45% develop metastatic disease.[83,84] In contrast to what is observed with many soft tissue sarcomas, both local recurrence and metastasis of low-grade fibromyxoid sarcoma can occur many years after diagnosis, which highlights the need for lifelong follow-up in these patients.[84,85] Sclerosing epithelioid fibrosarcoma is characterized by nests of epithelioid cells embedded in a sclerotic collagenous matrix. *EWSR1-CREB3L1* fusions have been identified in a moderate proportion of cases.[86] High rates of local recurrence (50% to 53%) and distant metastasis (43% to 86%) have been noted.[87,88]

Soft Tissue Tumors of Adipocyte Origin (Liposarcoma)

Liposarcomas are soft tissue sarcomas arising from adipocyte precursors. Liposarcomas are most frequently found in the deep soft tissues of the extremities and retroperitoneum; only 2% to 9% of liposarcomas are localized to the head and neck.[89] Liposarcomas account for ~2% to 4% of all head and neck sarcomas[1,11,19] (Table 27.3). There is a male preponderance (77%) for head and neck liposarcomas, which differs from the more even gender distribution (58% male) for liposarcomas located in other anatomic regions.[89] The majority of head and neck liposarcomas are located in the subcutaneous tissues of the head and neck; involvement of the skin, aerodigestive tract, or major salivary glands is less common.[89,90]

Compared with liposarcomas at other anatomic sites, liposarcomas of the head and neck are more likely to present at an early stage and higher degree of differentiation. Up to 89% of head and neck liposarcomas present as stage I or II, and an estimated 70% are well differentiated.[89] A number of different histologic subtypes are recognized by the WHO, including well-differentiated, dedifferentiated, myxoid, round cell, pleomorphic, and mixed-type liposarcomas. Within the head and neck, well-differentiated liposarcomas (WDLs) account for 23% to 45% of all liposarcomas, myxoid subtype for 36%, pleomorphic subtype for 10%, and dedifferentiated subtype for 7%. The remaining subtypes are rare.[89–91]

Atypical lipomatous tumor (ALT) and WDL are now recognized as identical entities with similar morphologic and karyotypic characteristics and

similar nonmetastasizing but locally aggressive clinical behavior. These entities most often present as painlessly enlarging masses.[90] ALT/WDL is characterized histologically by the presence of mature adipocytes. Genetically, supernumerary ring and giant rod chromosomes are noted, as well as amplification of 12q14-15, the region encoding *MDM2*.[3] Although ALT/WDLs are not associated with significant rates of regional or distant spread, local recurrence remains a significant problem, occurring in up to 43% of cases.[90] When regional or distant metastatic spread does occur, it is associated with dedifferentiation.

Dedifferentiated liposarcoma is an undifferentiated sarcoma with various histologic features arising from an ALT/WDL. Dedifferentiated liposarcomas are associated with molecular alterations similar to those in ALT/WDL.[26] It has been reported that up to 10% of WDLs may undergo dedifferentiation, although no rate of dedifferentiation has been reported specifically for lesions arising solely within the head and neck.[3] Along with loss of differentiation comes a risk for distant metastatic spread, which occurs in 15% to 20% of cases.[3] Like ALT/WDL, dedifferentiated liposarcoma is associated with a high rate of local recurrence.

Myxoid liposarcoma and round cell liposarcoma are synonymous histologic subtypes of liposarcoma that are characterized histologically by round or oval mesenchymal cells and small signet ring lipoblasts within a myxoid stroma.[3] These tumors most frequently occur in the lower extremities, although myxoid liposarcoma is also the second most frequent histologic subtype of liposarcoma occurring in the head and neck, accounting for one-third of all head and neck liposarcomas.[89] Like ALT/WDL, myxoid liposarcomas tend to be well differentiated. Myxoid liposarcomas are characterized by the t(12;16)(q13;p11) translocation, which is present in more than 95% of cases.[92] Myxoid liposarcomas have a peak incidence in the fourth and fifth decades, which is a decade earlier than for other liposarcoma subtypes.[3] Distant metastatic spread from myxoid liposarcomas predominantly occurs at extrapulmonary sites, and there is a high predilection for metastasis to the spine.[93–95] A higher rate of distant metastatic spread and worse survival has been noted for tumors with round cell morphology.[90,93]

Pleomorphic liposarcoma is a high-grade liposarcoma characterized by the presence of pleomorphic lipoblasts. Clinically, pleomorphic sarcoma

differs from other liposarcoma histologic subtypes in that it has an aggressive clinical course characterized by a high propensity for distant metastatic spread and poor overall prognosis.[89,96] Pleomorphic liposarcomas account for ~10% of all head and neck liposarcomas. Distant metastatic spread occurs in up to 35% of cases, and the most common site of metastasis is the lungs.[96]

The preferred treatment for all histologic subtypes of liposarcoma is complete surgical resection with negative margins. However, given the proximity of critical neurovascular structures in the head and neck, this is frequently impossible. Evaluation by a radiation oncologist and head and neck surgeon experienced in the management of these tumors is preferred in determining the best local management approach for these complex tumors. In general, liposarcomas are considered to be chemotherapy-resistant tumors, though myxoid liposarcomas have been demonstrated to be sensitive to trabectedin, an agent that targets the nucleotide excision repair machinery.[97,98]

Disease-specific and overall survival has been reported to be better for head and neck liposarcomas than for liposarcomas at other anatomic locations. In large part, this difference appears to be driven by a higher proportion of patients presenting with well-differentiated histologic subtypes and early-stage disease.[89] Five-year disease-specific survival rates for patients with head and neck liposarcomas range from 73% to >90%, and 5-year overall survival rates range from 66% to 80%.[89,90] Histologic subtype and grade both appear to influence survival outcomes. Disease-specific and overall survival have been reported to be lower for pleomorphic liposarcoma than for other subtypes, and dedifferentiated liposarcoma has been demonstrated to have lower overall survival rates than ALT/WDL and myxoid histologic subtypes.[89]

Soft Tissue Sarcomas of Neurogenic Origin

Malignant peripheral nerve sheath tumor (MPNST), also known as neurogenic sarcoma, neurofibrosarcoma, and malignant schwannoma, is a rare sarcoma arising from peripheral nerves. MPNSTs occur in young patients: the median age at diagnosis is ~35 years.[99] Risk factors for the development of MPNST include a history of prior exposure to radiation and neurofibromatosis type I. The lifetime risk of developing an MPNST in a

patient with neurofibromatosis type I has been estimated to be 8% to 13%.[100] In neurofibromatosis type I, MPNSTs have been noted to frequently arise from preexisting neurofibromas.

Approximately 15% of MPNSTs occur in the head and neck,[100] most commonly in the neck (Tables 27.3 and 27.4). MPNSTs are high-grade, aggressive neoplasms with a predilection for local recurrence and a potential for distant metastatic spread. A small percentage of tumors demonstrate regions of rhabdomyoblastic differentiation and are termed "triton" tumors. Surgical resection is the treatment of choice. The benefits of adjuvant radiation therapy and chemotherapy are not well characterized.

Soft Tissue Sarcomas of Unclear Histologic Origin

Synovial Sarcoma

Synovial sarcoma is a spindle cell mesenchymal malignancy with varying degrees of epithelial differentiation that carries the specific chromosomal translocation t(X;18)(p11;q11). Misdiagnoses for this entity have included carcinosarcoma and spindle cell carcinoma, which highlights the variable epithelial differentiation of this tumor. Synovial sarcomas typically present as slowly growing lesions and may be present for many years before diagnosis. Histologically, they may demonstrate either a monophasic or biphasic growth pattern. Synovial sarcomas may present at any age, although the median age at presentation for head and neck synovial sarcomas is in the third decade of life. There appears to be a slight male preponderance in most series.[101] Within the head and neck, there appears to be a predilection for the paraspinous part of the neck[101,102] (Table 27.3).

Reported rates of local recurrence range from 32% to 62%, and reported rates of distant metastatic spread range from 33% to 48%; however, regional disease is rare, with reported rates ranging from 0% to 14%.[101–103] In the largest series published to date, overall and disease-specific survival rates at 5 years were 72%.[101] Tumor size larger than 5 cm, positive margins, and skull base location have all been associated with a worse prognosis.[101–103] As with other sarcomas, surgical resection with negative margins remains the gold standard. Patients treated with adjuvant radiation therapy have superior outcomes, and use of radiation therapy in addition to surgical excision should

be routinely considered.[101] The use of adjuvant chemotherapy remains controversial, but many authors favor neoadjuvant chemotherapy because of the high risk of distant metastases and because responses to neoadjuvant chemotherapy are generally good, which can facilitate local therapies.

Alveolar Soft Part Sarcoma

ASPS is a rare soft tissue sarcoma accounting for fewer than 1% of head and neck soft tissue sarcomas (Table 27.3). Histologically, ASPS is characterized by nests of large uniform epithelioid cells separated by delicate septations with sinusoidal vascular channels. Although ASPS is most frequently found in the extremities, ASPS occurring in children frequently involves the orbit and tongue.[3,104] A gender ratio inversion—a female preponderance in young patients transitioning to a male preponderance in patients presenting later in life—has been noted.[3,105] ASPS is a highly vascular tumor with high signal intensity on T1 and T2 magnetic resonance imaging and significant enhancement on contrast-enhanced computed tomography. Clinically, ASPS is characterized by an indolent local growth pattern and low rate of local relapse following surgical resection. Despite this, distant metastatic spread is found on presentation in up to 65% of patients.[105,106] Most commonly, this involves the lungs and bones. Patients with lung metastases are also at significant risk for developing intracranial metastatic disease.[105] Brain imaging should be performed in patients with symptoms suggestive of intracranial metastatic disease or in those who have known pulmonary metastases.[105]

For ASPS, as for other sarcomas, surgical resection is the mainstay of therapy when distant metastatic disease is not present. Limited responses to doxorubicin-based, ifosfamide-based, and cisplatin-based chemotherapy regimens have been noted.[105,106] Given the high rates of local control in most series, adjuvant irradiation of the primary tumor site may not be necessary for cases in which wide negative margins can be achieved. Localized ASPS is associated with favorable long-term outcomes: a 5-year disease-free survival rate of 71% and overall survival rates of 60% to 88% have been reported.[105–107] Although limited reports of patients with head and neck ASPS preclude meaningful comparisons between ASPS of the head and neck and ASPS of other anatomic sites, there has been the suggestion of a lower

rate of distant metastatic spread and improved prognosis for tumors at head and neck sites.[108]

CARTILAGINOUS AND BONY SARCOMAS

Osteosarcoma

Osteosarcoma is the most common primary bone malignancy. Osteosarcomas of the head and neck represent a minority of all osteosarcomas, accounting for only an estimated 10% of all cases.[109,110] The median age at diagnosis for head and neck osteosarcomas is in the fourth decade of life, which is later than the median age at diagnosis for osteosarcomas of other anatomic locations.[110] A number of risk factors for the development of osteosarcoma have been reported, including Paget disease; hereditary retinoblastoma; Werner, Rothmund-Thomson, and Li-Fraumeni syndromes; and a history of prior radiation exposure. Histologic subtypes of conventional osteosarcoma (osteoblastic, chondroblastic, and fibroblastic subtypes) account for the vast majority of reported cases.[110] In a review of 496 cases in the National Cancer Data Base, osteoblastic osteosarcoma accounted for 77% of all cases and chondroblastic osteosarcoma for 16%.[110] The mandible and maxilla are overwhelmingly the most frequently involved sites, accounting for 39% to 56% and 32% to 45% of cases, respectively.[109–112] A classic radiographic appearance is of a mandibular lesion with a “sunburst” pattern (**Fig. 27.2**). From 50% to 63% of all head and neck osteosarcomas are classified as high-grade tumors.[109–112]

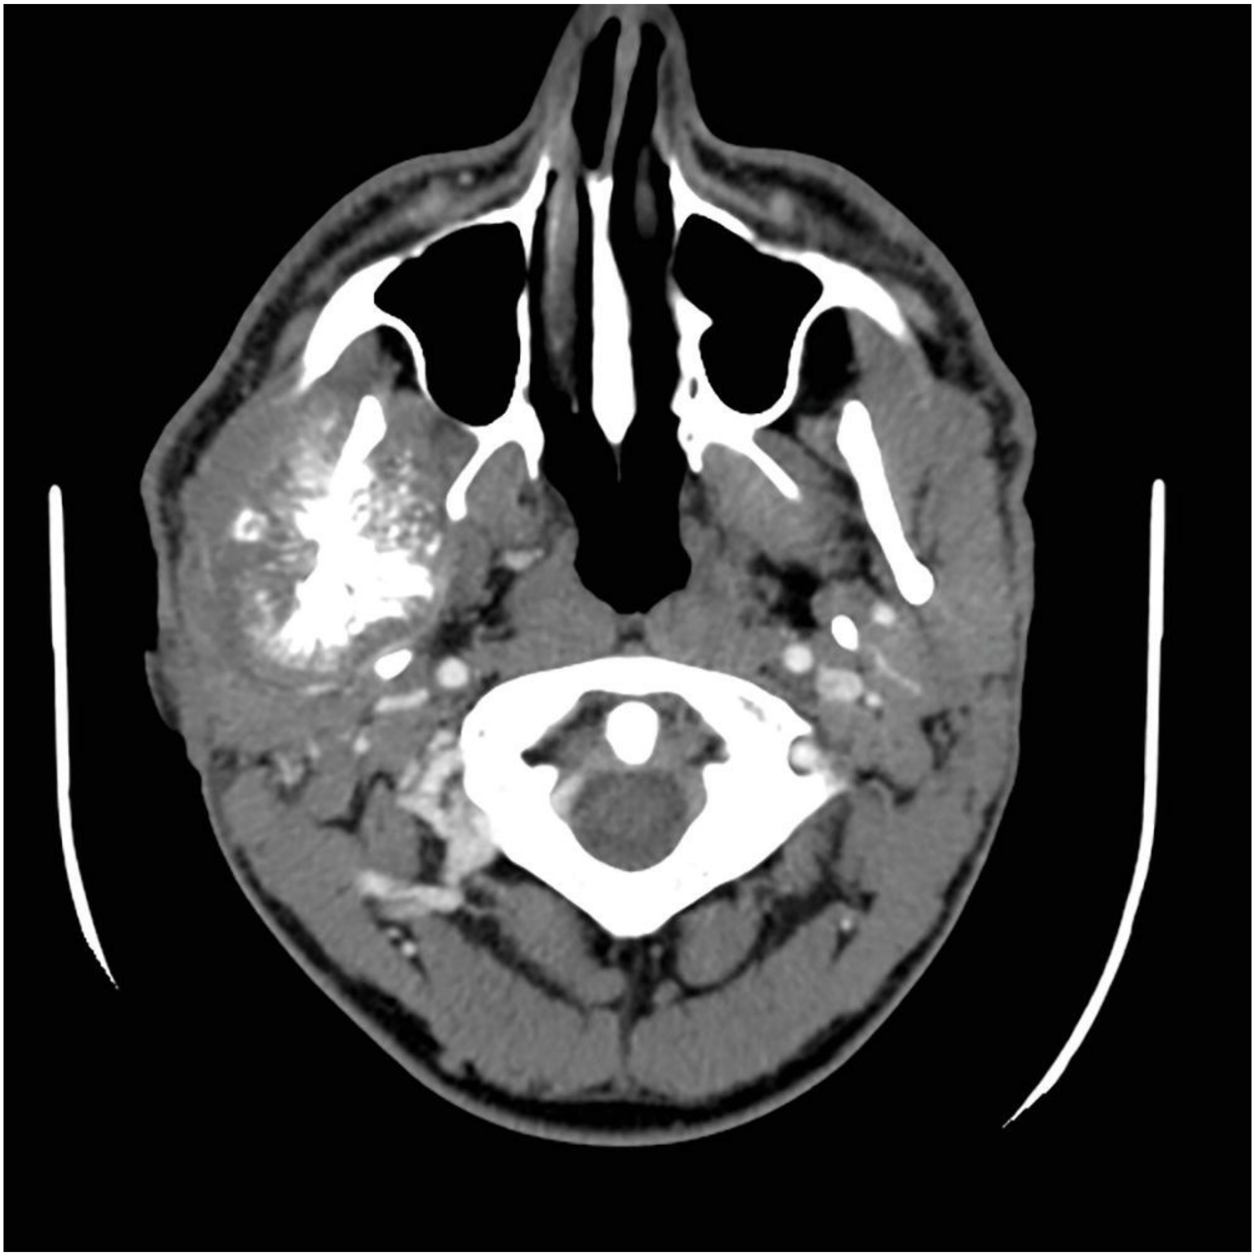

Figure 27.2. Osteosarcoma of the mandible with characteristic "sunburst" radiographic pattern.

The primary treatment for osteosarcoma is surgical resection; use of adjuvant chemotherapy and radiation therapy is dictated in large part by tumor grade, preoperative resectability, soft tissue extension, and postoperative or anticipated margin status in addition to the patient's ability to tolerate therapy. Surgical margin status and tumor grade are consistently reported as the most important prognostic factors in osteosarcoma. Patients with negative margins have reported 5-year survival estimates of 75%,

compared to 32% for those with residual disease following surgery.[110] Similar 5-year survival differences have been noted between patients with high-grade tumors (42%) and low-grade tumors (74%). Adjuvant radiation therapy has been demonstrated to improve local control and survival in patients with positive margins.[109] The role of adjuvant chemotherapy remains less well defined for head and neck osteosarcomas than for osteosarcomas at other anatomic locations. Head and neck osteosarcomas have been demonstrated to have lower rates of distant metastatic spread (4% to 29%) and high rates of local recurrence (20% to 63%).[109,111–113] Current evidence suggests that incorporation of adjuvant (often neoadjuvant) chemotherapy is warranted in high-risk cases.[110,113] Across all stages, histologic subtypes, and anatomic sites, 5-year disease-free and disease-specific survival estimates range from 49% to 70%, and 5-year disease-specific survival estimates range from 60% to 75%.[109,110,112,113]

Chondrosarcoma

Chondrosarcomas are thought to arise from cartilaginous cells that characteristically produce a chondroid matrix. Several histologic variants are recognized, including classic chondrosarcoma and periosteal, dedifferentiated, mesenchymal, and clear-cell subtypes. Both classic and periosteal chondrosarcomas are malignancies with a pure hyaline cartilage differentiation; the periosteal variant occurs in a juxtacortical location. The dedifferentiated, mesenchymal, and clear-cell variants are rarely reported in the head and neck.

Overall, chondrosarcomas of the head and neck are rare and account for ~5% of all chondrosarcomas.[114] Within the head and neck, the most common site of involvement is the bones of the head and neck, including the skull base and sinonasal tract, where 60% of cases arise, and the larynx, where 23% of cases arise; the remainder of cases occur in soft tissues of the head and neck and other miscellaneous sites.[115] The vast majority of chondrosarcomas of the head and neck (88%) are well or moderately differentiated, and regional disease and distant disease are rare (occurring in 6% and 7% of cases, respectively).[115]

Laryngeal chondrosarcomas are incredibly rare, accounting for only 0.2% of all laryngeal malignancies.[116] Laryngeal chondrosarcomas demonstrate a

predilection for whites, and the male-to-female ratio has been reported to be 3:1. The median age at diagnosis is 62 years.[116] In a series of 111 cases from the Air Forces Institute of Pathology, the vast majority of laryngeal chondrosarcomas were noted to occur in the cricoid (77% of cases) and thyroid cartilages (19%).[117] High-grade laryngeal chondrosarcomas are rare; 95% of chondrosarcomas are of low or moderate grade.[117] In two large series, regional lymph node involvement was not noted, and distant metastatic disease occurred in only 2% of cases.[116,117] Laryngeal chondrosarcomas typically present with local symptoms of dysphagia, voice changes, and dyspnea.[117] They have a pathognomonic appearance on computed tomography of calcified mass with a stippled appearance within a distorted and enlarged cartilage, most typically of the posterior table of the cricoid (**Fig. 27.3**). The recommended treatment is surgical excision. Given the low rates of regional and distant metastatic spread and the favorable grade of the majority of tumors, many authors advocate a laryngeal conservation approach to the initial treatment of laryngeal chondrosarcomas,[118] although this remains an area of controversy. Variable sensitivity to radiation therapy has been reported in the literature, but adjuvant radiation therapy tends to be reserved for high-risk lesions, such as high-grade tumors, tumors with positive margins, and/or tumors of the skull base. Local recurrence occurs in up to 18% of patients.[116,117] Despite this, long-term disease-specific survival remains good, highlighting the ability to successfully treat recurrences.

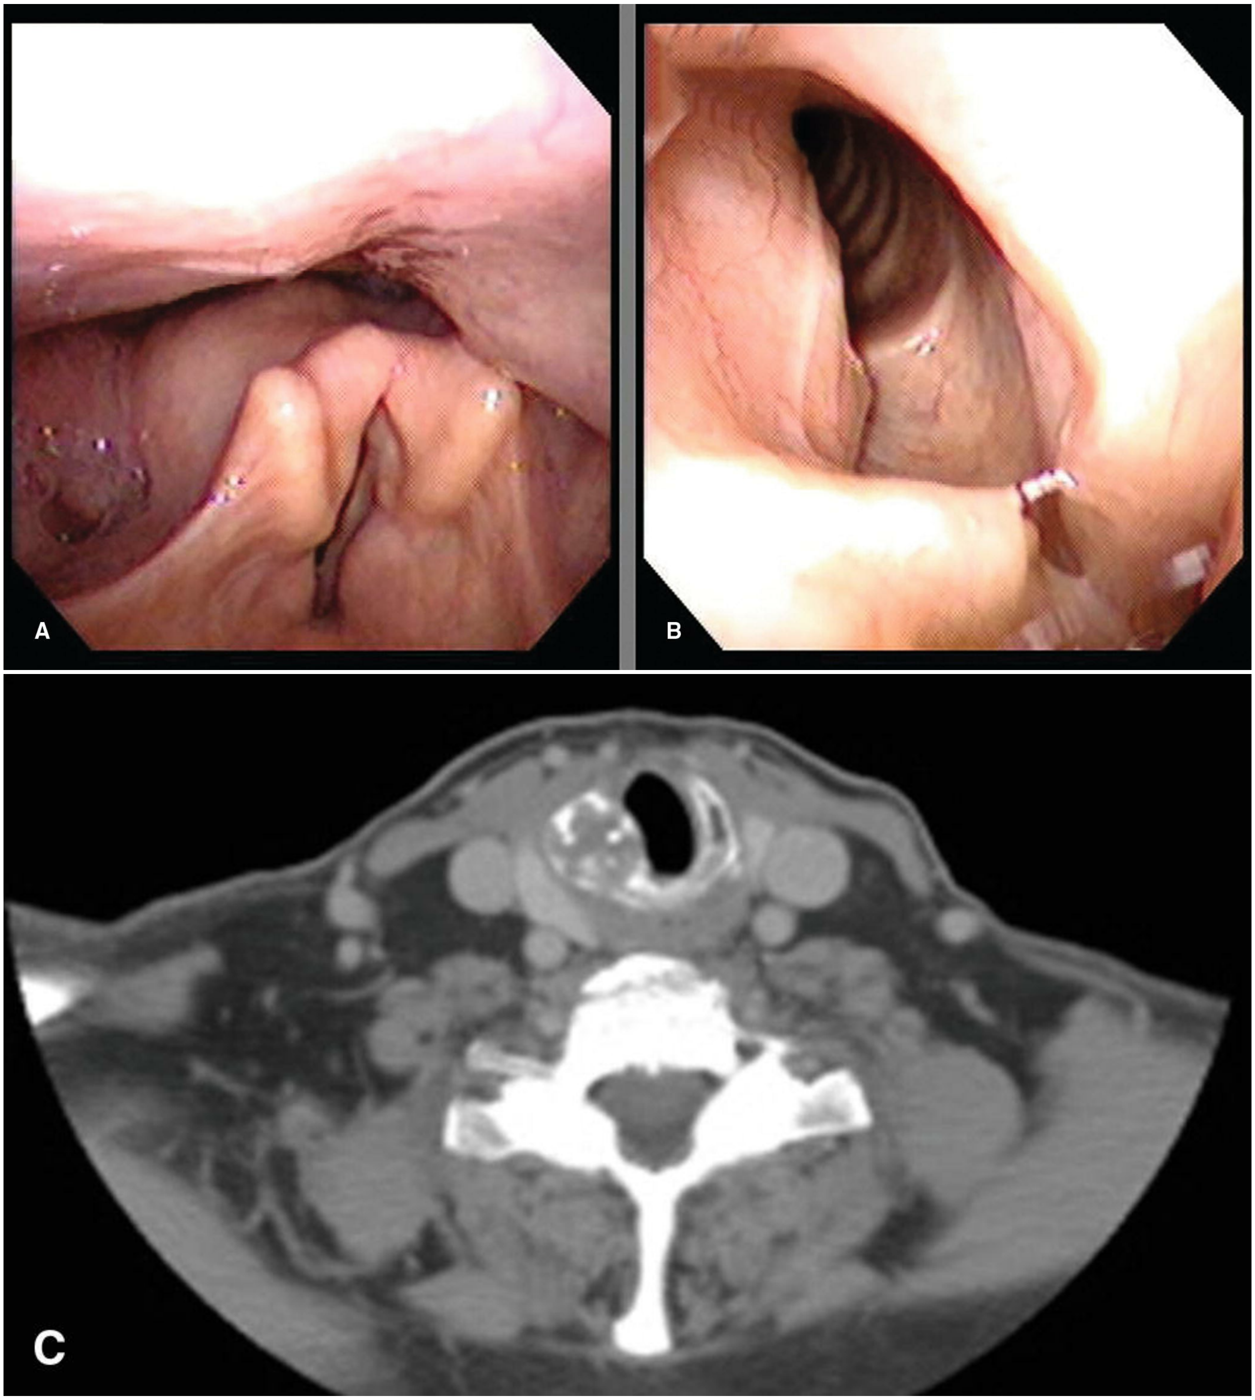

Figure 27.3. Chondrosarcoma of the cricoid cartilage **(A)** Submucosal mass arising from the posterolateral cricoid, **(B)** Intraluminal extent of chondrosarcoma visualized inferior to the right vocal cord, **(C)** computed tomography scan demonstrating the classic appearance of an expansile radiolucent mass with punctate calcification.

Chondrosarcomas of the skull base occur most commonly in the

petroclival synchondrosis, followed by the clivus; less common locations are the sphenoid and ethmoid sinuses.[119] As with laryngeal chondrosarcomas, high-grade lesions are rare, and the conventional chondrosarcomas histologic subtype predominates.[119] A unique diagnostic challenge for skull base chondrosarcomas is differentiation from chordomas, particularly for tumors with myxoid stromal.[119] Given the proximity to critical neurovascular structures, en bloc resection with negative margins is rarely achievable. Although radiation therapy for chondrosarcomas in other anatomic locations is controversial,[117] use of primary radiation therapy or adjuvant radiation therapy following partial resection is well accepted for skull base chondosarcomas.[118,119] In a systematic review of 560 patients with chondrosarcomas of the skull base, patients treated with surgery alone had a 5-year recurrence rate of 44%, compared to 19% for patients treated with definitive radiation therapy and 9% for patients treated with both surgery and radiation,[120] suggesting that surgery may have a role even when complete surgical resection is not possible. Although the best type of radiation therapy remains controversial, most authors agree that a highly conformal technique and high radiation dose to overcome intrinsic tumor radioresistance are critical components of radiation therapy for skull base chondrosarcomas.[121]

In general, treatment for head and neck chondrosarcomas consists of surgical excision with negative margins if possible. For high-grade lesions, tumors with positive margins, and tumors at the skull base, adjuvant radiation therapy is warranted. Local recurrence remains a concern even in low-grade lesions. Population-based estimates suggest 5- and 10-year disease-specific survival rates to be 87% to 89% and 71% to 85%, respectively.[115,116]

Ewing Sarcoma/Primitive Neuroectodermal Tumor

Ewing sarcoma and primitive neuroectodermal tumor (PNET) are small round blue cell tumors that display varying degree of neuroectodermal origin. Although these tumors were originally considered separate entities because of limited histologic evidence of neuroectodermal origin in classic Ewing sarcoma, progress in molecular classification has demonstrated that Ewing sarcoma/PNET tumor have similar cytogenic findings and should be considered in the same family of malignancies. A t(11;22)(q24;q12) translocation is present in 90% of cases, and a similar translocation, t(21;22)

(q22;q12), accounts for the remaining cases.[122] In both subsets, the translocation results in fusion of the *EWSR1* gene to an ETS gene, with the resultant chimeric protein acting as a transcription factor for ETS target genes.

Ewing sarcoma PNET tumor overwhelmingly occurs in childhood; the median age at presentation is in the second decade of life. Ewing sarcoma/PNET tumor is the second most common bony malignancy in children, after osteosarcoma, and typically involves the long bones, pelvis, and ribs. It is rare in the head and neck; head and neck tumors account for only 15% to 4% of all cases.[123] The mandible, skull, and maxilla are frequent sites of involvement for Ewing sarcoma/PNET of the head and neck, although this disease can also occur at soft tissue sites.[124–126] Regional node involvement is rare in Ewing sarcoma/PNET, but distant metastatic spread is present in 13% to 19% of patients at presentation, and up to an additional 45% of patients develop distant metastatic spread later.[124,127]

Similar to RMS, Ewing sarcoma/PNET is sensitive to chemotherapy and radiation therapy. Treatment parallels treatment for RMS, in which use of systemic neoadjuvant multiagent chemotherapy is standard. When wide local resection with negative margins is possible, this is preferred if the morbidity of surgery is not anticipated to be excessive. When negative-margin surgery is not possible or surgery is expected to be mutilating, which is often the case for Ewing sarcoma/PNET of the head and neck, radiation therapy should be used. Local recurrence occurs in up to 29% of cases.[124] Ten-year overall and disease-free survival estimates range from 63% to 66% and 52% to 56%,[126,127] respectively.

SUMMARY

Sarcomas arising within the head and neck can be challenging to treat and require an experienced multidisciplinary team to achieve the best outcomes. The goal of achieving local control must be balanced with the need to address the risk of distant metastatic disease, which is a major concern with many sarcoma histologic subtypes. Frequently, patients require multidisciplinary treatment consisting of a combination of systemic and local therapies. For most sarcomas, complete surgical resection is the cornerstone of local therapy. Given the frequent proximity of head and neck sarcomas to vital

structures in the region, complete resection can be challenging. For most sarcomas arising in the head and neck region, preoperative or postoperative radiation therapy is generally indicated to optimize local control, and preoperative irradiation has advantages over postoperative irradiation in many situations. For histologic subtypes with high rates of distant metastatic spread, adjuvant (typically neoadjuvant) systemic chemotherapy is often incorporated into the treatment regimen. As our knowledge of the molecular underpinnings of sarcoma continues to evolve at a rapid pace and as new targeted therapies are developed on the basis of these new insights, it is hoped that outcomes of treatment for sarcoma will continue to improve.

Acknowledgments

The authors wish to thank Stephanie Deming, Senior Scientific Editor, Department of Scientific Publications, The University of Texas MD Anderson Cancer Center, for manuscript editing; Dr. Dianna Roberts for assistance with the institutional tumor registry; and Ms Shauna P. Puente for manuscript preparation.

28 Reconstruction of Major Defects in the Head and Neck Following Cancer Surgery

Jerry Castro Cathy Lazarus Daniel Buchbinder Adam Jacobson Devin Okay Joseph Dayan Ilya Likhterov, Mark L. Urken

Contemporary surgical management of cancer of the head and neck is the product of the continued application of new oncologic and reconstructive techniques. Patient survival and functional rehabilitation have improved since the mid-1940s, before which orthovoltage radiation was the mainstay of treatment of cancer of the head and neck. With the introduction of modern techniques of anesthesia, antibiotics, blood banking, and new techniques of radical surgery, wide resection of primary cancers of the upper aerodigestive tract and incontinuity neck dissection of regional metastases has resulted in improved cure rates. Thereafter, advances in radiation therapy led to the introduction of “combined therapy.” As an accepted trade-off for improved survival rates, this aggressive approach often resulted in prolonged hospitalization, major functional and cosmetic deficits, and, in many cases, social isolation, as well as the inability to maintain gainful employment.

The development of reconstructive techniques for head and neck surgery did not progress at the same pace as combined therapy for eradication of cancer of the head and neck. In fact, most authors either failed to acknowledge the issue of reconstruction or deemed it unnecessary. Hayes Martin,[1] the father of modern head and neck surgery, wrote:

> “Excessive or too frequent resort[ing] to more complicated and technical procedures,

> such as skin graft for pharyngeal defects, skin graft of the tongue or buccal surface, … bone grafts in mandibular defects, and particularly nerve grafts for [seventh cranial] nerve defects, is not characteristic of the mature or resourceful surgeon."

Before 1963, most oral and pharyngeal defects were closed primarily, reconstructed with random-pattern skin flaps (such as the nape of neck flap), or reconstructed with tubed, pedicled flaps of skin from the trunk. These flaps rarely matched the tissue requirements of the defect. Furthermore, such repairs were unpredictable and frequently resulted in flap necrosis, salivary fistula, bone or carotid artery exposure, or other complications that led to prolonged hospitalization or the patient's death.

The previously limited ability of surgeons to resurface mucosal defects of the head and neck improved with the description of the forehead flap by McGregor[2] in 1963 and the deltopectoral flap by Bakamjian[3] in 1965. These well-vascularized, axial-pattern skin flaps permitted more reliable closure of oral and pharyngeal defects at the time of ablative surgery. Although these reconstructive techniques permitted extensive resection to be performed more safely, their limitations soon became apparent. The limited arc of rotation frequently necessitated multistaged, delayed procedures and prolonged hospitalization. The need to perform skin grafts for all but the smallest donor defects contributed to suboptimal aesthetic results. Furthermore, the limitations of the transferred tissue in restoration of function frequently led to permanent impairment of deglutition, articulation, and mastication. Despite their drawbacks, the forehead and deltopectoral flaps were the mainstays of soft tissue reconstruction of head and neck defects for nearly two decades.

The rehabilitation of patients with cancer of the head and neck has been revolutionized since the mid-1970s by the development of advanced reconstructive techniques. Pedicled myocutaneous flaps and free tissue transfers have allowed reliable and safe one-stage primary reconstruction of defects of the upper aerodigestive tract. In the late 1970s and early 1980s, the pedicled pectoralis major myocutaneous flap was popularized and became the predominant method used in reconstruction of the head and neck. Other regional flaps, such as the trapezius and latissimus dorsi flaps, were described for reconstruction of defects of the head and neck region. As clinical experience accumulated, the limitations of pedicled flaps for some reconstructive problems became apparent. These include the limited lengths of the pedicle with restriction of the arcs of rotation, excessive bulk, and

donor site morbidities. In addition, the inability of surgeons to reliably transfer vascularized bone for mandibular reconstruction stimulated the search for alternative techniques.

A new approach to transferring tissue became available in 1973 with the advent of microvascular surgery. Subsequently, free tissue transfer rapidly evolved from a reconstructive “last resort” into the preferred method of addressing a variety of complex defects of the head and neck. As new donor sites were discovered and microsurgical techniques were refined, the advantages of free tissue transfer for certain reconstructive problems became apparent. These advantages include the following: (1) superior vascularity of the tissues, resulting in improved tissue survival and wound healing in unfavorable recipient beds; (2) freedom from a limited arc of rotation and length of the vascular pedicle; (3) greater availability, variety, and versatility of donor tissue; and (4) presence of donor sites that are less morbid and conspicuous.

Surgeons are now able to perform more extensive resections with the comfort and confidence of knowing that the available reconstructive procedures can successfully repair the defect in the primary setting and provide the cancer patient with the best opportunity for a rapid functional and cosmetic rehabilitation, as well as prompt initiation of postoperative adjuvant treatments. A good example of the interplay between reconstructive and ablative surgery is seen in cases affecting the region of the cranial base, where vital structures such as the brain and carotid artery can now be reliably covered and protected with well-vascularized tissue. The ability to separate the cranial cavity from the sinonasal tract has been critical to the advancement of the emerging discipline of cranial base surgery. Despite longer and more technically demanding procedures, the success rate of microvascular free tissue transfers to the head and neck region has continued to improve, approaching 98% and 99%.[4,5] Consequently, free tissue transfer has become an essential part of the comprehensive management of many surgical defects in the head and neck.

This chapter presents our approach to the various problems of reconstruction of defects in the head and neck. Available techniques, indications for clinical application, and functional and aesthetic issues are discussed. Although skin grafts and local flaps are effective for the resurfacing of small mucosal and cutaneous defects, reconstruction of larger

defects usually requires transfer of tissue from regional or distant sites. This chapter addresses the latter techniques and also describes the contemporary approach to achieve functional dental restoration. Finally, an approach to the functional assessment of the head and neck cancer patient will be presented in order to provide a framework for assessing the outcomes of surgery and adjuvant therapy and its relationship to the patient's posttreatment quality of life.

Successful reconstruction requires accurate preoperative assessment and formulation of an individualized treatment plan. Careful consideration of a variety of factors is essential, the most important of these factors is the nature of the defect of the head and neck. Other important considerations include the following: (1) specific histologic features of the tumor, clinical stage, and associated prognosis; (2) age, sex, body habitus, and associated health problems of the patient; (3) available flap donor sites; (4) available recipient vessels; (5) patient compliance with perioperative care, patient expectations, and the psychosocial needs of the patient; and (6) clinical experience and skills of the surgeon. Consequently, a rigid "cookbook," algorithm-based approach for reconstruction of the head and neck is ill advised. Superior results are seen when the reconstructive team has a wide range of options, which permits the reconstruction to be customized to the individual patient, based on careful consideration of all pertinent tumor- and patient-related factors. Hence, just as the overarching approach to contemporary cancer management has stressed individualized treatment strategies, so too has the approach to reconstruction. In addition, it has been our experience that a multidisciplinary approach to the patient's reconstructive surgery and rehabilitation provides an opportunity for optimal outcomes. This approach begins in the preoperative planning stage and parallels the multidisciplinary approach to the overall cancer management.

GOALS OF RECONSTRUCTION

The primary goal of treatment of cancer of the head and neck is to effect a cure or significant palliation. In addition, every effort should be made to restore the patient to the premorbid level of functioning and quality of life. Advances in radiation and chemotherapy have altered the approach to cancers arising in many subsites of the upper aerodigestive tract, where surgery has been relegated to the salvage setting to eradicate persistent or recurrent

cancers. When surgery is used, especially in the oral cavity, it often involves surgical ablation of the primary site and removal of regional nodal metastases. Except in rare cases, some form of reconstruction is necessary. No reconstructive procedure, however elaborately or creatively conceived, should preempt adequate tumor resection nor should such a plan be rigidly adhered to if events during the ablation dictate that an alternative approach will result in a preferred oncologic outcome.

For the reasons outlined above, contemporary reconstruction of the head and neck often takes place in patients who have undergone prior radiation therapy. This is particularly true in the management of complications of radiation therapy such as osteoradionecrosis (ORN) and pharyngoesophageal stenosis.[6–8] The reconstructive surgeon must adopt a unique approach in patients with prior radiation therapy to the head and neck region, as there are significant wound healing challenges that can pose a threat to the safety of the surgical undertaking as well as impacting the ultimate functional and aesthetic outcomes.

Successful reconstruction of defects in the head and neck requires that the surgeon define the nature of the defect and create an appropriate strategy to replace the resected tissues with an appropriate substitute.[9] Each subsite of the head and neck presents unique challenges and requires different reconstructive approaches. The major subsites include the cranial base, radical parotidectomy, palatomaxillary, oromandibular, oropharyngeal, and laryngopharyngeal defects. Cutaneous defects of the head and neck may result from management of skin cancer or direct extension to the skin from cancers arising in underlying tissues. Optimal results usually require reconstruction with tissues that simulate the appearance and function of the resected tissue. The tissues required to achieve these goals may include the following: (1) epithelium, to resurface a mucosal or skin defect; (2) muscle, to restore motion or provide coverage of irradiated tissues; and (3) bone, to provide skeletal support. Less frequently, tissues such as fascia and adipose tissue may be required for static suspension or for restoration of contour. Complex defects of the head and neck, such as those resulting from oromandibular and cranial base resection, may require reconstruction with a composite flap. It is in such cases that microvascular free tissue transfer has been most widely used.

The first priority in reconstruction of defects in the head and neck should

be safety. It is essential to prevent life-threatening complications, such as carotid blowout, or cerebrospinal fluid (CSF) leak and subsequent meningitis, after resection of the cranial base. The next priority is to return the upper aerodigestive tract to a functional state. Restoration of oral competence, mastication, deglutition, and articulation are the major objectives of reconstruction of the oral cavity following ablative surgery. Maintaining mobility of the tongue, restoring occlusal relationships, preventing trismus, and setting the stage for functional dental rehabilitation are the specific strategies to achieve those goals. Advances in dental prosthetics and the ability of surgeons to reliably transfer vascularized bone have been essential in this regard.

Surgeons should be sensitive to the impact of physical appearance on the patient’s sense of well-being and to the patient’s ability to reintegrate into the society of their family, friends, and work environment. Reconstruction with local tissue is preferred for cutaneous defects because skin adjacent to the defect provides the optimal match in color and texture. If local tissue is unavailable, the skin quality of potential flaps to be transferred from regional or distant donor sites should be considered. Similarly, when maintenance of bulk in the flap is important aesthetically, the progressive atrophy of denervated muscle should be anticipated. The use of well-vascularized subcutaneous adipose tissue may provide a more effective long-term result. Aesthetic units should be managed as a total entity when possible, especially in resurfacing of defects of the cheek, nose, lips, forehead, and less critically, the neck. To maximize the aesthetic result in the patient with cancer of the head and neck, adjunctive procedures, such as scar revision and flap recontouring, can be performed subsequent to the initial reconstructive effort.

The patient’s age, comorbid conditions, disease status, and motivation may relegate the aesthetic outcome to a secondary concern, whereas functional outcomes are almost always of paramount importance. Defects of the oral cavity and oropharynx, especially those involving the tongue and palate, frequently require more elaborate techniques for the restoration of effective articulation and deglutition. Maintenance of a patent pharyngoesophageal segment and restoration of velopharyngeal competence are vital to achieving optimal functional outcomes. Understanding the function of the ablated tissues and the underlying physiology of the region helps to guide the surgeon in selecting the appropriate strategy for each

patient.

PREOPERATIVE PLANNING AND TIMING OF RECONSTRUCTION

Comprehensive management of patients with cancer of the head and neck begins with thorough preoperative planning. For select defects, multidisciplinary planning and implementation of the treatment approach can help to ensure that the best possible outcome is achieved. Patients with cancer typically present with numerous comorbidities and risk factors, including cardiac, renal, pulmonary, cerebrovascular, and hepatic disease. Malnutrition and general debility, secondary to the disease process or to previous surgery, radiation, or chemotherapy, are also common. A thorough initial history, review of systems, and physical examination should provide an evaluation of these risk factors that can be augmented with additional diagnostic studies. An assessment of cardiopulmonary risk factors, especially coronary artery disease, is essential in determining whether a patient is a candidate for a more elaborate reconstructive approach that includes microvascular surgery. Postoperative cardiopulmonary instability can be a threat to the patient and to the reconstructive effort. Mapping of the extent of the primary cancer by a combination of physical examination and radiographic assessment allows the reconstructive surgeon to estimate the probable extent of resection and consideration of the most likely reconstructive approach. In select cases, examination under anesthesia can provide extremely valuable information as to the expected extent of the resection.

The anticipated defect should be classified according to its osseous, soft tissue, and neurologic components. Consideration of the functional region encompassed by the deficit is of far greater importance than a description of the total area or volume of tissue involved. The possible need for coverage of the carotid artery or dura is also discussed. If free tissue transfer is contemplated, potential donor sites and recipient vessels should be evaluated to assess their suitability. Based on all available information, a reconstructive plan is formulated. A second, and even a third, “fallback” option should be considered in the event that the initial plan proves to be unfeasible or fails during the postoperative period.

Reconstruction of the maxilla and mandible may be optimized through

the use of computer-generated medical models. In select clinical situations, the creation of a medical model can greatly enhance the efficiency and the accuracy of the surgical plan. The most common instances where we have found medical models to be useful are for patients with existing segmental defects of the mandible and maxilla and for patients with tumors that significantly distort the normal bone contour, making fabrication of a rigid fixation plate difficult. The ability of computerized planning to accurately create a surgical model represents a major advance and one that should be anticipated in the preoperative period. The importance of this approach is due to the fact that the computer planning software can reestablish the normal "predisease" shape of the jaw that allows for a more precise plate contouring and a more accurate replication of the patient's normal facial contour (**Fig. 28.1**).

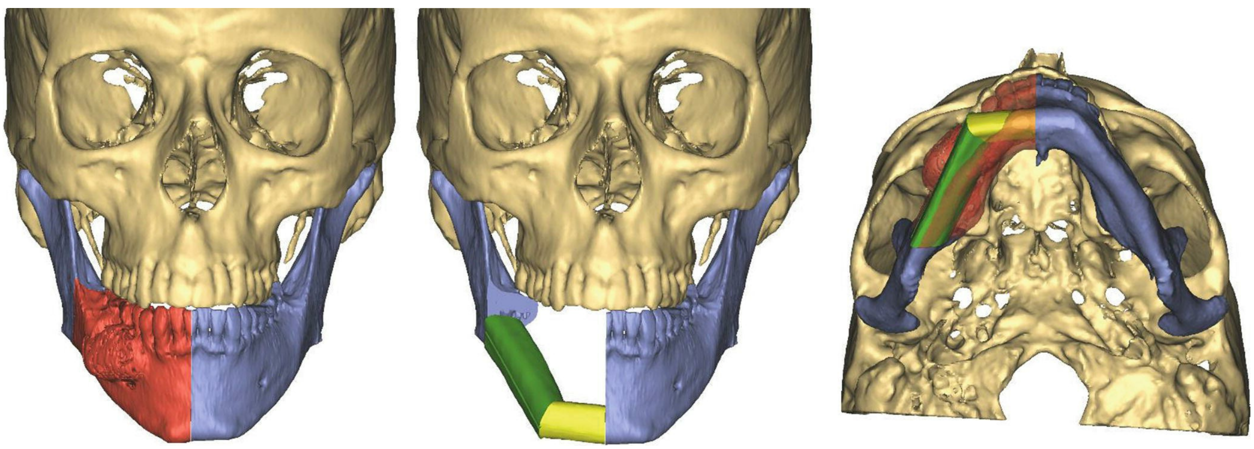

Figure 28.1. Computer-generated plan for reconstruction of a segmental right mandible defect with buccal cortex distortion.

Most reconstructive procedures in the head and neck are optimally performed in one stage at the time of ablation. Primary reconstruction, although lengthening the surgical procedure, provides an opportunity to introduce the necessary elements of the reconstruction and to ensure the highest likelihood of a safe and successful postoperative recovery. Optimal conditions for reconstruction are present at the completion of tumor resection: (1) the defect is widely exposed; (2) bone and soft tissue requirements are readily and accurately assessed; and (3) potential recipient vessels for microvascular anastomoses, if indicated, are already dissected. Furthermore, surgical margins can be cleared by frozen section pathologic analysis, which

permits definitive wound repair. This approach avoids the problems associated with delayed reconstruction, including fibrosis of remaining muscles and contraction of soft tissues within the wound bed. Consequently, primary reconstruction has been shown to provide superior functional and aesthetic results when compared with delayed reconstruction. In addition, the attitude of patients undergoing primary reconstruction is greatly improved when maximal form and function are promptly restored.

Certain reconstructive procedures of the head and neck, however, should be performed in a staged or delayed manner. Multistaged repairs of complex nasal and auricular defects are prime examples. In these instances, the surgeon should plan to perform the fewest number of procedures necessary to obtain optimal results in the shortest possible time. In cases in which tumor-free margins are in question, reconstruction should be delayed until permanent pathologic confirmation is made. Frequently, the functional and cosmetic results of an elaborate reconstructive effort can be maximized by subsequent revisions. These secondary procedures may include scar revision, flap debulking, and placement of endosteal dental implants for dental rehabilitation.

RECONSTRUCTIVE OPTIONS

In general, the least complex method that provides a safe reconstruction while restoring form and function should be selected. The reconstructive surgeon should first consider primary closure or the use of a skin graft. Larger defects usually require alternative methods, such as local, regional, or distant (free) flaps. This logical progression from simple to more complex techniques provides a systematic approach for evaluating whether a given technique satisfies the functional and cosmetic requirements of each defect in the head and neck.

Local Flaps

Local flaps are effective reconstructive alternatives for certain small- to medium-sized defects of the face, neck, and upper aerodigestive tract. When used judiciously, local tissue transfer is aesthetically and functionally superior to the use of more elaborate regional or distant free flaps. The use of tissue adjacent to the defect often provides the best match of skin in terms of

its color and texture.

The size and location of the defect and the properties of the available local tissue help to determine whether a local flap is an appropriate reconstructive method. The vascular supply of each local flap is unique and dictates the amount of tissue that can be reliably transferred. Defects of the nose and lips are optimally reconstructed with local muscle-skin flaps, such as forehead, nasolabial, Abbé-Estlander, and Karapandzic flaps. Small intraoral defects can be closed with palatal and buccal mucosal flaps.[10] A more detailed description of the various local flaps is beyond the scope of this chapter.

Regional Flaps

Large defects in the head and neck can be reconstructed with tissues from adjacent regions. Pedicled regional flaps have been used extensively to provide closure of large defects in the neck, face, scalp, oral cavity, and pharynx. They can be classified as fasciocutaneous, such as the deltopectoral flap and the submental island flap, or myocutaneous, such as the pectoralis major, trapezius, and latissimus dorsi flaps. In additional, the temporoparietal fascial flap can be raised as purely a fascial flap or in conjunction with the overlying skin. The temporalis muscle flap is a valuable source of vascularized muscle in the reconstruction of the infratemporal fossa, skull base, and orbitozygomatic defects. Most regional flap procedures can be performed in one stage. However, a “delay” may be instituted to more reliably increase the overall size of the flap. For most cutaneous defects of the neck, the thin, supple quality of the deltopectoral flap is preferred. However, for coverage of the carotid artery or reconstruction of a large oropharyngeal defect, the additional bulk and reliable vascular supply of a myocutaneous flap are advantageous. The arc of rotation is another intrinsic property that must be considered. Only the pedicled latissimus dorsi and lower island trapezius flaps have an extensive arc of rotation that can reliably reach large defects of the scalp. The selection of a specific regional flap depends on the location and size of the defect and the intrinsic properties of the regional flap.

Deltopectoral Flap

The deltopectoral flap is a medially based axial-pattern fasciocutaneous flap of the upper chest that is based on the second and third intercostal,

parasternal, perforating branches of the internal mammary artery. The distolateral extent of the flap is determined by the location of the defect relative to the rotational length of the flap; however, distal flap necrosis occurs frequently when the flap is extended onto the shoulder beyond the deltopectoral groove. If greater flap length is desirable, a delay procedure is often necessary to incorporate a random portion of skin over the deltoid muscle.[11]

The deltopectoral flap is primarily used for resurfacing cutaneous defects of the neck. The introduction of other regional or distant tissue transfer has limited the role of the deltopectoral flap for facial, oral, and pharyngeal reconstruction. Nonetheless, it remains a useful tool for selected reconstructive needs. Although traditionally harvested as a peninsula of skin, it can also be modified as an "island configuration" and tunneled into the neck beneath the skin of the upper chest. This produces a more pleasing contour to the neck and a more favorable reconstructive outcome.

The Submental Island Flap

The submental island flap provides tissue that satisfies the color and texture requirements of the facial skin. It is a reliable and useful flap in reconstruction of the cutaneous defects in the lower and middle thirds of the face. A flap up to 6 to 8 cm in vertical height can be harvested and primary closure achieved, especially in older individuals with older patients with increased skin laxity (**Fig. 28.2**). The flap is based on the submental branch of the facial artery, which must be carefully preserved. Potential for injury to this vessel during level IB dissection may limit the use of the flap when supraomohyoid neck dissection is indicated for oncologic reasons. Proximal ligation of the facial artery and vein with retrograde flow designed can enhance the arc of rotation of the flap.

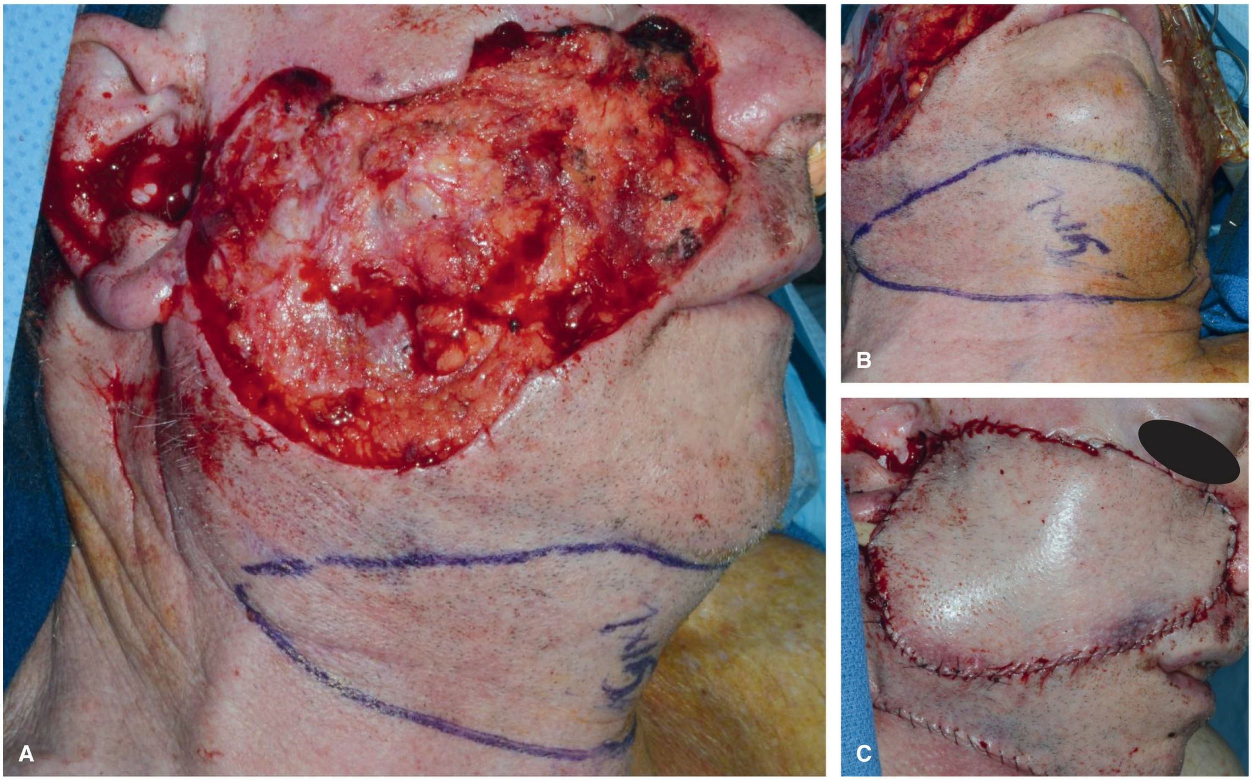

Figure 28.2. A and B: Submental flap is marked for the reconstruction of a large lower face defect. The horizontal dimension extends from angle to angle of the mandible. Vertical dimension is limited by the “pinch test.” **C:** Tension-free closure is achieved.

Myocutaneous Flaps

These axially based flaps have segmental vascular pedicles that enter the deep surface of the muscle, course longitudinally, and send perforating branches through the muscle and subcutaneous tissue to the overlying skin. A large amount of well-vascularized tissue can be transferred in a single stage to reconstruct almost any defect in the head and neck, from the pharyngoesophagus to the lateral skull base.

Despite their widespread use, regional myocutaneous flaps have certain disadvantages. In defects that require thin, pliable skin, the excess bulk of a myocutaneous flap may lead to a less than optimal result. Regional myocutaneous flaps have limited length, skin paddle size, and arc of rotation. The sacrifice of a regional muscle to provide a vascular supply to the overlying skin may result in some degree of functional disability as well as in moderate distortion of the anterior chest or back.

Pectoralis Major Flap.

The pectoralis major originates from the medial one-third of the clavicle (cephalic portion), the sternum and cartilages of the upper six ribs (central or sternocostal portion), and the external oblique aponeurosis (caudal portion). The primary vascular supply is from the pectoral branch of the thoracoacromial artery, with a lesser contribution from the lateral thoracic artery.

The pectoral branch of the thoracoacromial artery is visualized on the undersurface of the pectoralis major muscle and enters the muscle medial to the tendon of the pectoralis minor, whereas the lateral thoracic artery courses lateral to the tendon. In most instances, the pectoralis major muscle and the overlying skin are passed over the clavicle into the neck. In rare circumstances, a tunnel deep to the clavicle, created by removing and repositioning a small portion of the clavicular bone may be warranted.[12]

When first introduced, the pectoralis major flap was used primarily for reconstruction of mucosal defects of the oral cavity and pharynx and cutaneous defects of the neck. As previously mentioned, the pectoralis major flap is still considered the "workhorse" for head and neck reconstruction especially in settings where resources are limited and/or microvascular reconstruction is not available. In places where microvascular reconstruction is available, the pectoralis major flap plays an important role, especially in the setting of salvage surgery. It can be used to provide muscle coverage over the carotid artery or to supplement microvascular reconstruction. The pectoralis major muscle can also obliterate dead space, for example, after mediastinal dissection. The pectoralis major myocutaneous flap is extremely reliable, as indicated by a low incidence of reported complications. The incidence of total flap necrosis has been reported as 1% to 3%.[13] The incidence of partial flap necrosis, as high as 30% in some series, is probably related to the degree of caudal extension of the skin paddle over the rectus sheath. Depending on the patient's body habitus, the pectoralis flap may be less reliable for more cephalic defects of the face, scalp, and pharynx. Furthermore, the effect of gravity on the bulky pectoralis major muscle may be detrimental, especially when the flap is placed in an unfavorable recipient bed or when a patient is at risk for compromised wound healing.

Trapezius Flaps.

The trapezius muscle is a broad, thin, triangular muscle that covers most of the upper back and posterior neck. The vascular supply of the trapezius muscle is more complex and variable than that of the other regional myocutaneous flaps used for reconstruction in the head and neck. The dominant blood supply is from the transverse cervical artery (TCA), which consists of a superficial branch and a deep branch. The deep branch of the TCA is also known as the dorsal scapular artery (DSA). Lesser contributions from the occipital artery and the posterior intercostal perforators are also present.

Of the three distinct trapezius flaps, the superior trapezius flap[14] is the most reliable. The primary blood supply is from the paraspinous perforators with some contribution from the occipital artery and the ascending branch of the superficial branch of the TCA. Unlike the other trapezius flaps, its blood supply is unaffected by prior radical neck dissection with sacrifice of the transverse cervical vessels. The superior trapezius flap is used primarily for protection of the carotid artery and for the resurfacing of lateral cervical cutaneous defects (**Fig. 28.3**). Because it is superiorly based, the effect of gravity does not cause the flap to pull away from the bed. The donor site usually cannot be closed primarily, and therefore, a skin graft is needed. Also, a dog-ear correction is often required.

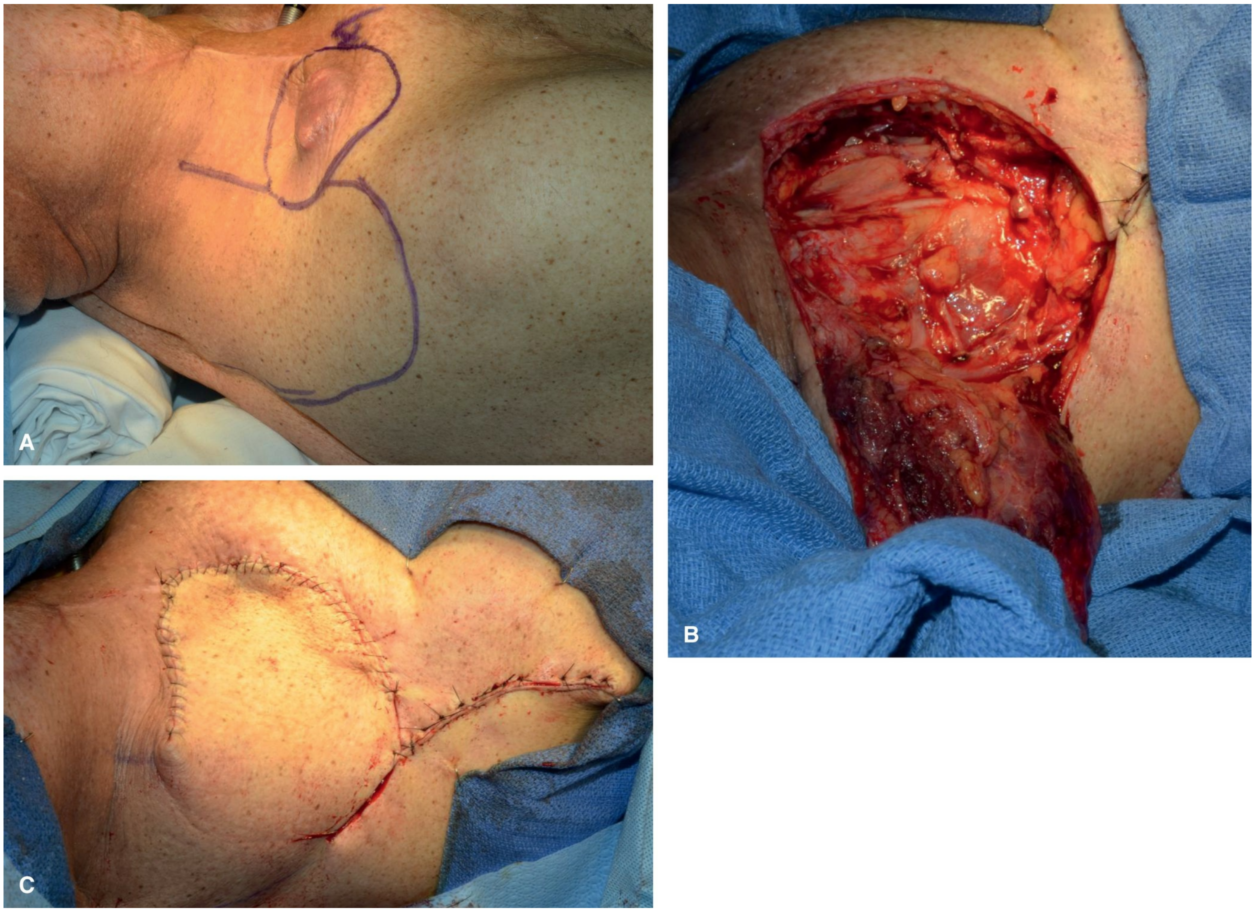

Figure 28.3. A: Superior trapezius rotational flap planned for the reconstruction of a cutaneous defect overlying the supraclavicular fossa. **B**: The flap is pedicled superomedially on the paraspinous perforators. **C:** Tension-free closure is achieved.

The lateral island trapezius flap[15] is based on the TCA. It can reach the anterior neck, oral cavity, and pharynx in some cases, but its arc of rotation is dependent on favorable vascular anatomy of the transverse cervical system in the posterior triangle of the neck and the degree of mobilization of the TCA and TCV. Because of this variable vascular anatomy, preliminary exploration of the posterior triangle is essential. If the TCA is coursing deep to the brachial plexus, it will be impossible to mobilize the lateral island trapezius flap. Following harvest of this flap, wide undermining should allow primary closure of the donor site defect.

The lower island flap[16] is the most versatile with the greatest arc of rotation of the three trapezius myocutaneous flaps. The skin paddle is designed over the inferior third of the trapezius muscle, between the vertebrae

and the scapula. The superior arc of rotation of this flap permits reliable closure of defects in the posterior neck, temporal bone, and scalp (**Fig. 28.4**). Less frequently, it has been used for reconstruction in the oral cavity and pharynx. The major disadvantage of the lower island flap is the necessity of placing the patient in the lateral decubitus position for the flap harvest.

Figure 28.4. A: Lower island trapezius flap is used in the reconstruction of a postauricular cutaneous defect. **B:** Tension-free closure is achieved as a result

of a large arc of rotation. **C:** Skin color match is adequate.

Latissimus Dorsi Flap.

When all pedicled myocutaneous flaps are considered, the latissimus dorsi flap has the largest potential skin area (25 × 40 cm) available for transfer to the head and neck.[17]–[20] Two separate cutaneous paddles may be designed based on the intramuscular bifurcation of the thoracodorsal vascular pedicle for reconstruction of through-and-through defects. The functional disability that results from the transfer of the latissimus dorsi muscle is reportedly less than that resulting from the use of either the pectoralis or the trapezius muscle.[18] This flap is frequently transferred as a free flap, and details relevant to the anatomy, surgical technique, and clinical application of the latissimus dorsi flap are discussed further in the following section on the Scapular System of Flaps.

Temporoparietal Fascia Flap

The thin and pliable tissue of the temporoparietal fascial flap is useful for lining of defects in the upper face where excess bulk is undesirable. Its location makes it invaluable in the reconstruction of auricular defects, and its thinness and pliability allow the cartilaginous architecture to be revealed. Variations in flap harvest include incorporation of the forehead or scalp skin and, less frequently, vascularized split calvarium bone. The integrity of the superficial temporal vascular pedicle is essential to ensuring flap viability.

Temporalis Muscle Flap

The temporalis muscle receives its main vascular supply from the anterior and deep temporal artery branches of the internal maxillary artery. It is used in reconstruction of the skull base, the infratemporal fossa, and the maxillectomy defects. Although employed extensively in the past, the use of this muscle in facial reanimation is currently limited to temporalis tendon transfer for suspension of the lower lip. The primary disadvantages of this donor site include a fairly limited reach and the resultant hollowing in the temporal area.

Microvascular Free Tissue Transfer

One of the most important benefits of free tissue transfer is the superior blood supply that maximizes tissue survival and wound healing in unfavorable, contaminated head and neck recipient sites. Thus, it promotes healing despite scarring, radiation damage, and salivary contamination of the recipient bed. The second major benefit relates to the freedom of being able to inset a free flap without being restricted by a limited vascular pedicle, as is common with regional flaps. The skin islands of the pedicled pectoralis major, trapezius, and latissimus flaps are often transferred from the distal and least vascular portions of the territory. Free tissue transfers are more efficient in that the flap can be placed into the defect with less concern for distal flap necrosis. Also, certain recipient sites, in particular the scalp and cranial base, may be beyond the reliable reach of most regional flaps. Even if a regional myocutaneous flap reaches the defect, the effect of gravity on the pedicle may place additional tension on a tenuous suture line.

Another advantage of free flaps is the greater variety and versatility of donor sites. Free tissue transfers such as the scapula megaflap or the iliac crest-internal oblique flap permit the harvesting of multiple tissue paddles based on a single vascular pedicle. Thus, free tissue transfers can be designed to restore more complex defects more precisely than can the tissues from adjacent regional donor sites. The disadvantages of free tissue transfer arise from the complexity of the technique and the increased surgical time required. As with regional pedicled flaps, the color and contour of free flaps in certain cases may not exactly match those of the recipient site. If the patient is a poor surgical risk, a more expedient and less complex technique that uses a regional flap may offer a safer reconstructive alternative.

It is essential that the characteristics of various free tissue transfer approaches be carefully considered[21] (**Tables 28.1** and **28.2**). Several anatomic areas, including the groin, abdomen, back, and extremities, provide reliable fasciocutaneous, musculocutaneous, and osteomusculocutaneous flaps. Each donor site has inherent advantages and disadvantages. For vascularized, bone-containing free flaps, the amount of bone stock available and the flexibility of the soft tissue component in relation to the bone are important considerations. The morbidity incurred at the donor site following free flap harvest must also be taken into account.

Table 28.1 Free Tissue Transfer Donor Sites: Anatomic Details

	Blood Supply	Pedicle Length	Artery Diameter	Vein Diameter	Nerve Supply
Fasciocutaneous Free Flap					
Radial forearm	Radial artery	18 cm (range of 15–22 mL)	3 mm (range 2.5–3.5 mm)	1.5 mm (range 1–2 mm)	Medial and lateral antebrachial cutaneous nerves
Lateral arm	Radial collateral artery of the profunda brachii artery	6 cm (range 4–8 cm)	1.5 mm (range 1–3 mm)	2.5 mm (range 1.5–3 mm)	Lateral brachial cutaneous nerve
Anterolateral thigh	Lateral circumflex femoral artery	12 cm (range 8–16 cm)	2.1 mm (2–2.5 mm)	2.3 mm (range 1.8–3.3 mm)	Lateral femoral cutaneous nerve
Scapula/ parascapula	Axillary artery → subscapular artery → circumflex scapular artery	10–12 cm	4 mm	Large diameter	3rd–5th intercostal
Myocutaneous Free Flap					
Rectus abdominis	Deep superior epigastric artery (DSEA), deep inferior epigastric artery (DIEA)	Deep inferior epigastric artery (DIEA) 7 cm (range 6–8 cm)	Deep inferior epigastric artery (DIEA) 3.5 mm (range 3–5 mm)	Deep inferior epigastric vein (DIEV) 4 mm (range 2–5 mm)	7th–12th intercostals
Gracilis	Branch of the medial femoral circumflex artery or profunda femoral artery	7 cm (range 6–8 cm)	1.5 mm (range 0.5–2 mm)	1.5–2.5 mm	Motor: anterior branch of obturator nerve Sensory: medial cutaneous nerve of the thigh
Latissimus dorsi	Axillary artery → subscapular artery → thoracodorsal artery	8.5 cm (range 6.5–12 cm)	3 mm (range 2–4 mm)	3.5 mm (range 2–5 mm)	Motor: thoracodorsal nerve Sensory: intercostals
Vascularized Bone-Containing Free Flap					
Fibula	Peroneal artery	2 cm (range 2–4 cm)	1.5 mm (range 1–2.5 mm)	3 mm (2–4 mm)	Lateral sural nerve
Iliac crest	Deep circumflex iliac artery	9 cm (range 8–10 cm)	2.8 mm (range 2–3 mm)	3.6 mm (range 2–5 mm)	T12 nerve
Scapula	Axillary artery → subscapular artery → circumflex scapular artery	10–12 cm	4 mm	Large diameter	3rd–5th intercostal
Radius	Radial artery	18 cm (range of 15–22 mL)	3 mm (range 2.5–3.5 mm)	1.5 mm (range 1–2 mm)	Medial and lateral antebrachial cutaneous nerves
Visceral Free Flaps					
Jejunal	Jejunal artery	5 cm (range 4–6 cm)	2 mm (range 1.5–2.5 mm)		
Gastro-omental	Right and left gastroepiploic artery	30 cm	Right artery 1.5–3 mm; left artery 1.2–2.9 mm		

Table 28.2 Free Tissue Transfer Donor Sites: Advantages and Disadvantages

	Advantages	Disadvantages	Ease of Dissection	Donor Site Morbidity
Fasciocutaneous Free Flap				
Radial forearm	Constant, reproducible vascular anatomy, two-team approach; long pedicle with large-diameter vessels	Requires skin graft unless cutaneous flap <2–3 cm	Easy	Maximal
Lateral arm	No risk to vascular anatomy of the hand; two-team approach	Donor site complications (pain, hyperesthesia)	Easy	Minimal
Anterolateral thigh	Long length and large pedicle; two-team approach	Color mismatch for facial reconstruction	Easy	Moderate
Scapula/parascapula	Color of the back may provide a better match than the radial forearm or thigh: extremely reliable.	Harvest requires lateral decubitus positioning.	Moderate	Minimal
Myocutaneous Free Flap				
Rectus abdominis	Skin island versatile (can be transverse, vertical, and/or oblique); two-team approach	Risk of herniation	Easy	Can be significant
Gracilis	Easy dissection; facial reanimation flap; two-team approach; scar well concealed	Skin island not reliable	Easy	None
Latissimus dorsi	Largest single flap that can be harvested	Flap can be bulky, lateral decubitus position.	Easy	Minimal
Vascularized Bone-Containing Free Flap				
Fibula	20–26 cm of bone may be harvested in adults: two-team approach.	Donor scar obvious; ankle dysfunction with aggressive physical activity	Easy	Limited
Iliac crest	10–16 cm of bone length available; skin paddle as large as 16 x 20cm; bone ideal for mandibular reconstruction; two-team approach	Risk of herniation/hematoma; dissection can be lengthy, tedious; skin paddle often thick and bulky, gait disturbance	Difficult	Sometimes significant
Scapula	Color of the back may provide a better match than radial forearm or thigh: extremely reliable.	Harvest requires lateral decubitus positioning.	Moderate	Minimal
Radius	Tremendous soft tissue versatility with long vascular pedicle and 10–12 cm of vascularized bone for intraoral defects	Major risk is fracture of remnant radius (can minimize risk by limiting harvest to 40% of circumference and plating remnant bone).	Easy	Maximal
Visceral Free Flaps				
Jejunal	Jejunum diameter approximates esophagus; as a free flap, the vascular pedicle can be lengthy (15–20 cm): two-team approach.	Require laparotomy	Easy	Laparotomy needed
Gastro-omental	Gastric mucosa is readily fashioned to repair pharyngeal defects; omentum can be used to provide carotid artery coverage and augment soft tissue.	Require laparotomy	Moderate	Laparotomy needed

Fasciocutaneous Free Flaps

Fasciocutaneous free flaps provide a segment of skin and subcutaneous adipose tissue of variable size and thickness for reconstruction of a wide variety of frequently encountered defects. Flaps commonly used for head and neck reconstruction include (1) the radial forearm flap, (2) the lateral arm flap, (3) the anterolateral thigh flap, and (4) the scapular and parascapular flaps (see under Scapular System of Flaps). The pliability of these flaps

allows for precise anatomic restoration of resected tissue during oral cavity, oropharyngeal, and hypopharyngeal reconstruction. The radial forearm, lateral arm, and anterolateral thigh flaps have the potential for sensory reinnervation, which may be helpful for the rehabilitation of mastication and deglutition in oral cancer patients. Because adipose tissue within revascularized flaps does not atrophy, fasciocutaneous flaps allow for precise and permanent restoration of contour deformities.

Radial Forearm Flap.

The radial forearm free flap is a fasciocutaneous flap that is harvested from the volar aspect of the forearm. It provides a large amount of thin, pliable skin that has the potential for sensory reinnervation via the antebrachial cutaneous nerves. Consequently, it has become the free tissue transfer of choice for the resurfacing of oral cavity and oropharyngeal defects.[22] It has also gained considerable popularity for reconstruction of the hypopharynx and cervical esophagus. In select situations, it has also been used to resurface the scalp and a variety of areas of the face, including the cheek, nose, chin, and forehead.

The radial forearm flap has numerous advantages:

1. It provides a large amount of relatively thin, often hairless, skin that can be folded on itself to conform to nearly any mucosal or cutaneous defect.
2. It has a long vascular pedicle and vessels of large size, facilitating dissection and revascularization.
3. Sensation can be restored to the skin paddle by the incorporation of the medial or lateral antebrachial cutaneous nerves.[23,24]
4. The donor site permits simultaneous two-team harvest and dissection under tourniquet control.
5. A moderate amount of subcutaneous adipose tissue can be left attached to the vascular pedicle, either for protection of the great vessels and the flap’s vascular pedicle or for augmentation of contour deformities, such as those seen following radical neck dissection.
6. The radial forearm flap can also be used as an osteocutaneous free flap because a 10- to 12-cm-long bone segment encompassing 40% of the circumference of the radius can be harvested with the skin paddle.[25]

However, when used as an osteocutaneous flap for mandibular or maxillary reconstruction, the limited bone stock restricts the potential for

functional dental restoration.

The disadvantages of the radial forearm free flap are primarily aesthetic. Unless extremely small, the forearm donor defect requires skin grafting. In addition, the color and texture match to facial skin is only fair. A potentially devastating complication of the radial forearm flap is vascular compromise of the hand. To avoid this complication, a preoperative Allen's test is essential to assess the circulation of the hand. Other complications include insufficient flow to the hand despite a normal Allen's test, numbness of the hand as a result of trauma to the superficial branches of the radial nerve, devastating infection resulting in suppurative tenosynovitis, and poor take of the skin graft secondary to failure to preserve the paratenon over the flexor tendons, leading to exposure of the forearm tendons as a result of incomplete healing of the skin graft over the donor defect.

Lateral Arm Flap.

Although this flap is harvested most frequently as a fasciocutaneous flap,[26] it can also be raised with a monocortical segment of vascularized humerus, triceps tendon, or brachialis muscle. Alternatively, the flap can be de-epithelialized and used as a vascularized fascia-adipose tissue flap for soft tissue augmentation. Dye injection studies indicate that the lateral arm flap can incorporate a cutaneous paddle that ranges from 8 × 10 cm to 14 × 15 cm. The width of skin that is harvested with the lateral arm flap is usually limited to 6 to 8 cm or one-third of the circumference of the arm, which is the largest cutaneous defect that can be closed primarily.

In the head and neck region, the lateral arm flap has been used most frequently for facial and intraoral reconstruction.[27,28] For soft tissue augmentation, it is of intermediate thickness relative to the thin radial forearm flap and the thicker anterolateral thigh and scapular system of flaps.

The lateral arm flap has several advantages over other fasciocutaneous flaps commonly employed in head and neck reconstruction. Unlike the radial forearm flap, which requires harvesting of the radial artery, harvesting of the posterior radial collateral artery (PRCA) with the lateral arm flap poses no risk for limb ischemia, and the donor site rarely requires a skin graft. Unlike the scapular fasciocutaneous flap, the lateral arm flap may be harvested with the patient in the supine position, allowing a simultaneous two-team approach.

Relative disadvantages of the lateral arm flap include a linear scar on the lateral aspect of the arm and anesthesia of the forearm as a result of transection of the posterior cutaneous nerve to the forearm. Dissection of the vascular pedicle of the lateral arm flap can be more tedious than harvesting procedures for the radial forearm or scapular fasciocutaneous flaps. This pedicle has an average length of 4 to 8 cm, which limits its application to certain head and neck defects.

Anterolateral Thigh Flap.

The anterolateral thigh flap is a fasciocutaneous flap that is harvested from the anterior thigh in the area overlying the septum between the rectus femoris and the vastus lateralis muscles. It is based on the descending branch of the lateral circumflex femoral artery and its venae comitantes. The vascular pedicle can be up to 16 cm in length with large-diameter vessels. Primary closure of the donor site can usually be achieved, even following the harvest of large skin paddles. Sensory reinnervation is possible with incorporation of the lateral cutaneous nerve of the thigh. Due to these features, it has become quite popular for use in reconstruction in the head and neck.[29,30]

The anterolateral thigh flap is often used in pharyngoesophageal defects or other large mucosal defects. Its advantages include a large area of skin for harvest and a relatively straightforward dissection with minimal donor site morbidity. Its location allows for an easy two-team approach, and no special positioning is required.

Disadvantages of this flap include excessive flap thickness in obese patients, the potential for hair-bearing skin in men, and the necessity to take a cuff of vastus lateralis muscle in 60% of patients in whom the skin is supplied by perforators that traverse the muscle rather than by a pure septocutaneous route.[31]

Myocutaneous Free Flaps

Myocutaneous free flaps are a versatile reconstructive tool for the head and neck surgeon because they provide bulky tissue with reliable vascularity to the overlying skin and offer distinct advantages over regional myocutaneous flaps, namely, a greater versatility in design and the 3-dimensional freedom of maneuverability for flap insetting. Their use is most appropriate for the reconstruction of extensive defects of the tongue, scalp, skull base, and

paranasal sinuses. In addition, some free muscle flaps can be reinnervated for reanimation of the paralyzed face. The most commonly used musculocutaneous free flaps include (1) rectus abdominis, (2) gracilis, and (3) latissimus dorsi (see under Scapula System of Flaps).

Rectus Abdominis Flap.

A unique feature of the rectus abdominis flap is that a substantial amount of muscle and skin can be harvested. Musculocutaneous perforators are located in the periumbilical region and oriented toward the inferior border of the scapula. Because of these perforators, the skin of a significant portion of the abdomen may be transferred reliably.[32]

The rectus abdominis flap is one of the most versatile and commonly performed free tissue transfers in head and neck reconstruction.[33] It is used frequently when bulky soft tissue is required for reconstruction. For example, it is useful following total glossectomy. One of its greatest uses is in skull base reconstruction, especially in an irradiated patient, to prevent a CSF leak and an ascending infection and to provide vascularity to a free calvarial bone graft.

The rectus abdominis flap offers numerous advantages:

1. Its primary vascular pedicle—the deep inferior epigastric artery and vein (DIEA, DIEV)—is long and of large diameter.
2. It can be harvested with the patient in the supine position, allowing a two-team approach.
3. A large amount of tissue can be harvested and primary closure of the donor defect can still be achieved (**Fig. 28.5**).
4. The rich vascularity of the abdominal wall allows great flexibility in the design of the paddles. Multiple skin paddles of varying thickness, based on the periumbilical perforating vessels, can be designed for use in the reconstruction of complex three-dimensional defects. The skin paddles can be oriented in a transverse, a vertical, or an oblique direction.
5. Donor site morbidity is minimal, as long as the rectus fascia is repaired to prevent formation of a ventral hernia.
6. The durable anterior rectus fascial sheath and tendinous inscriptions facilitate placement of sutures during insetting of the flap. This allows for a watertight closure and obliteration of dead space, which are critical in the oral cavity and in reconstruction of the cranial base.[34]

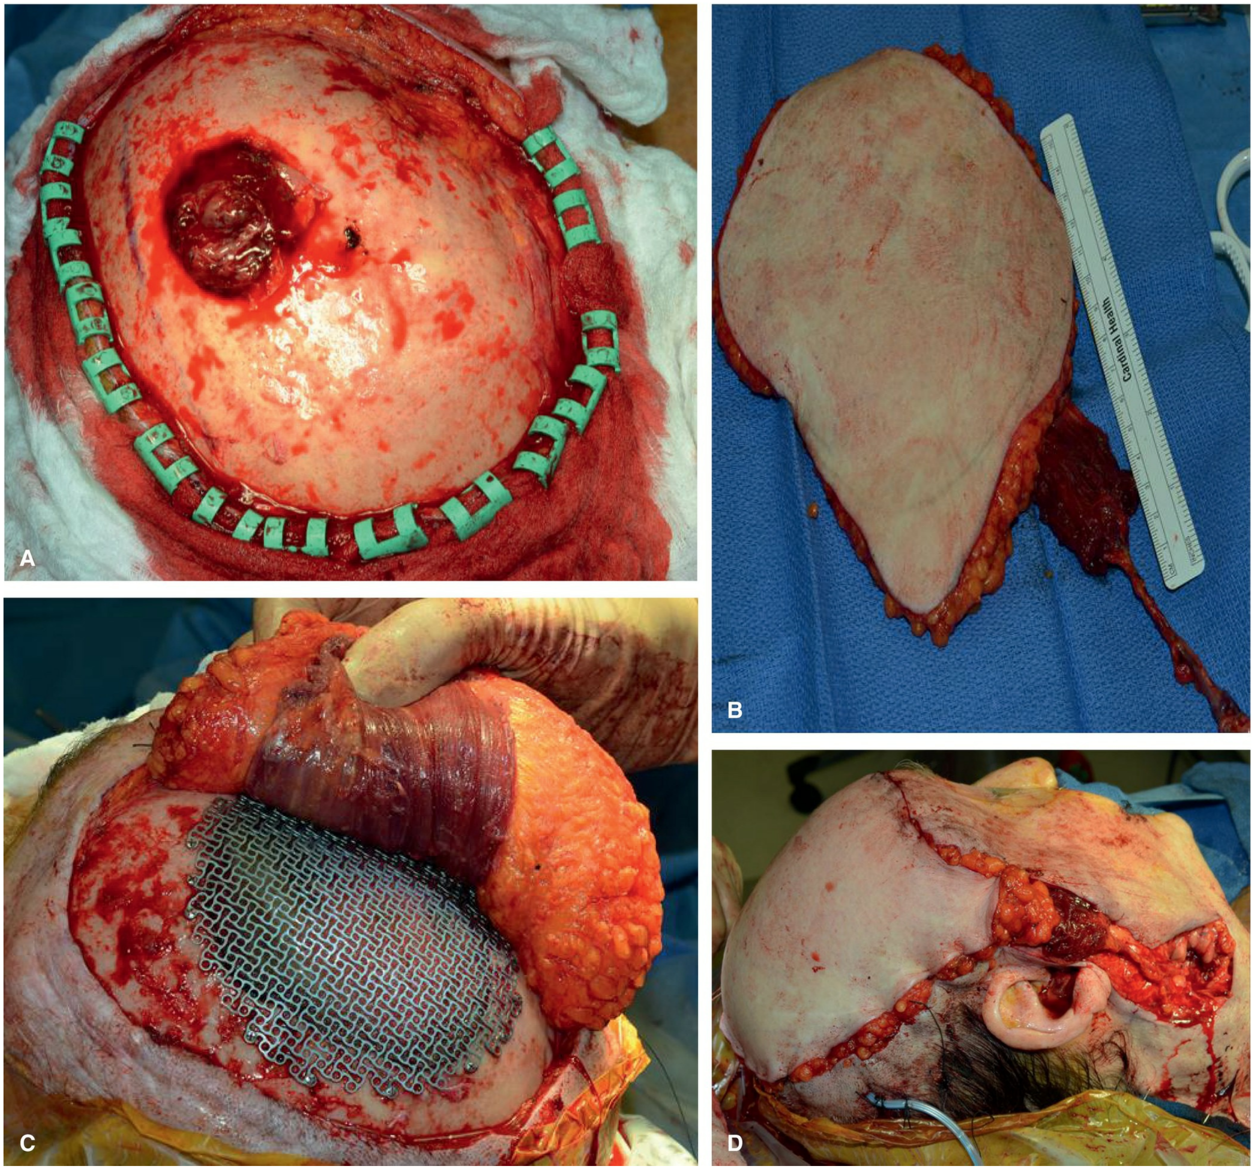

Figure 28.5. A: Large scalp defect with an area of full-thickness skull defect. **B:** Rectus abdominis flap with the deep inferior epigastric vascular pedicle. **C:** The muscle component of the flap is used to cover the mesh reconstruction of the skull defect. **D:** Sufficient skin is available for coverage of a large soft tissue defect. The vascular pedicle is carried through the preauricular incision and anastomosed to vessels in the superior neck.

The major potential disadvantage of the rectus free flap is its excessive bulk, especially in obese patients. This can be corrected by subsequent debulking procedures or by intraoperative modification of the flap's design. An alternative solution is to harvest the muscle alone or in combination with a variable thickness of subcutaneous tissue. A skin graft can be placed to

resurface the muscle if necessary. In any case, postoperative atrophy of the muscle layer should be anticipated.

Gracilis Flap.

The gracilis muscle is a long strap-like muscle that arises from the pubic symphysis and ramus and inserts below the knee onto the fibula. The gracilis muscle is favored by many surgeons who perform free tissue transfer for facial reanimation because the muscle's individual fascicular territories allow the use of smaller muscle units for restoration of specific facial movements. It can also be used as an innervated myocutaneous flap for reconstruction of the tongue or for radical parotidectomy defects when the mimetic facial muscles are resected or cannot be reinnervated.[35,36]

Vascularized Bone-Containing Free Flaps

Vascularized, bone-containing free flaps have revolutionized the reconstruction of segmental mandibular and palatomaxillary defects by reliably restoring continuity of bone and soft tissue in the primary setting. The fibula, iliac crest, and scapula all provide vascularized bone of adequate stock to replace the resected segment. All have advantages, limitations, and donor site morbidities, leading to their use in different circumstances. The most important differences relate to the quality, quantity, and reliability of the soft tissue component of the composite flap. Other essential differences include (1) the potential for osseointegration of the bone component[37,38]; (2) the length and caliber of the vascular pedicle; (3) the ease of positioning, harvesting, and insetting of the flap; and (4) the potential complications and functional deficits associated with the sacrifice of bone and adjacent soft tissue at the donor site.

Fibula Flap.

The principal attribute of the fibula free flap is the exceptional length of bone it provides, making it the only bone-containing free flap that is adequate for total or subtotal mandibular reconstruction.[39] Up to 26 cm of fibula bone can be harvested in the adult male, and the rich periosteal blood supply of the fibula from the peroneal artery allows the creation of multiple wedge-shaped osteotomies for precise contouring of the neomandible or maxilla, without compromise of bone viability (**Fig. 28.6**). It is important that the periosteum

over the bone to be used is not stripped, and thus, the bone and periosteum are cut together when creating osteotomies.[40] The thick bicortical bone accepts osseointegrated implants for dental rehabilitation.[41]

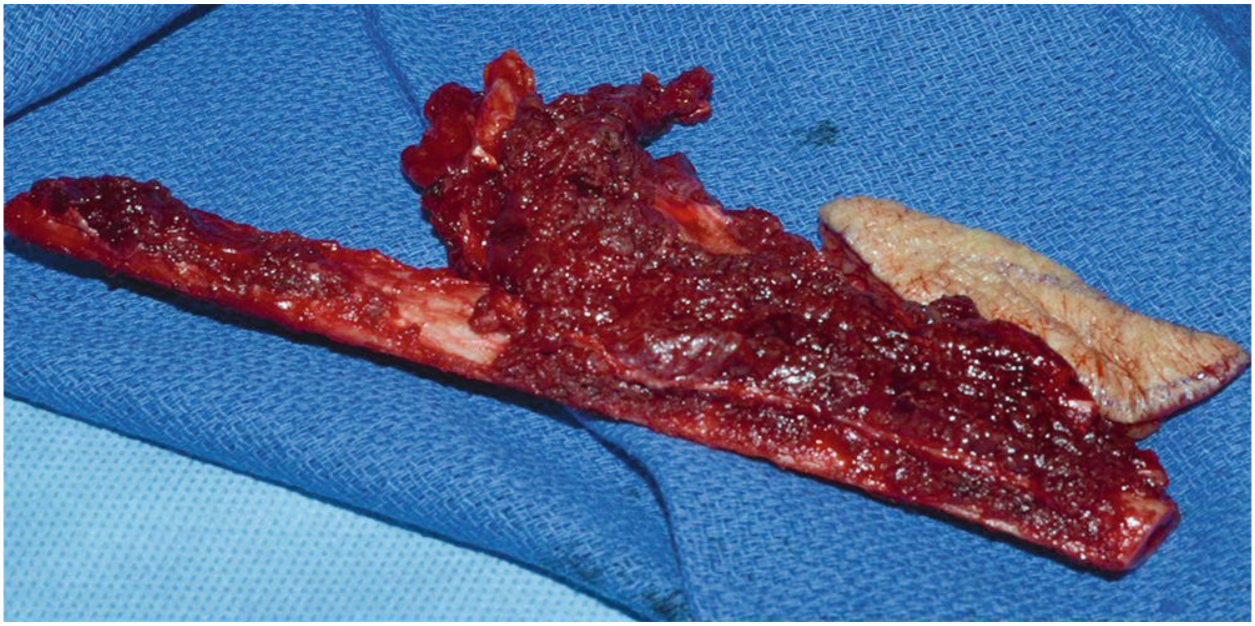

Figure 28.6. Fibula flap harvested. Periosteum is preserved in the distal portion of the flap to ensure viability of the bone.

The peroneal artery supplies the fibula and also gives rise to septocutaneous perforators that run in the posterior crural septum to supply the skin of the lateral calf. Because there are variations in the location of the perforators to the skin paddle, it is best to design a long anterior curvilinear incision that will allow exposure to the intermuscular septal perforators along the entire length of the available bone (**Fig. 28.7**). The posterior incision can then be modified based on the location of the perforator(s) and dimensions of the soft tissue defect.[42]

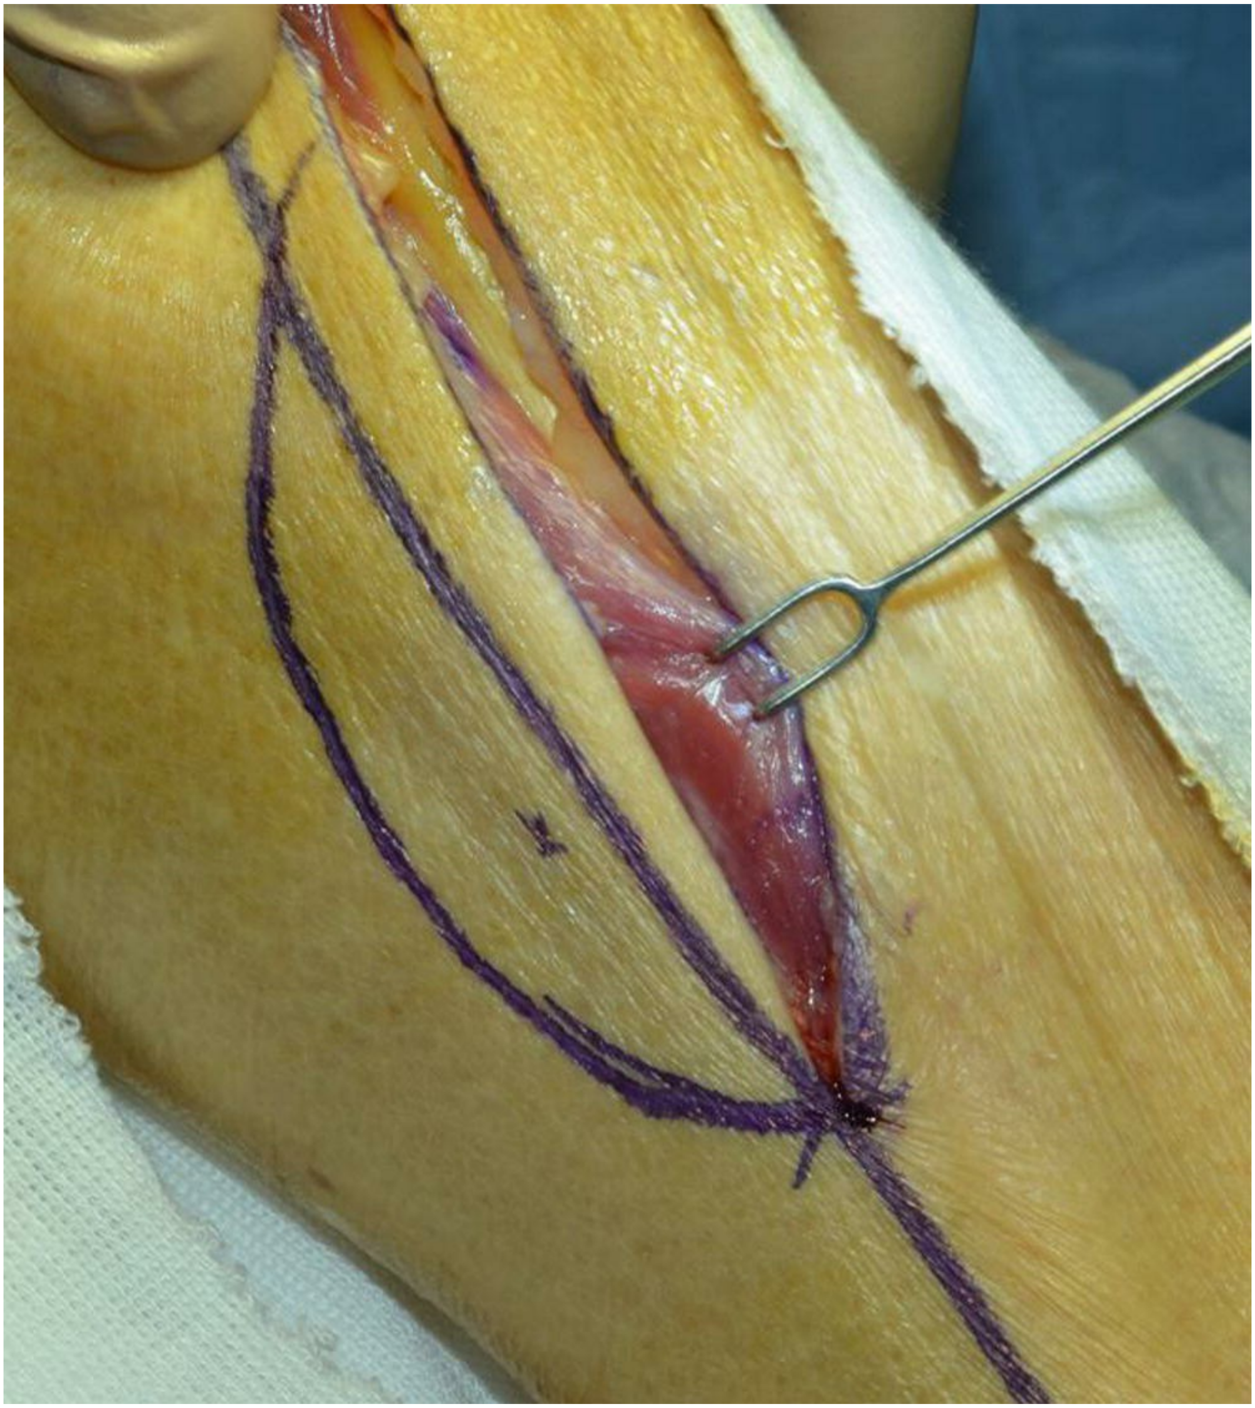

Figure 28.7. Anterior incision is made over peroneus longus and brevis muscle, and the perforator to the skin paddle is located prior to planning the posterior incision.

Advantages include simultaneous two-team harvest with the patient in the supine position. Furthermore, sensory reinnervation of the skin paddle is

possible through incorporation of the lateral sural nerve into the flap design. Due to the quality of the bone and soft tissue, it has been used extensively for palatomaxillary reconstruction.[43]

The main disadvantage of the fibula free flap is the limitation imposed by its soft tissue component. Fasciocutaneous and musculocutaneous perforators of the peroneal artery supply the skin over the lateral calf and permit the harvest of a composite osteocutaneous flap. However, the poor arc of rotation of the skin island relative to bone and its unpredictable pattern of vascularity limit its application to soft tissue reconstruction. Although methods to increase the reliability of the skin paddle have been described,[44] extensive composite oromandibular defects should be reconstructed with an alternative flap, such as the scapula osteocutaneous free flap or the internal oblique–iliac crest composite free flap. Alternatively, a bone-containing free flap can be used in combination with a separate fasciocutaneous free flap or a regional pedicled flap. The presence of atherosclerosis or congenital vascular anomalies of the lower extremity must be identified preoperatively and contraindicate the harvest of the fibula free flap. A preoperative angiogram, CTA or MRA, should be performed to delineate these abnormalities.

The donor site morbidity associated with the fibula osteocutaneous flap is minimal. Two potential complications are injury to the peroneal nerve, which results in foot drop, and instability of the knee or ankle joints. Both of these complications can be avoided provided that the proximal and distal 6 to 8 cm of fibula bone is preserved.

In summary, the osseous and composite osteocutaneous fibula flaps are valuable additions to the available composite flaps used for oromandibular and palatomaxillary reconstruction. The donor site provides the largest length of available bone with limited functional impairment relative to other bone donor sites.

Iliac Crest Flap.

The large amount of bone available from the ileum has made it a popular source for nonvascularized bone grafts, corticocancellous chips as well as vascularized bone transfer. The advantages of the ileum as a donor site are numerous. They include (1) the thick bicortical bone stock, which facilitates dental prosthetic rehabilitation with osseointegrated implants; (2) the ability of the donor site scar to be well hidden by conventional undergarments; and

(3) the ease of flap harvest by a separate surgical team with the patient in a supine position. In addition, the anterior ileum is similar in shape to the native hemimandible. A total of 10 to 16 cm of bone can be harvested, and osteotomies can be made to reconstruct hemimandibular or angle-to-angle defects. Furthermore, depending on the soft tissue needs of the patient, the iliac crest free flap can be harvested as an osseous flap, an osteocutaneous flap, or a tripartite osteomyocutaneous flap when used in combination with the internal oblique muscle. The iliac crest free flap with the internal oblique muscle has been applied to palatomaxillary reconstruction with good results, allowing placement of osseointegrated implants and closure of the palate with the use of the soft tissue components.[45]

The bulkiness, limited pliability, and restricted mobility of the skin paddle relative to the bone, limit the use of the osteocutaneous flap for reconstruction of complex composite defects. Alternatively, the highly mobile, thin, and well-vascularized internal oblique muscle can be used to resurface defects in the oral cavity and pharyngeal mucosa. Similarly, a portion of the muscle can be used to cover the bone graft and reconstruction plate. Skin grafting of the internal oblique muscle is unnecessary because the well-vascularized flap rapidly mucosalizes. The denervated muscle subsequently undergoes atrophy and provides a thin, well-vascularized, and immobile layer of tissue over the mandible.[46]

The iliac crest free flap has been applied to the reconstruction of a variety of defects in the head and neck. The osteocutaneous flap has been used for reconstruction of the anterior mandible in association with total or subtotal glossectomy defects. In this instance, the iliac bone is placed transversely in the floor of the mouth to support the skin paddle, which is used to reconstruct the tongue. Excellent long-term maintenance of the height of the neotongue has been reported with this flap design.[47] The iliac crest free flap has also been used for reconstruction of skull base and maxillectomy defects.[48]

The harvest of the iliac crest free flap involves a considerable amount of dissection. Because most of the lower abdominal wall muscles and part of the inguinal ligament are divided, ventral hernia formation is a significant potential risk. Meticulous closure of the donor site, including the use of mesh for select cases, helps to minimize this risk. The patient experiences postoperative hip pain and weakness, but this generally subsides after several weeks. Despite these potential donor site problems, extensive clinical

experience with the iliac crest free flap has demonstrated its reliability in achieving functional oromandibular reconstruction for even the most complex composite mandibulectomy defects.

Scapular System of Flaps.

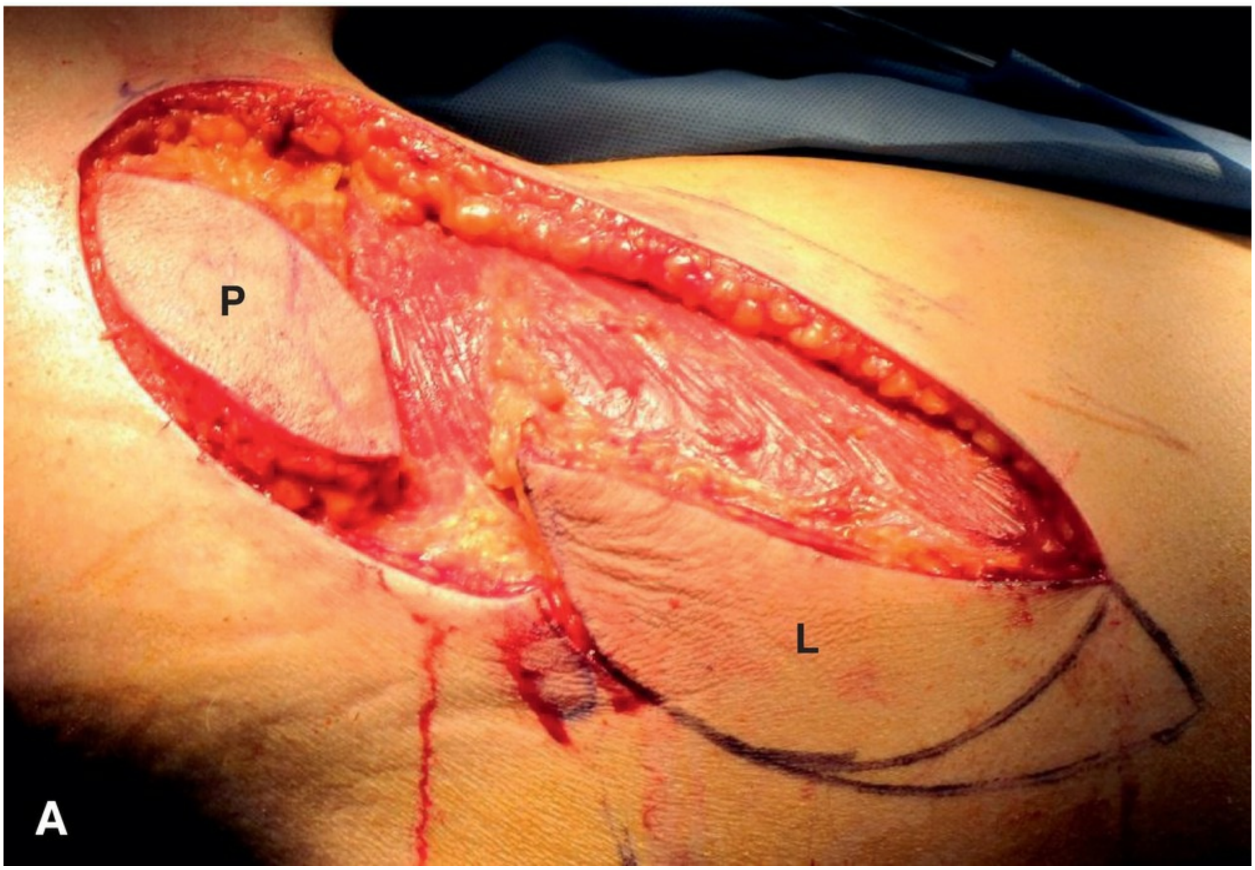
Flaps based on the distal ramifications of the subscapular artery provide a wide array of available tissue for reconstruction of defects in the head and neck. These flaps include the scapular and parascapular fascial or fasciocutaneous free flaps, the lateral or medial scapular osteocutaneous free flaps, the serratus anterior flap, the latissimus dorsi muscle or myocutaneous flap, the latissimus dorsi-rib flap, and the serratus anterior-rib flap.[49]–[52]

After its takeoff from the subscapular artery, the thoracodorsal artery descends along the surface of the serratus muscle for a distance of 9 cm before entering the latissimus dorsi muscle. The latissimus dorsi muscle may be harvested as a pedicled or free muscle flap, a myocutaneous flap, or an osteomyocutaneous flap incorporating a segment of rib. The thoracodorsal artery is consistently accompanied by the thoracodorsal vein and the thoracodorsal nerve, which is the motor nerve to the latissimus dorsi muscle. This neurovascular pedicle has been used to provide reinnervated muscle for total glossectomy reconstruction and facial nerve rehabilitation. It is important to note that the functional advantage of reinnervated muscle in total glossectomy reconstruction has not been demonstrated conclusively.

The angular branch arises from the thoracodorsal vessels or the branch to the serratus anterior and supplies the periosteum of the tip of the scapula. Dissection and inclusion of this branch allows for up to 8 cm of scapular tip to be harvested independently from a separate lateral scapular bone flap based on the circumflex scapular artery. This permits the transfer of two separate scapular bone segments based on a single subscapular vascular pedicle and separated by a 13- to 15-cm arc of rotation.[53]

The scapular system of flaps has been used for a wide variety of reconstructive problems in the head and neck. The scapular and parascapular flaps have been employed as osteocutaneous flaps for reconstruction of oromandibular and orbitomaxillary defects,[54,55] whereas fasciocutaneous flaps have been found to be useful for augmentation of a variety of congenital and acquired facial cutaneous and contour deficiencies.[56]–[58] The latissimus dorsi flap has been used for reconstruction of a wide variety of

oromandibular, pharyngoesophageal, midface, craniotemporal, and craniofacial defects.[59] Several skin, bone, and muscle flaps can be harvested on a single subscapular vascular pedicle, creating the so-called megaflap[60] (**Fig. 28.8**). Up to 875 cm2 of tissue has been reported to be transferred on a single pedicle with the use of this technique. Separate arcs of rotation around the periosteal, transverse cutaneous, and descending cutaneous branches of the circumflex scapular artery and the muscular and angular branches of the thoracodorsal artery provide for extreme flexibility in the use of this flap for reconstruction of extensive and complex defects in the head and neck.[61]



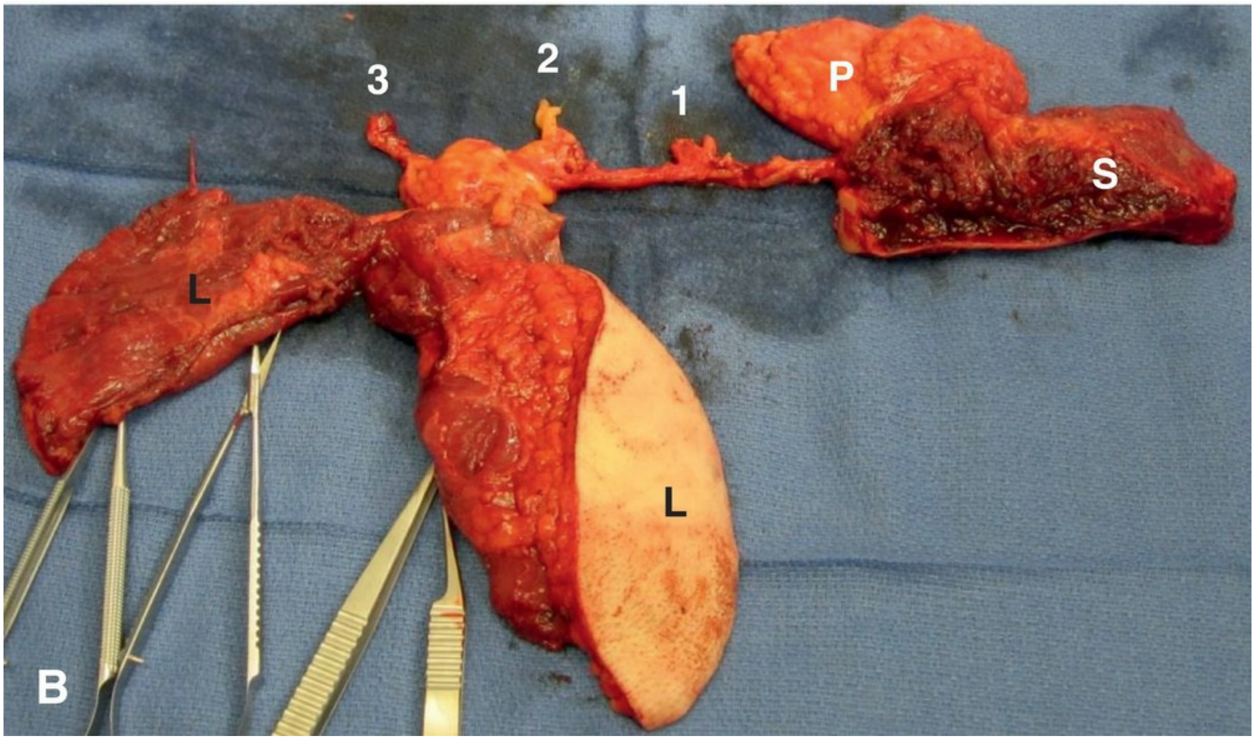


Figure 28.8. Subscapular megaflap. **A:** Multiple skin paddle can be designed. Here, a parascapular (P) skin paddle supplied by the descending cutaneous branch of the circumflex scapular artery and an anterior latissimus dorsi skin (L) paddle supplied by the vertical branch of the thoracodorsal artery are shown. **B:** Multiple components of the flap allow for reconstruction of complex defects. (1, Subscapular artery and vein; 2, angular branch; 3, branch to serratus anterior; P, parascapular skin paddle; S, lateral border of the scapula bone; L, latissimus dorsi muscle divided into two paddles based on the vertical and the transverse branches of the thoracodorsal artery.)

The major disadvantage of the scapular system of flaps is the need for the patient to be in the lateral decubitus surgical position required for flap harvest. This position frequently requires intraoperative repositioning of the patient and precludes simultaneous flap harvest during the ablative portion of the surgery. Both the iliac crest and the fibula provide better bone stock for mandibular reconstruction to support an implant-borne dental prosthesis. Postoperatively, patients should have immobilization of the shoulder for 5 days followed by physical therapy consisting of gradually increased range-of-motion exercises.

Visceral Free Flaps

In cases where thin, pliable tissue is required for immediate reconstruction, visceral free flaps are an option. Jejunum and the greater curvature of the stomach are sources of visceral tissue that have been used as free flaps for upper aerodigestive tract reconstruction, especially for circumferential pharyngoesophageal defects.

Jejunal Free Flap.

The jejunal free flap is a popular technique for reconstruction in patients who require circumferential reconstruction following laryngopharyngectomy with preservation of the cervical esophagus.[62–64]

Superior and inferior enteric anastomoses are performed in an end-to-end fashion. The superior enteric anastomosis between the jejunum and the pharynx is often carried out after the antimesenteric border of the jejunum is incised for a distance of 2 to 4 cm, to enlarge the lumen of the graft and to provide a more suitable size match with the upper resection margin. Exteriorization of a portion of jejunal mucosa allows for postoperative monitoring through assessment of flap color, peristalsis, and the quality of mucosal bleeding. The external monitor is left in place during the first postoperative week, when the risk of flap failure is highest, after which the mesentery to the monitor is divided and the exteriorized segment of jejunum is removed.

Jejunal free flaps have been used after laryngopharyngectomy, esophagectomy with laryngeal preservation, wide-field resection of stomal recurrences, and pharyngoesophagectomy for chronic pharyngoesophagocutaneous fistulae. For noncircumferential defects, jejunal autografts can be opened along the antimesenteric border and used as patch grafts for a wide variety of oral and pharyngeal reconstructions. The potential morbidity of a laparotomy must be balanced against the use of the wide variety of cutaneous flaps outlined above.

Jejunal autografts have several advantages over other methods of pharyngoesophageal reconstruction. Jejunal mucus production is beneficial to patients with xerostomia secondary to previous radiation therapy. Compared with patients undergoing gastric pull-up, perioperative morbidity and mortality are less. Also, jejunal autografts easily reach the oro- and nasopharynx without the excessive anastomotic tension and mucosal ischemia that can occur after gastric pull-up.[65]

Disadvantages of free jejunal autografts are apparent. A successful outcome depends on the results of two microvascular and three enteric anastomoses, which require expertise in both microvascular surgical techniques and gastrointestinal surgery. The inferior pharyngeal anastomosis may be difficult to perform in cases in which tumor extends into the thoracic esophagus. Many authors feel that the peristaltic contractions of transplanted jejunum are not coordinated with the swallowing mechanism and that these contractions may therefore contribute to postoperative dysphagia. However, the motor activity of jejunal autografts decreases over time after transplantation and, functionally, becomes inert conduits. One of the major criticisms of jejunal free flaps has been their failure to enable adequate neoesophageal speech after laryngectomy. However, conflicting reports document successful speech rehabilitation with the use of tracheojejunal fistulas.[66,67]

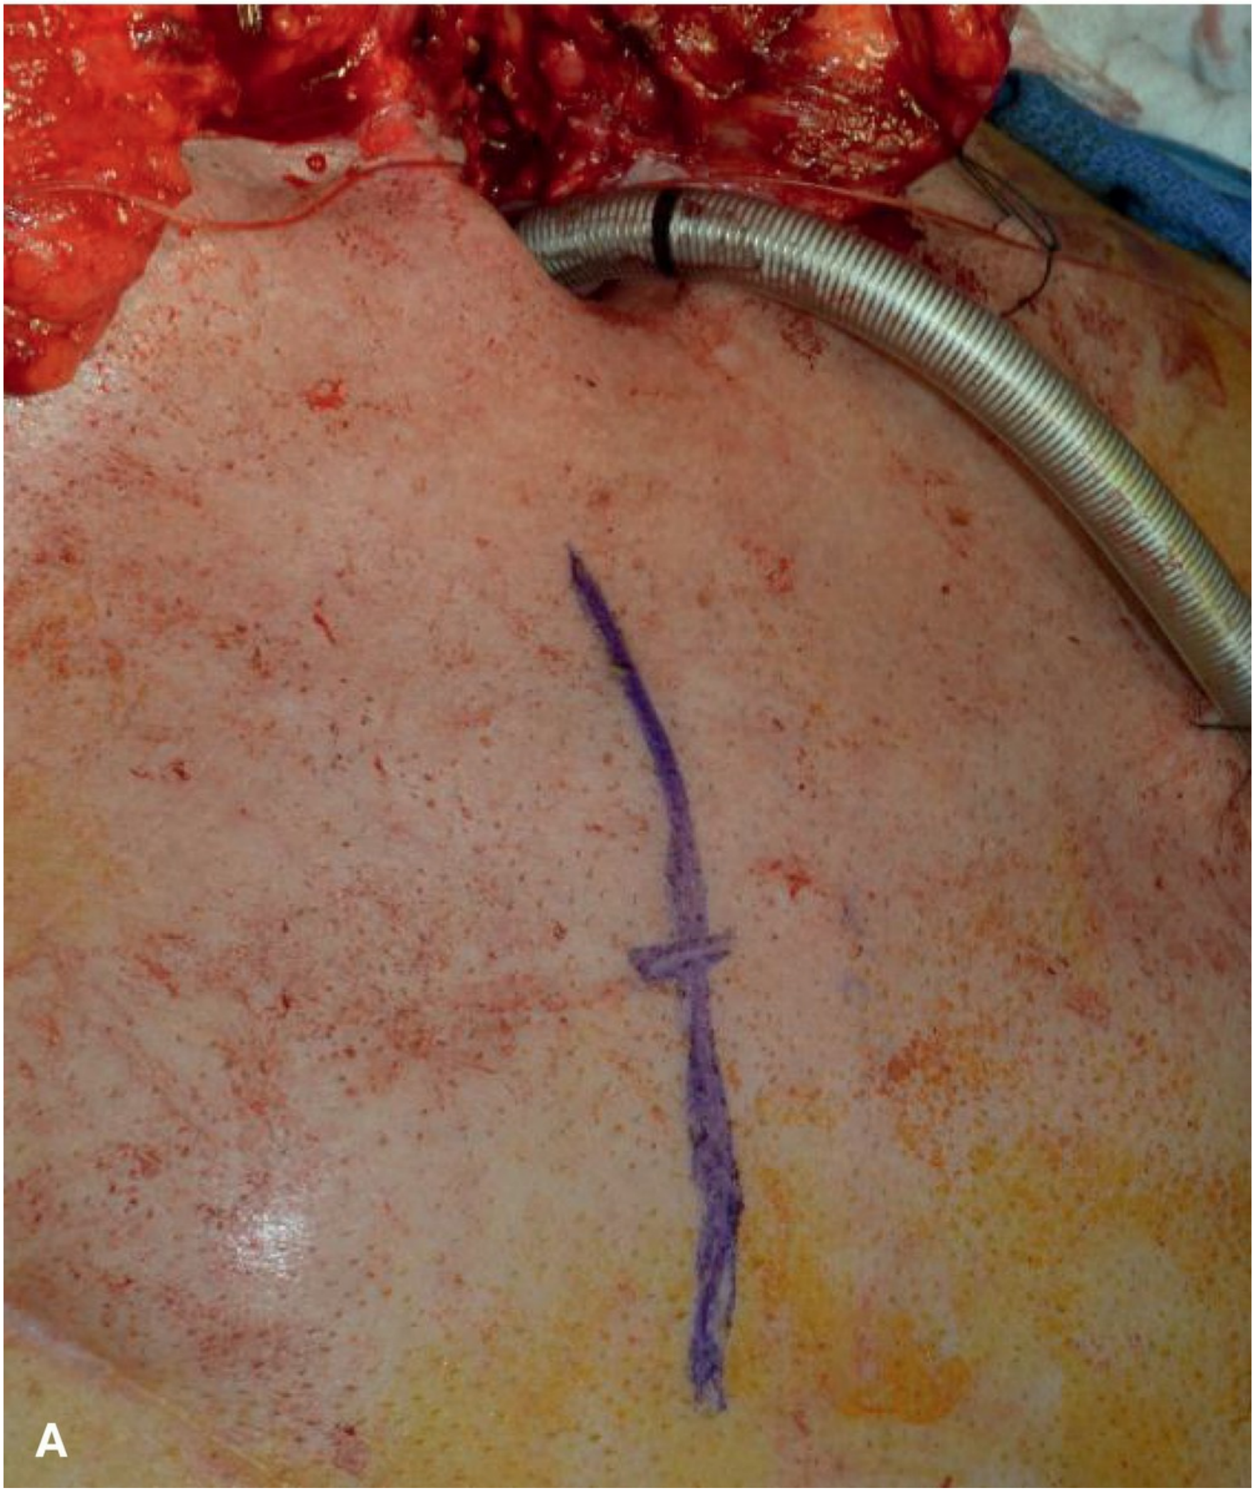
Gastro-omental Free Flap.

Hiebert and Cummings[68] reported the first successful case of pharyngoesophageal reconstruction using a segment of revascularized gastric antrum in 1961. Since that time, the gastro-omental flap has been employed for a variety of reconstructive needs in the head and neck.

The gastro-omental flap is pedicled on the right gastroepiploic artery and vein, which arise from the celiac trunk via the gastroduodenal artery and vein. A 10 × 10-cm segment of gastric mucosa from the greater curvature can be harvested for the purpose of reconstructing pharyngoesophageal mucosal defects. A tubed segment of gastric mucosa can be harvested very rapidly with an enteric stapling device and then opened at each end to achieve a suitable epithelium-lined tube. The greater omentum is frequently harvested with the flap to provide carotid artery protection after concurrent neck dissection or protection of the mediastinal contents when a mediastinal dissection is performed.[69] The inclusion of omentum with the tubed gastric mucosal flap is particularly useful for overcoming impaired wound healing in patients who have undergone previous radiation.

The chief advantage of the gastro-omental flap is that it provides ample pliable soft tissue that closely approximates native pharyngeal mucosa. The long vascular pedicle can reach more remote recipient vessels, including those in the contralateral neck or the internal mammary artery and vein (**Fig.**

28.9). The secretory capacity of the gastric mucosa has been helpful in controlling the symptoms of xerostomia in patients who have received previous radiation therapy. During the first postoperative 7 to 10 days, mucus production is copious, and patients with retained larynges often require airway protection with a cuffed tracheotomy tube. Gastric mucosal rugae quickly flatten after transfer. Omentum contains a rich lymphatic network, and omental transfer has been used to treat various forms of chronic lymphedema, although clinical experience with omental flaps for treatment of lymphedema of the head and neck has been disappointing.[70] Experimental evidence suggests that omentum possesses special qualities that promote the formation of fibrous tissue and capillary ingrowth, as well as hemostasis, making it favorable for reconstruction of previously irradiated or contaminated surgical defects.[71]



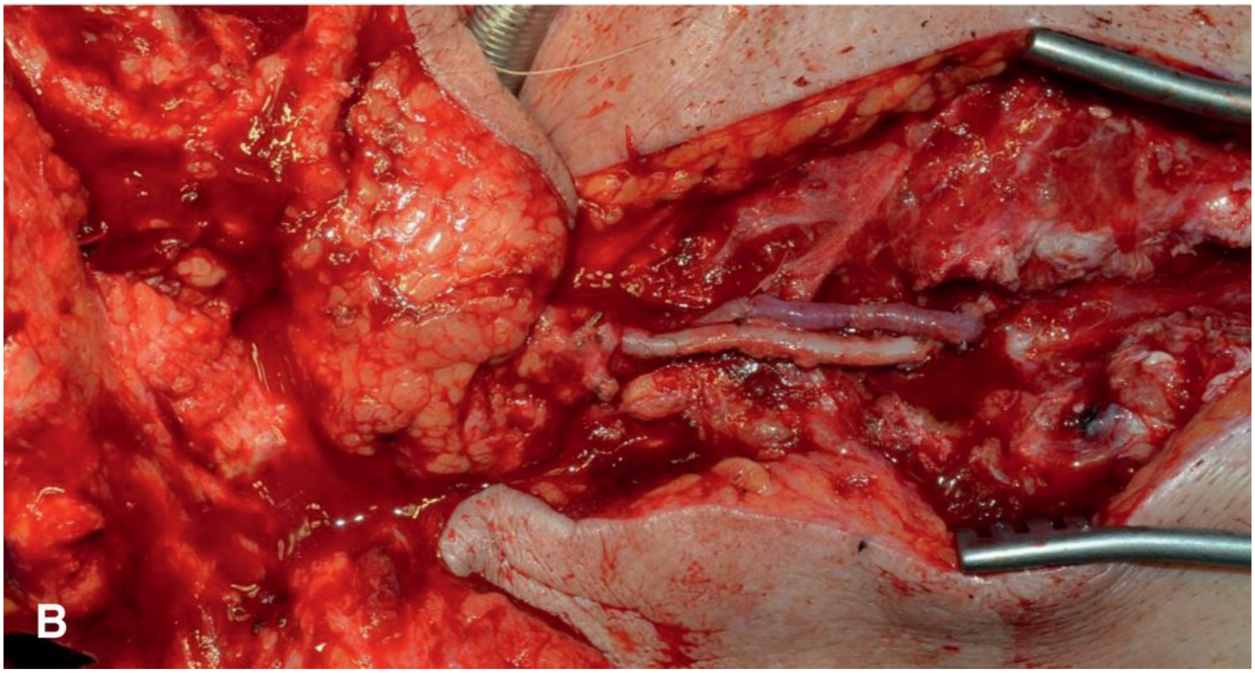


Figure 28.9. Internal mammary artery and vein. **A:** Parasternal incision is planned in order to expose the second and third costal cartilages. **B:** After the removal of the medial aspects of the second and third costal cartilages, the internal mammary artery and vein are exposed, ligated distally, and transposed in a cephalad direction.

Disadvantages of the gastro-omental flap include the need for two surgical teams and the morbidity related to laparotomy. Previous gastric surgery is a contraindication to flap harvest, and adhesions related to previous abdominal surgery or peritonitis may make dissection of the omentum more difficult. Gastrointestinal obstruction is a potential complication and may be caused by pyloric spasm or stenosis, volvulus, or adhesion formation.

OROMANDIBULAR RECONSTRUCTION

The goals of reconstruction following ablative surgery for cancer of the oral cavity are to maintain/restore oral function and to preserve lower facial symmetry. Functional parameters such as articulation, mastication, deglutition, oral competence, and airway protection play a significant role in postoperative quality of life. Despite recent advances in reconstructive surgery, achievement of these goals remains a complex task. The numerous

technical challenges are compounded by the need to operate in a contaminated field that is also at high risk for salivary leak in the immediate postoperative period. It is also made more complex by virtue of the need to package the start of adjuvant postoperative radiation therapy, or combined adjuvant therapy with radiation and chemotherapy, into a 6-week postoperative window.

Classification of composite defects is a critical initial step in achieving a successful reconstruction of the oral cavity. Stratification of these defects should account for the status of bone, soft tissue, and neurologic structures in this region.[72,73] The mandible can be divided into various segments based on a number of factors, including the functional impairment that results from disruption of the muscles of mastication and the suprahyoid muscles that insert into the mandible and participate in laryngeal suspension and elevation. The complexity associated with reconstruction of specific structures, such as the condyle and temporomandibular joint, should also be reflected in the classification scheme.

The classification of soft tissue defects is more complex owing to the highly specialized and dynamic nature of the oral lining and muscles (**Table 28.3**). Because of the critical importance of the tongue in oral function, glossectomy defects should be analyzed carefully. The mobile tongue should be distinguished from the base of the tongue, and the extent of tissue loss should be quantified. Denervated tongue should be distinguished from functional tongue tissue. Adjacent soft tissue defects are defined, including those involving the palate, pharynx, floor of the mouth, lips, and buccal mucosa. External cutaneous defects of the cheek, chin, and neck must also be addressed. Neurologic deficits involving the hypoglossal, lingual, facial, and inferior alveolar nerves must be specified (**Table 28.4**). Although it is always best to try to use a simple classification system, the complexity of the oral anatomy as well as the degree of detail that can be restored to these anatomic regions using modern reconstructive techniques demands an equally detailed description. Furthermore, the condition of the remaining dentition and tissues must be considered. A heavily irradiated or densely scarred recipient bed generally requires well-vascularized tissue for reconstruction.

Table 28.3 Classification of Soft Tissue Defects in the Oral Cavity

Reconstruction of the Mandible

The number of approaches that have been applied to the restoration of mandibular continuity attests to the complexity of the problem.[74–77] Two major criticisms of mandibular reconstruction in the past were the high failure rate of primary reconstruction using conventional techniques and the inability of patients, whose mandibles were restored, to wear dentures that allowed them to effectively chew. Prior to the availability of vascularized bone grafts, the low success rate of mandibular restoration with free bone grafts and alloplastic materials discouraged primary reconstruction.[78] Avascular mandibular substitutes, which relied on neovascularization and creeping substitution, were prone to infection and extrusion. In contrast, vascularized bone grafts undergo primary healing even in unfavorable recipient beds,[79] and success rate of oromandibular reconstruction using vascularized bone-containing free flaps is now well over 96%.[77] Endosteal dental implants, which function as tooth root analogues, have provided a solution to the problem of denture instability and poor retention. This form of dental rehabilitation can provide superior functional results as documented by the testing of bite force and chewing performance.[80–82]

The fibula, scapula, and iliac crest composite flaps are the most commonly used vascularized bone-containing free flaps for restoration of mandibular continuity.[39,54,77,83–85] Each of these composite flaps differs with respect to (1) the quality and quantity (length and cross-sectional area) of

available bone and soft tissue; (2) the length and caliber of the vascular pedicle; (3) donor site morbidity; and (4) the feasibility of a simultaneous two-team approach. When appropriately applied, all three flaps can achieve predictable bony and soft tissue restoration of complex oral cavity defects. There is no single composite flap that satisfies the needs of all patients. It is therefore essential that the reconstructive surgeon be familiar with all three donor sites to individualize the rehabilitation of each patient. Careful flap selection is important to achieving optimal functional and aesthetic results, with more rapid reintegration of the patient into society.

Soft Tissue Reconstruction

The restoration of tongue function is the most critical factor and the most challenging problem in the rehabilitation of patients with cancer of the oral cavity. A small resection of the mobile tongue may be closed primarily with minimal disturbance of function. When a defect of the tongue extends into the adjacent floor of the mouth, reconstruction with a redundant split-thickness skin graft helps to prevent tethering of the tongue. Local flaps transferred from adjacent buccal, palatal, or lingual mucosa have been used to reconstruct small to medium defects of the tongue. These procedures may, however, result in tethering and reduced mobility of the tongue.

Larger defects that involve at least one-half of the mobile tongue result in a greater degree of oral dysfunction. Patients who have undergone resection of the entire tongue, or who are left with a denervated tongue remnant, have the greatest difficulty with articulation, deglutition, and protection of the airway. For total glossectomy defects, decisions regarding the management of the larynx to prevent overwhelming aspiration are based on a variety of factors, including age, pulmonary reserve, and motivation of the patient. In all cases, it is critical that the mobility of the residual tongue be preserved by the use of transplanted, redundant, thin, pliable tissue and that the reconstruction of the mobile tongue and adjacent defects of the floor of the mouth be compartmentalized to ensure separation of the root of the tongue from the lingual surface of the mandible. The pliability and rich vascularity of the radial forearm flap provide the flexibility in design that makes this flap an ideal source of tissue for customized reconstruction of many defects of the oral cavity.[86] A considerable amount of suprafascial vascularized adipose tissue can also be harvested with the radial forearm flap when bulk is

necessary to achieve contact between the neotongue and the palate, as well as the walls of the pharyngeal chamber. Furthermore, sensation to the skin paddle of the forearm flap can be restored by anastomosis of the antebrachial cutaneous nerves to appropriate recipient nerves in the head and neck.

For mandible-sparing total glossectomy defects, it is desirable to reconstruct the neotongue with sufficient bulk consisting of adipose tissue rather than denervated muscle, with the goal of achieving long-term tongue-to-palate contact. Regional myocutaneous flaps tend to atrophy and sag over time owing to the effects of denervation and gravity on the muscle pedicle. Free myocutaneous flaps, including rectus abdominis and latissimus dorsi flaps, may provide superior long-term results. The muscular component can be directly sutured to the mandible to support the position of the skin paddle and to combat the long-term effects of gravity. Motor reinnervation, achieved with the use of the stump of the hypoglossal nerve, helps to maintain the bulk of the transferred muscle, although meaningful movement of the neotongue has not been adequately documented. Another parameter to consider in the functional reconstruction of total glossectomy defects involves sensory reinnervation to enhance control of the food bolus. Bulkier, sensate fasciocutaneous free flaps, such as lateral thigh, anterolateral thigh, and lateral arm flaps, may be helpful in this regard (**Fig. 28.10**).

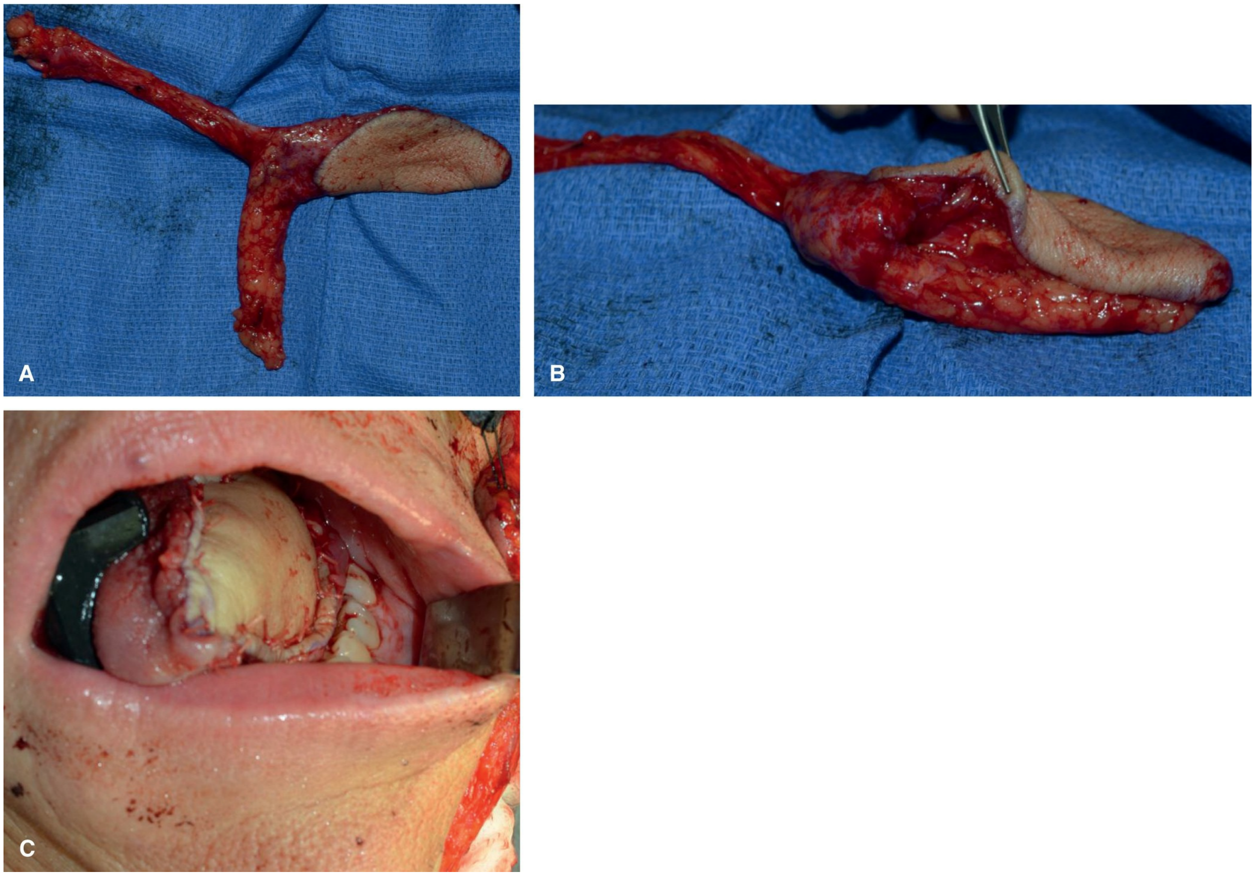

Figure 28.10. A: Radial forearm free flap is harvested with the proximal subcutaneous tissue component (beavertail). **B:** Folding of the beavertail under the distal skin paddle adds volume that may be necessary for functional restoration of a hemiglossectomy defect **(C)**.

A variety of reconstructive options are available for total or near-total glossectomy defects associated with a segmental mandibulectomy. For lateral defects, a mandibular reconstruction plate can be used in conjunction with a soft tissue free flap. However, we have noted an incidence of delayed external plate extrusion with this technique that approaches 30% when patients are followed for longer than 12 months. For reconstruction of anterior mandibulectomy defects, the composite iliac crest flap is inset with the bone in a horizontal position to support the accompanying skin paddle, which is used intraorally to replace the tongue.[87]

For larger or more complex soft tissue defects associated with a segmental mandibulectomy, a single composite free flap may be inadequate to meet reconstructive needs. Only the scapular skin paddle has a sufficient degree of mobility relative to the position of the bone component to allow for

reconstruction of the complex anatomy of the oral cavity (**Fig. 28.11**). However, the scapular skin flap is relatively thick and is not amenable to sensory reinnervation. The skin paddle of the fibula free flap is amenable to sensory reinnervation with the use of the lateral sural cutaneous flap. However, this skin flap has a limited arc of rotation with respect to the underlying bone. The skin paddle of the iliac crest composite flap is excessively bulky for intraoral application in patients with a large body habitus and is not amenable to sensory reinnervation.

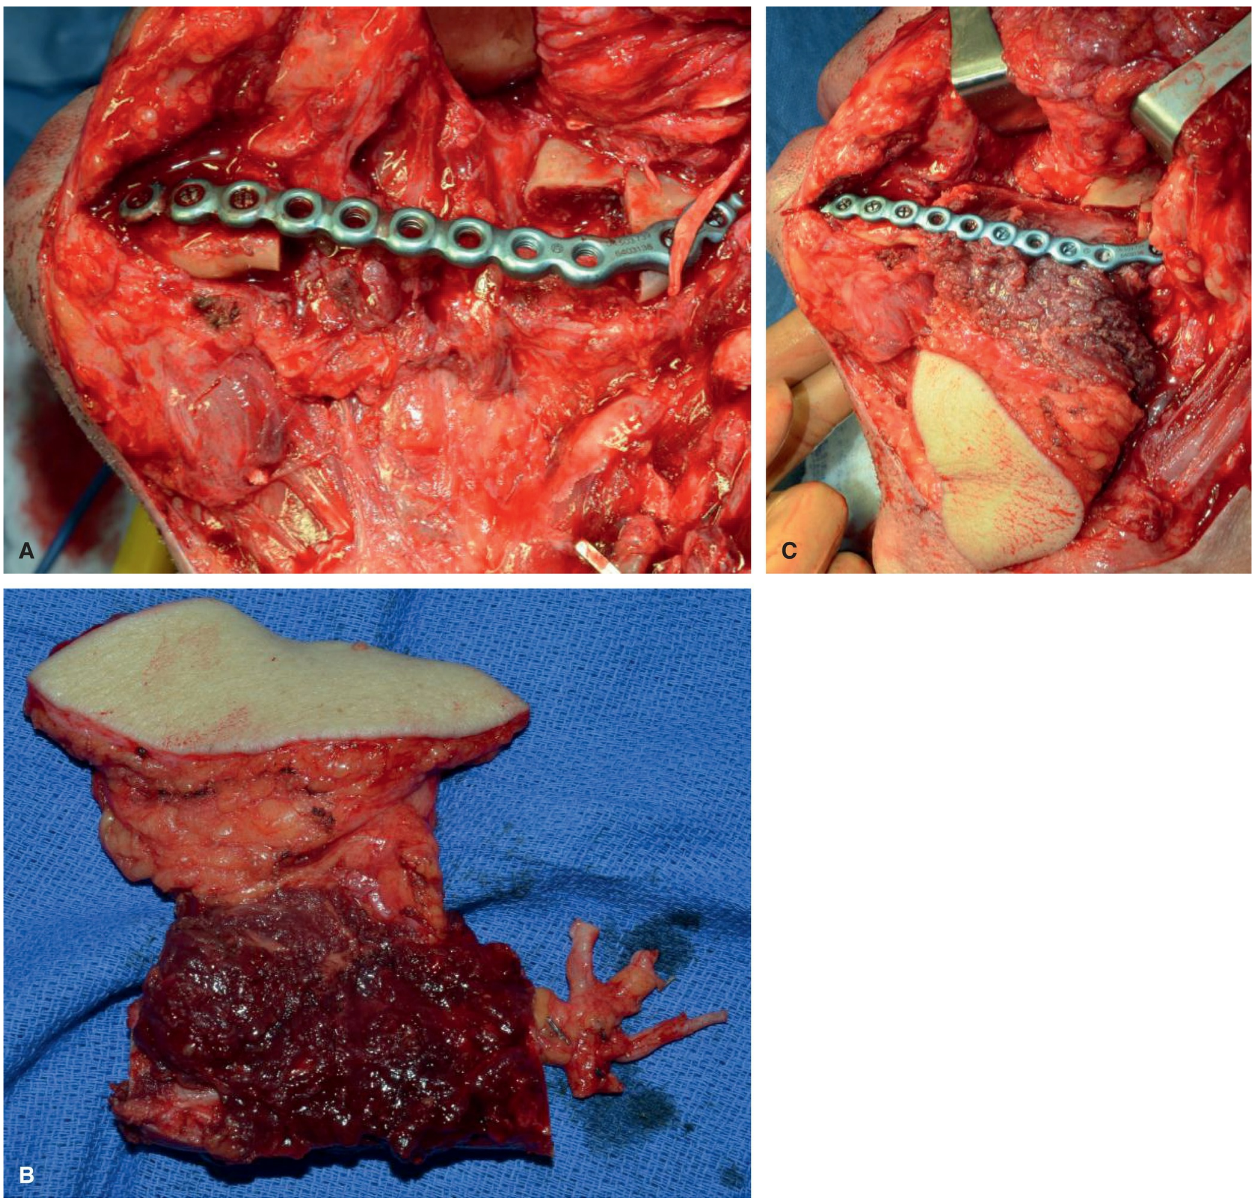

Figure 28.11. A: Segmental mandibular defect reconstructed with a lateral border of the scapula bone. Parascapular skin paddle allows sufficient

mobility around the bone for reconstruction of the intraoral and the external soft tissue defects **(B and C)**.

When a mandibulectomy is performed concurrent with a significant glossectomy, pharyngectomy, or soft palate resection, the radial forearm and lateral arm neurosensory free flaps have been used successfully in conjunction with a vascularized, bone-containing free flap.[88–90] These soft tissue flaps provide the necessary pliability to replicate the native contour of the oral cavity.

Despite reconstructive efforts, virtually all patients who undergo major resection of the oral cavity and oropharynx have some degree of dysarthria, dysphagia, and, sometimes, aspiration. Although many patients are able to compensate, some have prolonged disability. Speech and swallowing therapy is an essential component to maximize the ultimate success of the reconstructive effort.

PALATOMAXILLARY RECONSTRUCTION

As experience in oromandibular reconstruction increased, the transfer of bone-containing composite flaps entered into the mainstream of head and neck surgery. Validation of the functional and aesthetic success in mandibular reconstruction allowed surgeons to turn their attention toward the superior half of the oral cavity and use similar techniques in the functional restoration of palatomaxillary defects.

In many respects, the midface region is a less complicated structure than the oromandibular complex. Most importantly, it is immobile and plays a passive role in mastication and deglutition. Its primary functional role is to provide an opposing surface for the mandible in order to support mastication, as well as a surface to facilitate the tongue’s propulsion of the food bolus during the oral phase of deglutition. The maxillary alveolar ridges support the upper dentition. It also provides the infrastructure for normal midface projection. The three-dimensional shape of the maxilla is somewhat complex, due to the third dimension of the zygomatic bodies, which are in a different plane than the alveolar processes.

The goals of rehabilitation/reconstruction of palatomaxillary defects are to restore the form of the midfacial area while preserving the function of the palatomaxillary complex, which includes the provision of an opposing occlusal surface, support for the globe, and the maintenance/creation of a patent nasal airway. Functional dental rehabilitation is a critical goal that can be achieved through the application of dental implant technology. Numerous techniques, including prosthetic devices, local flaps, regional flaps, and free tissue transfer, have been applied to the restoration of these complex defects.

Palatomaxillary prostheses have been the most popular method of rehabilitation for many palatomaxillary defects. The advantages of prosthetic rehabilitation include a rapid rehabilitation of dentition and return to function, simplification of the surgery, and facilitation of the direct visualization of the surgical site. Biomechanical considerations when the use of a tissue-borne prosthesis is planned include the size of the defect and the number and quality of the remaining dentition for stabilization of the prosthesis. In situations where the remaining maxillary teeth are limited, an osseointegrated implant system is desirable as an alternative solution to fixate the prosthesis. To achieve this goal, the amount and distribution of the remaining alveolar bone are critical factors in determining the feasibility and anticipated success of implant placement. In addition, another very important factor is the radiation status of that remaining bone, which impacts greatly on prognosis for implant success.

Although still the most popular form of restoration of most palatomaxillary defects, prosthetic management has significant drawbacks. Instability of the prosthesis, poor separation of the oral and nasal cavities, patient discomfort, malodor due to stasis of secretions, and daily cleaning and maintenance are genuine concerns associated with prosthetic rehabilitation. Poor hand eye coordination in older patients can make daily prosthetic maintenance a challenging endeavor. Trismus can also be a significant limiting factor that makes prosthetic solutions much more difficult. Consideration of these problems has led to the investigation of alternative methods of rehabilitation. Free tissue transfer has become a reliable method of optimizing rehabilitation of the patient with a palatomaxillary defect.

In 2001, we published a new classification scheme for palatomaxillary defects to provide a framework for communication, treatment planning, and determining the functional prognosis of different restorative/reconstructive

techniques.[91] This system was fundamentally based on the biomechanical properties of the defect with respect to the likelihood for prosthetic success. In that regard, the size of the defect, as well as the number and quality of the remaining dentition, impacts greatly on the different classes. The horizontal component of the defect was determined by the presence of the molars and canine teeth, considered the “pillars” of prosthodontic stability and retention. Class 1a defects were defined as defects of the central hard palate without involvement of the alveolar ridge. Class 1b were defined as either a posterior defect involving one molar, with other remaining pillars of prosthodontic stability in place, or a defect of the anterior premaxilla. Class 2 defects are defined in either the horizontal or vertical plane, whereby at least two of the pillars of stability are preserved. Class 2 defects preserve at least one-half of the hard palate. Larger class 3 defects involve subtotal or total palatal defects wherein either 1 or no pillars are preserved. Subclassification of these defects can be done through designation of the vertical component through designation of additional defects of the zygomatic body(^{z}) and orbital floor (^{f}). Superscripts, which designate the resection of the orbit (^{o}), facial skin (^{s}), and the exposure of the intracranial contents (^{ic}), provide important additional defect classifiers.

Small defects, classes 1a and 1b, that involve the hard palate and a small portion of the tooth-bearing alveolus may be rehabilitated with either a prosthesis or soft tissue reconstruction. Prostheses placed in these defects are usually very stable and well tolerated. However, some patients may have difficulty with the daily prosthetic hygiene required or may simply be unhappy with the effort required to maintain the prosthesis. Numerous techniques for soft tissue reconstruction of this area have been described, including temporalis muscle flaps, buccal mucosal flaps, and the palatal island flap.[10] For reconstruction of small to medium-sized defects of the hard palate and maxillary alveolus, our choice is the palatal island flap[92] (**Fig. 28.12**). In cases of larger defects that cannot be covered effectively by the palatal island flap, or when the patient has had previous irradiation that precludes local tissue transfer, the radial forearm flap provides a reliable and functional closure.[93] Following this type of soft tissue reconstruction, the presence of three pillars of prosthetic retention provides ample support for a conventional tissue-borne prosthesis using clasps as anchors.

Figure 28.12. Palate island rotational flap based on the greater palatine vascular pedicle.

Larger class 2 defects, including the hemipalatectomy defect, are perhaps the most common, and their ideal rehabilitation/reconstruction is controversial.[45,94] Prosthetic management of these defects is challenging, especially in the edentulous patient. The key ingredients for prosthetic stability are the midline palatal shelf and the lateral scar band resulting at the interface of the skin graft and the buccal mucosa. The remaining dental arch and palate may be insufficient to adequately support a prosthetic device, leading to instability and poor separation of the nasal and oral cavities. Free flap soft tissue reconstruction provides an undesirable option for these patients. With only two pillars of prosthetic stability, the placement of soft tissue into this defect eliminates the stabilizing properties of the midline palatal shelf and the lateral scar band. As a result, the patient is actually put at a disadvantage with respect to ultimate dental rehabilitation. Free flap

reconstruction with vascularized bone from the scapula, fibula, and iliac crest has been reported with good results and allows the greatest chance of functional dental restoration with osseointegrated implants. The scapula free flap provides the greatest degree of soft tissue mobility, but the bone stock is often too limited for placement of implants.[94] The fibular free flap provides a large amount of bone that is adequate for implant placement and represents our method of choice when the defect is limited to the horizontal component.[43] Limitations of the fibular composite flap include the limited soft tissue mobility and difficulty in providing adequate form to the orbital rim and zygomatic body when a vertical component exists.

The iliac crest flap with the internal oblique muscle has been extensively described for palatomaxillary reconstruction.[95] The composite flap provides the greatest amount of bone stock for reconstruction of defects with a large vertical component, including the zygoma and the orbital floor. In addition, the internal oblique muscle, with its axial-pattern blood supply in up to 80% of cases, affords the necessary mobility to achieve both palatal and nasal closure. The relatively short vascular pedicle can pose a challenge for flap revascularization. However, cephalad dissection of the facial artery and vein can usually circumvent the necessity for introduction of vein grafts. The latter maneuver must be performed in concert with meticulous dissection and preservation of the marginal mandibular branch of the facial nerve.

Large class 3 defects that include subtotal and total palatal defects are optimally reconstructed with vascularized bone. The ability to contour the fibular flap to match virtually any alveolar ridge defect and to provide the necessary bone for dental rehabilitation with osseointegrated implants makes it a very favorable reconstructive option. In our experience, it is desirable to seal the sinonasal side of the defect as well as the oral side with vascularized soft tissue. To achieve this goal, it is often necessary to introduce a separate vascularized soft tissue flap.

Through application of both regional and free tissue transfers, palatomaxillary defects can be reconstructed in a one-stage technique with very favorable functional and aesthetic outcomes. With the continued increase in the reliability of microvascular free tissue transfer, it is logical to apply it to defects that have been conventionally managed with prosthetic solutions.

PHARYNGOESOPHAGEAL RECONSTRUCTION

Over the past several decades, pharyngoesophageal reconstruction has undergone an evolution from multistaged reconstructions using local tissue as “turn-in flaps” to single-stage reconstructions using free tissue transfer. Simultaneous with this evolution, there was a shift from surgery as the primary form of treatment for cancers of this region to “organ-sparing” therapy with combined chemoradiation. Currently, surgery is often held in reserve for salvage therapy, making it technically more difficult as well as more challenging from a wound healing perspective. The use of healthy, nonirradiated tissue is of paramount importance in order to decrease the likelihood of wound breakdown. With this in mind, the head and neck reconstructive surgeon must have a thorough knowledge of a wide variety of different donor sites, which can be accessed to provide the critical tissue for a successful reconstruction.

In order to best reproduce the pharyngoesophageal segment, one must understand the anatomy, goals of reconstruction, defect characteristics, and potential donor sites. When attempting to reconstruct the pharyngoesophageal segment, the goals can vary depending on the status of the larynx. If the larynx is in place, the reconstruction must center on reconstituting the swallowing conduit and preserving as much sensate mucosa as possible in order to minimize the likelihood of chronic aspiration. The reconstructive goals with an intact larynx are to restore breathing without a tracheostomy, speaking without an artificial prosthesis, and swallowing without aspiration.

Following total laryngectomy, the primary reconstructive goals are to separate the respiratory and digestive tracts, to protect the great vessels from a potential salivary leak, and to prevent a mediastinal infection. Secondary reconstructive goals are to restore pharyngoesophageal function, including rehabilitation of speech and swallowing.

The vast majority of reconstructions are performed in the same setting as the oncologic procedure. However, in certain situations, a diverting pharyngostome is recommended in patients who are at high risk for a salivary leak. In this situation, the final closure of the pharyngostome is performed in a staged fashion.

It is helpful to classify pharyngoesophageal defects for the purpose of treatment planning and determining the prognosis for functional recovery. Disa et al.[96] described a system for classifying the pharyngoesophageal defects in patients following laryngectomy, which was later modified by Urken et al.[97] as follows:

Type 0: small defects of the pharyngoesophageal segment, which are amenable to primary closure. The implication of a type 0 defect is that there is sufficient native mucosa remaining with a favorable blood supply that allows for primary repair without creation of a stricture.

Type I: noncircumferential defects in which a viable strip of mucosa spans the distance between the proximal pharynx and the distal esophagus and measuring a minimum of 2 cm in width. This defect requires a patch-like reconstruction with either a skin or mucosal flap.

Type II: circumferential defects limited to the neck and extending no further cephalad than the level of the vallecula.

Type III: extensive circumferential or noncircumferential loss of mucosa and extending further cephalad than the vallecula.

Type IV: any defect that extends caudal to the level of the clavicles.

Urken further modified Disa's original classification system to include a superscript (^{i}) to indicate that the wound healing is impaired because of prior radiation therapy. This factor was deemed critically important because in this situation, the likelihood of developing a postoperative fistula or stricture is more likely. Urken also modified Disa's classification system to include a superscript (^{s}) to indicate that the defect includes a segment of overlying skin, which requires a flap of skin to be introduced for wound closure.

Methods employed for pharyngoesophageal reconstruction include local skin flaps, regional skin flaps, regional myocutaneous flaps, visceral pedicled flaps (including gastric pull-up and colon transposition), and microvascular free flaps (**Table 28.5**, Pharyngoesophageal Reconstruction).

Table 28.5 Flaps Utilized in Pharyngoesophageal Reconstruction

Local	Cervical Skin
Regional	Deltopectoral Pectoralis major
Visceral pedicled	Gastric pull-up Colon transposition
Free flap	Ulnar forearm Radial forearm Anterolateral thigh Latissimus dorsi Gastro-omental Jejunum Lateral arm

Many patients who undergo a total laryngectomy and partial pharyngectomy have type 0 defects. These patients have enough remaining native mucosa for a primary closure of the alimentary tract without the need to import regional or distant tissue. The disadvantage of this technique is that if there is no sufficient mucosa, these patients are at higher risk of fistula formation and subsequent pharyngoesophageal stenosis. It has been shown that the introduction of nonirradiated tissue can improve wound healing capacity and decrease the likelihood of fistula formation.[98]

Local Skin Flap Reconstruction

Reconstruction of a pharyngoesophageal defect with local skin flaps, similar to the technique described by Wookey,[99] is uncommon in contemporary reconstruction of the head and neck. This technique is best suited for type I and II defects but is reserved for rare circumstances because it requires a multistaged reconstruction, and a single-stage reconstruction is clearly more ideal for patients. This technique is usually reserved for patients who are at high risk to undergo more complex methods of reconstruction because of severe medical comorbidities. Another scenario where a staged reconstruction may be considered is when the ablative surgeon encounters more extensive tumor than anticipated, and the surgeon may not be prepared

to perform a more elaborate reconstruction prior to documenting clear margins on permanent section. Finally, the technique using local skin flaps is often employed when reconstructing a pharyngostome or a mature pharyngocutaneous fistula.

Regional Flap Reconstruction

Reconstruction of the pharyngoesophageal segment with regional tissue is best suited for noncircumferential type I and type II defects. Both the deltopectoral flap and the pectoralis major flap can be used to transfer skin paddles, which can be used to patch a defect in the anterior wall. By transposing skin from the chest wall, one can achieve a single-stage closure when the pharyngeal remnant is too small to close primarily. Regional flaps are less ideal for circumferential defects because of the difficulty of comfortably tubing these flaps because they are not thin or supple.

Type IV pharyngoesophageal defects often require a gastric pull-up in order to replace the cervical and upper thoracic esophagus. For this approach, the surgeon removes the entire esophagus allowing for transposition of the stomach into the cervical region. The advantage of this maneuver is that it allows for a single enteric anastomosis to reduce the risk of fistula formation and avoids an anastomosis in the mediastinum where a fistula can be life threatening.

Free Flap Reconstruction

There are two enteric free flaps commonly used in pharyngoesophageal reconstruction. Jejunal free flaps are usually indicated for type II defects. The advantage of this flap is that it contains secretory gastrointestinal mucosa, and this mucous production may be beneficial to patients with xerostomia. Gastro-omental free flaps are indicated for reconstruction of type II and type III pharyngoesophageal defects. The ability to transfer the omentum, which is a highly vascular and robust tissue, makes this flap a very good choice for through-and-through defects, especially in the radiated setting.

The radial forearm, ulnar flap, lateral arm flap, and anterolateral thigh flap all provide larger surface areas of the skin, which can be used to reconstruct type I, II, or III defects. Each of these flaps has its own intrinsic properties, which may make it more or less preferable as a donor site on a

case-by-case basis.

Reconstruction of the pharyngoesophageal segment has the potential for both short-term and long-term complications. In the postoperative period, a pharyngocutaneous fistula or a major wound breakdown can occur and requires prompt local wound care and possible revision surgery. If a salivary leak occurs and is not recognized, it could lead to a wound infection and leading to the potential erosion of the great vessels resulting in a carotid artery blowout. Therefore, it is vitally important to assess these patients closely during the critical phase of wound healing.

Following the initiation of oral intake, patients can experience difficulties with chronic dysphagia due to an adynamic pharynx. Pharyngoesophageal stenosis may develop as a result of cicatricial scarring, which most commonly occurs at the junction of the pharyngoesophageal segment with the thoracic esophagus. Dynamic barium swallow assessment, using modified barium swallows (MBSs) are an invaluable tool for the evaluation of patients with postoperative dysphagia in order to determine the etiology of a patient’s complaint and a solution to their problem.

FACIAL REANIMATION AFTER MAJOR HEAD AND NECK CANCER RESECTION

Facial paralysis can be a devastating problem for patients following tumor extirpation. Both functional and aesthetic sequelae often lead to isolation, depression, and a limited quality of life. Although the sequelae of ablative and reconstructive surgery for head and neck cancer may leave a patient with deformity of facial and cervical contour and color matched skin, it is asymmetric movement of the face or complete lack of mimetic movement, which immediately catches the human eye and stigmatizes that patient as being “deformed.” Facial reanimation remains one of the most challenging aspects of head and neck reconstruction and requires a patient-specific diagnosis and treatment plan. There are a variety of treatment options from static procedures, local muscle transfers, nerve transfers, and nerve grafts, which all have a role depending on the particular situation. Adjunctive procedures and Botox injection therapy also have important roles in

improving symmetry and overall facial balance. The purpose of this section is to provide a practical framework to construct a sound surgical plan for a patient in the context of their underlying disease.

Consequences of Facial Paralysis and Goals of Reanimation

Complete facial paralysis results in brow ptosis, paralytic ectropion, and loss of smile and lip motion. The most serious consequence is potential blindness related to chronic exposure of the cornea if not addressed early. Chronic epiphora is a common complaint from patients and is caused by overproduction of tears related to corneal dryness as well as impaired lacrimal drainage as a result of the paralyzed orbicularis oculi lacrimal “pump” mechanism. Moisturizing the cornea throughout the day and ensuring eyelid closure at night are part of routine eye care in the management of patients with facial paralysis. Oral incompetence and difficulty with speech and deglutition are also potential problems, as well as loss of superior visual fields related to the descent of the paralyzed brow.

Static eyelid procedures are typically required in the adult population. Children and teenagers generally do not require an eyelid weight or lower lid procedure because passive eye closure and a positive Bell reflex are often adequate given their favorable skin quality. If the iris is visible when the patient closes their eye, damage to the cornea and potential loss of vision may ultimately ensue. A platinum or gold weight is placed deep to the orbicularis oculi muscle to facilitate closure of the upper eyelid. We generally prefer platinum because of its higher density and lower profile.

Lower eyelid malposition with scleral show or full-blown paralytic ectropion needs to be addressed as well. A pre-existing negative cheek vector and delayed lower eyelid snapback test in the setting of facial paralysis can result in profound vision-threatening ectropion. Without muscle tone, midface volume is lost as it descends due to gravitational forces, further compounding the paralytic ectropion because of the loss of cheek support to the lower eyelid. A combination of lower eyelid procedures and restoration of midfacial volume are synergistic in treating lower eyelid malposition. A lower eyelid sling or lid-tightening procedure may be required and is often performed by an oculoplastic surgeon. In salvage cases where vision is in

immediate jeopardy, a formal lateral tarsorrhaphy can provide adequate protection. From an aesthetic standpoint, it is not ideal, but it can be reversed in the future if desired.

Dynamic Versus Static Procedures

Dynamic rehabilitation of the paralyzed face is always preferable to static reconstruction if the patient is an appropriate candidate. Although there are a number of dynamic procedures available, reliability and predictability of reinnervation is a priority in the oncologic patient when life expectancy may be relatively limited. Elderly patients with slow nerve regeneration potential and patients with a poor prognosis or who are in poor health are typically better suited for a static procedure. Although quality of life will be diminished, a static sling can provide symmetry at rest and preserve some degree of oral competence.

The choice of dynamic reconstruction depends on the time of denervation, the status of the target muscles and nerves, and the availability of potential donor nerves. The facial nerve is the only donor nerve that can provide spontaneous facial motion. Panfacial reanimation should be the goal. The ideal situation is found when the patient's native facial musculature is intact and there is a proximal facial nerve, permitting reinnervation to occur. Patients with paralysis for over 2 years are unlikely to have significant functional muscle available due to denervation atrophy. In patients who present <2 years following paralysis, a needle EMG should be obtained to determine the viability of individual facial muscles. If there are fibrillations present, the patient may be a candidate for a nerve transfer or "babysitter procedure".[100] If the EMG is silent, then a free functional muscle transfer can be considered. A young patient with a good prognosis from the underlying disease that led to the paralysis, who can tolerate a 2-year process of facial rehabilitation, is a good candidate for two-stage cross-facial nerve grafting and free muscle transfer if the native muscles are unavailable. However, in older patients, the time for nerve regeneration may be significant. An alternative is to use a free gracilis muscle transfer that receives innervation from the nerve to masseter. This will provide single-stage reanimation in 3 to 6 months, although motion will be strictly voluntary and require the learned process of biting to trigger facial movement. Although the latter is an excellent strategy in younger patients, older patients may find this learned

approach to facial movement to be a challenge.

Immediate Nerve Repair and Nerve Grafting

If the facial nerve can be repaired directly, a tension-free repair is always preferable, typically performed with epineurial sutures using 10-0 nylon suture.[101] If there is any tension on the repair, a nerve graft should be used instead. One common situation is a patient who undergoes radical parotidectomy with preservation of distal facial nerve branches and the proximal facial nerve trunk is intact. If only a portion of the facial nerve is resected, then a nerve graft is a reliable first choice. When the entire facial nerve is resected, nerve grafting to one or two distal nerve targets at most is typically performed. Nerve grafting from the main trunk to all branches is less predictable and may lead to overall weak motor function and considerable synkinesis. In general, we prefer targeting a single distal zygomatic branch that stimulates both smile and lower eyelid motion if this is the sole means for reinnervation. A minihypoglossal transfer can be supplemented to restore lower lip motion and depression to improve symmetry and perioral tone and avoid stretching of the lower lip over time.

The great auricular nerve and the sural nerve are the most commonly used donor nerves for facial nerve interposition grafting.[102] Other donor nerves include branches of the cervical plexus including ansa cervicalis and the medial antebrachial cutaneous nerve. The greater auricular nerve is convenient because it is in the surgical field but has limited length (8 to 10 cm), and the resultant loss of sensation to the earlobe and postauricular region can be bothersome to the patient. The sural nerve is often used because it can be harvested simultaneously and provides greater length (up to 35 cm) than the great auricular nerve. It is located lateral to the Achilles tendon and immediately lateral to the lesser saphenous vein. Sensation to the lateral foot and lower leg are lost following harvest, but this does not typically interfere with gait or strenuous activity. The more proximal portion of the nerve has a smaller caliber and is typically a better size match when performing cross-facial nerve grafts.

The medial antebrachial cutaneous nerve of the forearm is a sensory nerve branch from the medial cord of the brachial plexus and accompanies the basilic vein down the arm before piercing the deep fascia in the middle of the proximal part of the arm. The nerve divides into an anterior and posterior

branch in the distal third of the arm to provide sensation to the anterior medial surface and the posteroulnar surface of the forearm. The donor graft is obtained by making a longitudinal incision in the skin 2 cm anterior and 2 to 3 cm distal to the medial epicondyle. Because of its location in the subcutaneous layer of the forearm, it is a relatively easy and accessible donor nerve to harvest with minimal donor site morbidity.[103] The medial and lateral antebrachial cutaneous nerves can be harvested along with the superficial branch of the radial nerve with a radial forearm free flap, providing vascularized nerve grafting in a previously radiated or hostile environment.[24]

Immediate Nerve Transfers in the Setting of a High Facial Nerve Sacrifice or Absence of a Proximal Facial Nerve Donor

If the proximal facial nerve trunk is unavailable or is intraosseous and far from the distal nerve targets, a combination of nerve grafting and dual nerve transfers can be performed as advocated by Dayan and colleagues.[104] Because time to reinnervation from a high facial nerve injury can take a year or more with unpredictable results, patients who have a limited prognosis would most likely benefit from a nerve to masseter and minihypoglossal transfer, which often provides innervation within 3 to 6 months. These nerve transfers are fairly reliable even in the setting of postoperative or prior radiotherapy. In addition to the dual nerve grafts, a nerve graft from the proximal facial nerve trunk to a distal facial nerve branch targeting both upper and lower portions of the eye sphincter is performed, providing supplemental innervation to the eye sphincter, albeit with a long reinnervation time. The nerve to masseter is transferred to a distal facial nerve branch stimulating both the zygomaticus major muscle (smile) and lower eyelid motion. Finally, a minihypoglossal transfer to the lower lip depressor is performed. This often requires a nerve graft, which is repaired end to side to the hypoglossal nerve following creation of an epineurial window and transection of 30% of the cross-sectional area of the cranial side of the hypoglossal nerve.[100] This provides maximum neural input to the face and minimizes synkinesis because the distal targets and nerve inputs are separate. An upper eyelid platinum weight is also placed in addition to a very modest (5 mm length) lateral tarsorrhaphy, which is not cosmetically

noticeable but provides some degree of lower lid support while the patient is awaiting reinnervation. One of the major benefits of this approach is that the nerve to masseter maintains lower eyelid motion and cheek support with a relatively rapid and reliable reinnervation. In our series, none of these patients required any static lower eyelid procedures for support.[104] This is a significant benefit in terms of quality of life and avoiding the treatment challenges associated with a long-standing paralytic ectropion. Sacrifice of the nerve to masseter is generally well tolerated, as proximal branches can be left intact. However, palpation of the masseter muscle should be performed preoperatively, and consideration should be given to any anticipated sacrifice of the temporalis muscle as loss of both muscles may lead to weakness and asymmetric movement of the lower jaw. Minihypoglossal transfer is also well tolerated, but overaggressive sectioning can lead to dysarthria. Complete sacrifice of the hypoglossal nerve should not be performed. There are alternative nerve donors with a spectrum of advantages and disadvantages including the spinal accessory nerve, phrenic nerve, ansa cervicalis, and nerve to temporalis.

Immediate Muscle Transfer Following Facial Nerve Sacrifice

The benefit of immediate muscle transfer following tumor resection is rapid smile function following the ablation. This is a viable option for patients and may be ideal for those with a poorer prognosis or older patient population. One significant drawback is that muscle transfer for smile does not provide any dynamic rehabilitation to the eye sphincter, which is a priority in facial rehabilitation. We generally favor nerve transfers or grafts to preserve eye sphincter function whenever possible, as long as the waiting time for reinnervation is appropriate given the patient’s disease status.

Muscle transfers including masseter and temporalis transfer have been described, although the vector and outcome of a temporalis muscle transfer is generally preferable. Motion is not spontaneous and requires biting down for smile function. Refinements and modifications of this procedure have been described including a minitemporalis transfer[105] and the Labbe procedure,[106] which in principle is a tendon transfer of the distal temporalis muscle to the oral commissure. Excellent results have been obtained using these techniques.

Free Functioning Muscle Transfer

In patients who underwent resection of the facial musculature or patients who have had facial paralysis for more than 2 years, free functioning muscle will be required. Patient selection is critical in the oncologic population. Patients with a poor prognosis or significant medical comorbidities are clearly not good candidates. There are a number of considerations regarding donor muscle selection and donor nerve selection. Adequate pedicle length, donor site morbidity, and muscle excursion are among the considerations.[107] A variety of muscles have been described including the gracilis, pectoralis minor, latissimus dorsi, serratus anterior, and others. The gracilis muscle is commonly used because of its convenient, rapid harvest, long excursion, and reliable pedicle. The pectoralis minor muscle has advantages in the pediatric population with dual innervation and the potential for multiple vectors of motion.[108] Latissimus dorsi provides ample pedicle length and caliber, but is generally bulky.

The patient's smile vector is evaluated and marked preoperatively and simulated on the contralateral side. Depending on the smile, distal insertion of the muscle is typically along the base of the nasal ala, nasolabial fold, modiolus, and sometimes the lower lip. Inset of the muscle is performed prior to anastomosis and neurorrhaphy as this will determine the final position of the neuromuscular pedicle. Zuker and Manktelow[109] typically debulk the gracilis muscle with the proximal end of the muscle secured to the deep temporal fascia, superior to the zygoma to allow for adequate excursion. One consideration following oncologic resection is that skin coverage may be thin and adherence to the overlying muscle transfer can be unsightly. The gracilis can be harvested with an overlying layer of vascularized adipose tissue to provide a more supple appearance.

Nerve donor selection is an important consideration. The facial nerve is always preferable, when available, for achieving spontaneous motion. If the proximal facial nerve stump is available, it can be used, but plugging into the main trunk of the facial nerve will likely result in excessive contraction. A distal facial nerve branch or smaller nerve graft from the main trunk can be considered. Alternatively, cross-facial nerve grafting in the first stage with free muscle transfer 9 to 12 months later is a good option for a young, motivated patient with a good prognosis. At least two cross-facial nerve

grafts are typically used for eye closure and smile, with other grafts for lower lip depression if desired.[110] A positive Tinel sign can be traced during repopulation of the cross-facial nerve graft as it progresses toward the paralyzed side. Its presence does not predict function, and cross-facial nerve grafts are generally less powerful and less reliable than local nerve transfers. If there is a question of viability of the nerve graft at the time of muscle transfer, a biopsy of the nerve graft can be performed intraoperatively to confirm the presence of healthy fascicles versus fibrotic unusable nerve graft. Nerve to masseter transfer can be discussed with the patient ahead of time and used as a backup.

In patients who are not candidates for a cross-facial nerve graft, or who prefer a single stage with greater power and predictability at the expense of no spontaneous motion, a nerve to masseter is a good alternative. Reinnervation is rapid and donor site morbidity is minimal.

Adjunctive Treatments

There are a number of adjuncts to improve the overall aesthetic and dynamic appearance following oncologic treatment. Loss of volume following resection and radiation can be successfully treated with structural grafting using adipose tissue.[111] This provides a more supple and symmetric appearance particularly following radiotherapy. Botox is commonly used on the nonparalyzed side to achieve improved dynamic symmetry and minimize the discrepancy in motion between the paralyzed and nonparalyzed side. A brow lift is typically required when complete paralysis is present. In older patients who scar well (at least 60 years old, preferably 70), a direct brow lift is very effective. Although endoscopic brow lift is appropriate in certain patients, it should be avoided in those with a high forehead as this will be accentuated following the procedure, and further lifting will generally need to be repeated in the future. Patients with a high forehead are best suited with a brow lift using a pretrichial incision, although numbness of the scalp will occur. Patients who have lost lower lip innervation may develop an elongated and atonic lower lip and require wedge resection to improve oral competence. Physical therapy is an important component of facial rehabilitation of synkinesis or when nerve transfers are used. Synkinesis can be minimized with proper therapy and Botox; and surgical management may be appropriate in certain circumstances, although this is beyond the scope of this chapter.

In conclusion, there is a wide array of techniques available for facial reanimation, and careful selection among them must be made in the context of the patient's disease, goals, and clinical presentation and is critical to a successful outcome. It is also critical to appropriately manage a patient's expectations in order to make certain that return to normalcy is not anticipated and to ensure that the patient and their family are not disappointed with a less than perfect result.

IMPLANT REHABILITATION AND MAXILLOMANDIBULAR FREE FLAP RECONSTRUCTION

Contemporary management of the patient with cancer of the head and neck integrates surgical reconstructive techniques with prosthetic rehabilitation in order to optimize function and aesthetics.[82,112,113] The complexity of vascularized bone free flap reconstruction of maxillomandibular defects necessitates treatment strategies that meet patient expectations in terms of their function, aesthetic, psychological, and social concerns. Edentulous cancer patients who do not achieve oral rehabilitation after cancer surgery can exhibit significant psychological challenges.[114] New approaches to maxillomandibular defects effectively provide a more conventional setting for prosthetic reconstruction of the dentoalveolar arch and surrounding structures. Composite free flaps from the fibula, iliac crest, and scapula regions address both the bone defects as well as the soft tissue requirements to restore the oral cavity, as well as the midface region.[39,45,61,115] Preservation of tongue motion and the restoration of tongue volume are critical in obtaining a favorable functional outcome if tumor extension involves a significant portion of the tongue or floor of the mouth.[95] Vascularized bone-containing free flaps (VBFF) can be used to restore continuity defects of the mandible or reproduce the stable base of the maxilla. Vascularized bone flaps from the fibula or iliac crest donor sites provide vascularized bone required for the use of osseointegration to enhance prosthetic rehabilitation. Composite free flaps from the scapula region are selected when the soft tissue requirements of the defect are significant or when the use of the fibular donor site is contraindicated due to the poor

vascular runoff in the lower extremity or advanced age of the patient. However, the scapular flap has a comparatively poor bone volume for osseointegration. Despite this anatomic limitation, it is often possible to place two to four implants into the scapular bone, probably not more than 10 mm in length, for support of a removable prosthesis.[38,73]

The fact that a bone-containing free flap brings its own blood supply presents additional strategies for implant-assisted prosthetic rehabilitation of acquired defects resulting from the treatment of large benign and malignant tumors of the jaws. The rich vascularity of the transferred bone provides a substrate for osseointegration allowing implant placement prior to the delivery of adjuvant radiation therapy. Placement of implants at the time of the initial reconstructive procedure shortens the overall treatment time to achieve prosthetic restoration. Following primary placement of implants, the restorative team must allow 12 to 16 weeks for undisturbed healing and osseointegration of the fixtures.[116] Once the patient completes radiation therapy and the soft tissue reaction from the radiation treatment has subsided, the fixtures are uncovered. At that time, soft tissue modification such as flap debulking or vestibuloplasty procedures can also be performed. A surgical stent can be used and secured to the implants for healing purposes prior to the fabrication of the definitive prosthesis. The surgical stent can be made with or without teeth depending on the clinical situation and the desire of the patient. The stent promotes undisturbed healing, maintains vestibular height, and improves the function and appearance of the lips and mouth.

Primary implant placement is key in developing a comprehensive approach to ablative surgery, subsequent reconstruction, and prosthodontic rehabilitation with adjunctive radiation. This also holds true for placement of implants into native bone at the time of tumor resection to optimize prosthetic rehabilitation without any additional surgical reconstructive procedures. Primary placement of implants can circumvent the need for hyperbaric oxygen prior to secondary placement of fixtures in patients who receive radiation therapy following their reconstruction.[81] In addition, primary placement of implants minimizes time with an unstable prosthesis and compromised function in the edentulous patient. We reported an 86% rate of success of implants placed into VBFF in the primary setting who were subsequently radiated (n = 81 implants).[117]

If a patient has received irradiation to the head and neck region, it is

important to review the simulation plan, including dosimetry and fields, to determine whether native bone or the VBFF has been adversely affected, resulting in a compromised situation for osseointegration. Patients who undergo hyperbaric oxygen protocol[118,119] do so to enhance the vascularity of the surgical bed prior to implant surgery. Hyperbaric oxygen has been reported to be beneficial to postradiated native mandible[120,121] and fibula free flaps.[122,123]

The decision for fixed versus removable prosthetic restorations is dependent upon clinical factors such as bone availability, the number and position of implants to assist or support the restoration, maintenance of hygiene, and manual dexterity of the patient. In addition to these clinical factors, other comfort and psychosocial considerations will also affect prosthetic design. When addressing the reconstruction of the dental arch with osseointegrated fixtures, our preference is to provide patients with a fixed implant-supported restoration. In cases where the remaining arch is edentulous and where a lateral mandibular free flap reconstruction is performed, the fixtures should be placed in the anterior native mandible. This is an ideal location for implant placement in patients undergoing lateral jaw resection for posterior alveolar or floor of mouth/lateral tongue or tonsillar primary tumors because this area is usually spared of radiation. To minimize cantilever forces of the distal extension of the prosthesis, it is advisable to place a minimum of four or five implants with the greatest anterior–posterior spread to restore the total dental arch. Posterior placement of the distal implant on the contralateral side of the mandible is potentially limited by the inferior alveolar neurovascular bundle and mental nerve. Three to four implants placed into VBFF are recommended for unilateral maxillomandibular defects. As the defect crosses the midline, more implants are necessary to support the prosthesis requiring up to six implants to support a fixed restoration.[124]

There are also issues of peri-implant soft tissue maintenance. When muscle from the free flap is used for lining the oral cavity, the neomucosa around the implants might require repeated surgical debridement of hyperplastic inflammatory tissue around the transmucosal abutments. This problem may require excision and simple repair or possible split-thickness skin grafting (STSG) if there is repeated robust growth of this unwanted tissue.

The advantages of the fibula free flap have made this a “workhorse” flap for mandibular reconstruction. The length of the bone that can be harvested allows for near-total mandibular reconstruction (from condyle to condyle). There is good to excellent bone stock for osseointegration. The bicortical nature of the fibula offers ~12 to 15 mm of bone height for endosteal implant placement.[37] Unlike the scapula or iliac crest free flaps, which are monocortical, implants placed into the fibula should engage both cortices to improve initial stability, osseointegration, and the longer-term ability to resist masticatory forces.[125]

The fibula is tubular and triangular in cross section and the three surfaces have dedicated characteristics. One surface has cutaneous perforators arising from the peroneal artery and vein, the vascular pedicle runs along another surface, and the lateral aspect is used for internal fixation hardware that will secure the flap in position to allow for undisturbed bone healing. The orientation of the skin paddle will determine whether the base or apex of the triangle is oriented as the neoridge of the maxilla or mandible.[42] These factors have significant implications as to whether implants can be placed in the immediate setting, at the time of the surgical reconstruction.

The use of the fibula can present a geometric challenge for prosthetic reconstruction. The fibula is best positioned at the inferior border of the mandible to reproduce contours of the lower third of the face. This may lead to an intraoral alveolar height discrepancy with the native mandible. Additionally, because the alveolus is naturally positioned lingual to the inferior mandibular border, the fibula will be positioned such that implants will be facial to the dentition in the opposing arch. In such cases, an implant-assisted removable overdenture can be constructed so that lip and cheek support and oral competence are promoted. The use of a bar framework positioned lingual to implants can overcome the height discrepancy and facial position. The contours of the mandibular prosthesis can provide support to the lower lip to restore projection and symmetry to the lower face. The loss of motor function from injury of the marginal mandibular branch of the facial nerve can be ameliorated with this means of lip support.

A critical step to optimal functional rehabilitation involves the restoration of bilateral occlusal contacts, where occlusal guidance and protection schemes are restored to that of a fully dentate individual. The position of the mandible is determined by both condylar elements and dental occlusion.

Reconstruction of the mandibular discontinuity defect with a VBFF allows for both condylar determinants to function normally. The status of the occlusion and dentition will have a significant effect on function. Rehabilitation with a fixed dental prosthesis (FDP) provides better results for functional mastication and facial aesthetics as well as less discomfort and psychological disability than removable of prosthetic counterparts.[126–129] These restorations are screw retained, allowing the prosthesis to be retrievable as opposed to a cemented restoration. This design facilitates surveillance of the soft tissue beneath the denture.

Treatment planning should involve the placement of more implants rather than a minimum number for support of a fixed restoration. In the event of an implant failure, prosthetic success is still achievable with a shorter restoration of the dental arch or an implant-assisted overdenture.

Other approaches have been used to overcome the height discrepancy of the fibula free flap relative to the native mandible. One is to position the fibula more superiorly and use the reconstruction plating system to reproduce contours of the inferior border. Another is the “double-barrel” technique where the fibula is folded to increase the height of the bone and reduce the discrepancy between the occlusal plane and reconstruction.[130,131]

The significant height discrepancy of the fibula to the occlusal plane can be overcome by employing a cast mesostructure–superstructure design for a screw-retained fixed restoration. The mesostructure is milled so that the implant support is centralized over the mandibular neoridge and the corresponding superstructure acts as a fixed partial denture set with screws into the mesostructure. This type of prosthetic restoration allows the significant height discrepancy from the implant head to the occlusal plane to be mitigated by two corresponding milled framework structures. Prosthodontic framework design, with the use of computer-assisted planning, improves predictability for implant rehabilitation after VBFF surgical reconstruction. Implant position and angulation is determined from computer tomography (CT) scans where tooth position is visualized.

Computer-assisted planning (CP) is a novel technologic addition to surgical reconstruction and implant placement. We consider its application routinely for patients with VBFF surgical reconstruction of maxillomandibular defects. In the absence of postoperative radiation, secondary placement of implants with CP is an approach that adds accuracy

and facilitates rapid prosthodontic rehabilitation, within 4 to 6 weeks following VBFF reconstruction. One of the additional benefits of computer planning is the ability to place implants in a way that avoids the screws associated with rigid fixation. Alternatively, the decision can be made to remove internal fixation hardware that may interfere with the placement of a sufficient number of implants for a fixed restoration. In this situation, implant surgery is performed once bony union of the VBFF osteotomies is established, ~6 to 8 weeks after surgical reconstruction. We reported a retrospective case series (n = 28 patients) in which computer-aided design and computer-aided manufacturing (CAD–CAM) were employed. The inclusion criteria were patients who underwent VBFF reconstruction and computer-assisted planning for FDP restoration in preparation for implant surgery. Implant success, with immediate load (IL), as well as provisional and definitive FDP restorations in VBFF, was reported for the first time in a patient cohort.[132] Patients were evaluated for implant success; CT-derived surgical templates, immediate provisional restorations, and prosthodontic framework design.

Ninety-nine osseointegrated implants, of the 116 implants placed, were used for prosthetic restorations achieving an 85.4% success rate. One hundred and two implants achieved osseointegration (87.1%). Twenty-five of 28 patients (89.3%) received definitive implant-supported FDP restorations. Two patients received removable implant-assisted restorations, and one patient was unable to complete rehabilitation due to implant failure. Thirteen (13) of 28 patients received immediate or early-loaded fixed restorations at the time of stage I implant surgery. The success rate for implants that were placed in the immediate restoration group was 89.3% (50/56). All 13 patients with immediate restorations had CT-derived surgical templates for their implant surgeries. Twelve of 13 immediate restorations were successful.[132] Computer-assisted implant rehabilitation may enhance the chances for functional recovery for patients who undergo maxillomandibular reconstruction with VBFF. Although overall treatment time may be similar to those patients without immediate restorations, this approach is justified based on the potential to provide patients with fixed provisional restorations during the time for osseointegration and definitive FDP fabrication.[132]

Dental Implantation in Palatomaxillary Reconstruction

Obturators can provide a safe and effective way to successfully restore maxillectomy defects and remain a standard to maxillofacial prosthetic rehabilitation. There are shortcomings though to functional recovery. As defects become larger, nasal escape can compromise speech and swallowing. These side effects also have implications on patient comfort and psychosocial interaction, making surgical reconstruction of palatomaxillary defects a more comprehensive and ideal approach to achieve optimal functional rehabilitation.[133,134]

The use of vascularized free bone flaps to reconstruct large palatomaxillary defects achieves surgical closure and restores the alveolar defect as well as providing a platform for the placement of osseointegrated fixtures.

Our classification system essentially addresses size and location of palatomaxillary defects and considers the biomechanical properties that contribute to prosthetic instability and compromised function.[91] As noted in the discussion above on palatomaxillary reconstruction, larger defects lend themselves to the introduction of VBFFs to provide palatal closure and favorable bone for implant placement. In the event that a fibula is used, the bone should not be used for final projection and support of the lip and mouth. That role is given to the definitive prosthesis and tooth replacement. VBFF plating to the nasomaxillary buttress is positioned just beneath the anterior nasal spine, the pyriform aperture, and the nasal sill. The maxillary anterior teeth are facial to this plane, such that implant placement would then be favorable for a prosthetic restoration. However, there is a tendency for bone availability to be more lateral as the reconstruction moves posterior toward the zygoma. This may lead to implants that are placed in a position that is facial to the dental arch, surrounded by movable cheek mucosa, becoming poor candidates for prosthetic rehabilitation. CP with a radiographic scanning appliance can improve implant position to overcome this relationship. Vascularized bone offers the ability to re-establish the bony dental arch for the placement of osseointegrated implants, which allows for the distribution of masticatory forces across an intact maxillary arch. Surgical reconstruction with fibular or iliac crest free flaps and implant-supported fixed dental prostheses replace analogous structures of a stable palatomaxillary complex. An FDP restoration for a class II defect reconstructed with VBFF leaves remaining sensate palatal mucosa exposed over the tongue promoting

lingual–palatal feedback during function. Furthermore, the VBFF permits the primary reconstruction of the orbital rim and the prominence of the zygomatic body with autologous tissue.[135]

A class III defect extends beyond the midline, involving both canines and ipsilateral molar dentition resulting in a bilateral defect with poor prosthodontic prognosis and severely compromised speech and swallowing. Class III defects are best restored with a VBFF, patient factors not withstanding. As a maxillectomy defect increases in size and the remaining dentition and palate decreases in size, a VBFF is clearly preferred over a fasciocutaneous or musculocutaneous free flap for functional recovery. VBFF reconstruction, osseointegration, and an FDP can restore stable dentoalveolar structures and occlusal contacts to optimize speech and swallowing functions.

SPEECH AND SWALLOWING ASSESSMENT

Evaluation of the patient’s voice, speech, and swallow functioning pre- and post treatment is critical to accurately define functioning at baseline and at periodic intervals after treatment of head and neck cancer. The evaluation should include a thorough assessment of vocal tract functioning, a clinical and instrumental assessment of swallowing, a determination of overall performance status, and administration of patient-rated quality of life (QOL) scales to assess patient QOL. In order to track change in function over time and better predict function with treatment, assessments should be conducted at defined periodic timepoints, including pre- and post treatment (i.e., 1, 3, 6, 12, 24, 36 months post treatment).[136,137] Specified evaluation timepoints enhance the ability to define function over time within patients as well as comparisons between patients undergoing similar or different treatment modalities.

The functional assessment should include a clinical identification and severity rating of any speech, voice, resonance, loudness, rate, or breath support impairment during conversational speech. A thorough oral mechanism examination, with assessment of the lip, tongue, palate, larynx, and jaw range, rate, coordination, and strength of motion for isolated and rapidly repeated/alternated nonspeech and speech tasks. Symmetry and

accuracy of motion should be examined. Surgical interventions should be identified with the intraoral examination, with identification of microvascular flap reconstructions and potential impact on function. Range of motion should be measured for lingual tasks including protrusion and lateral motion, and jaw opening should be measured using the TheraBite measuring disc.[138,139] We have developed a novel tongue ROM measuring system to quantify lingual mobility in the surgically treated partial glossectomy patient. This system takes into account lingual protrusion, lateral motion to the commissures, and lingual elevation to the upper alveolar ridge.[139] Lingual strength should be assessed using a manometric measure, such as the Iowa Oral Performance Instrument (IOPI) or tongue bulbs via the Kay-Pentax Swallow Station.[136,140] Salivary production should be measured, particularly if the patient is to undergo and/or has undergone adjuvant irradiation or chemoradiotherapy. The Saxon test is a simple measurement tool whereby the patient chews on a dry 4 × 4 gauze, which is weighed dry and after 2 minutes of chewing.[141] Laryngeal function testing should include clinical assessment of laryngeal function for phonation, cough, and throat clearing, as well as formal acoustic analysis of variables such as fundamental frequency for speech (F0), absolute intensity, pitch and intensity perturbation measures, signal-to-noise and noise-to-harmonic ratios, and maximum pitch range. Respiratory function testing for phonation should include maximum phonation times for sustained /a/ following normal and deep inhalation and well as loudness testing. Resonance testing should be performed particularly with individuals undergoing hard and soft palate resection. This assessment can include nasality testing utilizing a Nasometer or aerodynamic assessment of nasal/oral airflow during phonation utilizing devices such as the Rothenberg mask.[142,143] Oral function testing should also include examination of one- and two-point discrimination for the lips and tongue, as well as assessment of taste sensitivity.[86,144,145]

Performance status should be assessed with reliable and validated tools, such as the Performance Status Scale that examines diet type (i.e., Normalcy of Diet domain), speech understandability (i.e., Understandability of Speech domain) and impact of surgery on ability to eat socially (i.e., Eating in Public domain).[146,147] Clinician-rated voice scales include the grade, rough, breathy, asthenic, strained (GRBAS) scale and the CAPE-V.[148–150] The Karnofsky Performance Scale, a clinician-rated scale of overall functional impairment,

can also be administered.[151]

Patient-rated QOL scales should be administered to establish a baseline and examine the effects of treatment on patient-rated QOL, including speech, voice, swallowing, and overall head and neck QOL. Reliable and validated voice and speech QOL tools include the Speech Handicap Index, the Voice Handicap Index, VHI-10, and Voice-Related QOL.[152–156] There are many swallowing QOL scales, such as the SWAL-QOL, EAT-10, MD Anderson Dysphagia Inventory, University of Washington Quality of Life Instrument, Vanderbilt Head and Neck Symptom Survey, and Head and Neck Cancer Inventory that are patient-rated symptom-specific scales.[157–162] In addition, other QOL instruments such as the EORTC-HN35 and the FACT-H&N, measure symptoms such as xerostomia, taste changes, pain, fatigue, etc, which are related to head and neck cancer treatment and can have an impact on overall QOL.[163,164]

Instrumental assessment of swallowing should be performed to evaluate swallow physiology. The videofluoroscopic swallow study (VFSS), also known as the MBS assessment, should be conducted to assess oropharyngeal swallow physiology, as well as screen esophageal phase swallow functioning.[165,166] Once the swallowing impairment is defined, therapeutic strategies are implemented during the evaluation to determine whether swallow safety or efficiency can be improved.[165] Flexible endoscopic evaluation of swallowing (FEES) can also be utilized to assess pharyngeal phase swallowing and infer components of oral phase functioning.[167] Therapeutic strategies can also be implemented during the FEES examination to determine whether swallow safety or efficiency can be improved. Alterations in anatomy that result from ablative and reconstructive surgery can be identified with both techniques. Baseline instrumental assessments are recommended pretreatment to define initial swallow functioning.

During the functional assessment, once the speech or voice impairment has been identified, trial therapeutic strategies should be attempted to determine whether the impairment can be modified, such as improving articulatory precision in a dysarthric oral cancer patient, improving voice quality in a dysphonic patient, or improving intelligibility by modifying rate, loudness, or breath support in a patient with reduced intelligibility. In addition, therapeutic exercise strategies can be implemented once

instrumental assessment of swallowing has been conducted to improve oral and pharyngeal phase swallow functioning.[168]

Outcomes

Functional outcomes, including oral outcomes, performance status, and patient-rated QOL, have been examined in patients who have undergone oral tongue resections. Although patients overall demonstrated lower maximal lingual strength than seen in healthy individuals, patients who demonstrated lingual strength above a cutoff of 30 kPa demonstrate better speech and swallow functioning, performance status, and QOL than those with lingual strength <30 kPa.[136] Jaw ROM also correlated with normalcy of diet and performance status.[136] In addition, performance status correlated with patient-rated QOL in these patients. Adjuvant therapy of radiotherapy or chemoradiotherapy resulted in significantly poorer functioning.

Tongue ROM has been found to correlate with performance status, oral outcomes, and patient-rated QOL in the partial glossectomy patient.[139] In 36 patients who underwent ¼ to ½ tongue resection with and without free flap reconstruction, patients overall demonstrated lower tongue ROM scores than seen in healthy individuals. However, these patients scored a mean of 75 on the Performance Status Scale Normalcy of Diet domain,[145] indicating crunchy solid foods, as well as a score of 83, indicating ability to eat in public, despite any diet modification. The Karnofsky Performance Status mean score for these patients was 93, indicating the ability to carry on normal activity. Diet type correlated with tongue ROM, with higher tongue ROM scores correlating with fewer diet restrictions. Patient-rated QOL in these patients revealed overall scores of mildly impaired eating QOL. When examining tongue ROM and QOL, tongue ROM significantly correlated with QOL, with higher tongue ROM values correlating with improved QOL. A similar correlation was found with the Speech Handicap Index QOL scores and tongue ROM, with higher tongue ROM scores correlating with better speech QOL scores. Lingual ROM post surgery clearly plays a role in ability to eat and speak and has an impact on patient-rated QOL. When examining the effects of surgery including microvascular free flap reconstruction for ORN of the mandible on functioning, the majority of patients reported improved QOL after ORN surgery.[169] Further, QOL for speech, swallowing, and overall functioning correlated with oral nutrition and performance

status.[169] ORN surgery did not, however, markedly improve swallowing-related QOL for those individuals with preoperative dysphagia due to chemoradiotherapy. Patients undergoing ORN procedures need to be counseled regarding the potential negative impact of prior dysphagia on swallowing after surgery.

CONCLUSIONS

There have been major advances in the management of cancer of the head and neck over the past two and a half decades. Technology has had a significant impact on head and neck reconstruction, impacting on the safety and reproducibility of microvascular surgery and functional dental rehabilitation. The important steps that have led to the current “state of the art,” namely, identification of reconstructive problems, creative problem solving, and then assessment of functional outcomes, must be followed into the future in order to continue to enhance the QOL of patients who undergo reconstruction following surgery for cancer of the head and neck.

29 Oral and Maxillofacial Rehabilitation of Patients with Head and Neck Cancer

Richard C. Cardoso Theresa M. Hofstede Patricia C. Montgomery Jack W. Martin Adam S. Garden Ruth A. Aponte-Wesson, Alexander M Won. , Mark S. Chambers

INTRODUCTION

Optimal care of patients with cancer of the head and neck requires the combined efforts of a team of health care providers whose collective goal is not only to cure patients of malignant disease but also ensure the well-being and maintain quality of life of patients during and after treatment. In most patients with cancer, challenges seen in the oral cavity mirror those of the general population—moderate to advanced periodontal disease, dental caries, poorly restored dentition, dental and soft tissue pathologies associated with the use of tobacco and alcohol, poor nutritional status, general hygiene neglect, or a combination of these factors.[1,2] Evaluation, treatment, and prevention of any preexisting oral and dental disease are important aspects of the overall treatment outcome for patients with cancer.[1,2] Patients undergoing aggressive anticancer treatment encounter treatable, if not preventable, oral mucosal and dental sequelae that, if left untreated, could produce morbid events.[3] Complications vary with each patient, depending on the individual's oral and dental status, the type and location of malignancy, and the therapeutic approach.[4] Common and frequent treatment-limiting factors, such

as mucositis, infection, and bleeding, can be minimized and, in some cases, eliminated, if evaluated and treated early by an involved, trained oral oncology team. Early dental intervention can also decrease risk factors for oral complications [e.g., osteoradionecrosis (ORN)]. In some cases, ablated structures can be replaced immediately with prostheses that restore function and esthetics thereby maintaining quality of life.

Treating physicians have a medical, ethical, legal, and fiscal responsibility to ensure that patients receiving surgery, radiation therapy, and/or chemotherapy for cancer of the head and neck receive a thorough, systematic oral examination.[1,4] For decades, physicians have placed a major emphasis on the prevention of malignancies through the identification and control of factors, such as tobacco use and alcohol consumption, which are associated with carcinogenic tissue changes.[5–10] Despite a decrease in smoking, however, the incidence of squamous cell carcinoma of the oropharynx continues to increase; this is attributed to infection by human papillomavirus (HPV).[11] HPV-associated cancers are thought to be more responsive to treatment, and therefore, a de-escalation of treatment has been suggested; however, the oncologic efficacy and preservation of function of this type of reduced treatment remain to be shown in prospective clinical trials.[11] Patients with HPV-related disease are generally younger, and given they have more curable disease, the likelihood is that these patients will live longer and thus have a greater cumulative risk of developing long-term complications including treatment-related oral and dental problems.

Therefore, careful coordination between head and neck oncologists of all disciplines must enlist oral health experts for the assessment and delivery of preventive and rehabilitative oral care prior to the initiation of oncologic treatment. Miscommunication or lack of communication between the treating oncologists and oral health experts can contribute to posttreatment complications.[12,13] Oral oncology/maxillofacial prosthodontics is the branch of dentistry specifically concerned with minimizing the oral morbidities associated with cancer therapy and includes the prosthetic rehabilitation of intraoral and extraoral structures that have been affected by disease, injury, surgery, or congenital malformations.[14,15] Patients should be referred to the oral oncologist as early as possible to ensure the appropriate assessment of their oral/dental status, discussion of the prosthetic treatment options of oral/facial defects, and patient education to minimize the oral morbidities

associated with cancer care. The primary head and neck oncologist can then integrate results of this evaluation into the overall treatment plan.

This chapter describes the scope and integration of oral oncology concepts into the treatment of patients with cancer as well as general and specific aspects of oral complications arising from cancer therapy and outlines practical approaches for preventing, recognizing, and treating the oral sequelae associated with chemotherapy and radiation therapy. This chapter also presents current concepts regarding oral and facial prosthetic rehabilitation and oncologic principles associated with the care of patients with cancer of the head and neck.

GENERAL CONSIDERATIONS

An oral/dental consultation before chemotherapy, radiation therapy, or head and neck surgery is extremely important in the oral management of patients with head and neck cancer.[1,16–21]

Oral complications associated with cancer therapy can be classified into several general types—acute (i.e., stomatitis, infection, bleeding, mucositis, and pain) and chronic (i.e., loss of function, ORN, and xerostomia).[22] In most cases, preexisting conditions strongly influence the development or persistence of these complications in the oral cavity. Simple measures, such as good oral hygiene, can often minimize treatment-induced morbidities (i.e., reduce the incidence and severity of mucositis). Complications arise primarily in three anatomic sites—the mucosa, periodontium, and teeth.[4]

Complications arising during cancer therapy may result either from the malignant disease process itself or from treatment (e.g., complications of chemotherapy related to myelosuppression/immunosuppression, or direct cytotoxic effects of chemical agents on oral tissues). For patients receiving a tumor-ablative procedure involving the oral cavity or oropharynx, the treating oral oncologist should aim to control oral and dental complications. As part of the immediate surgical planning, the oral cavity should be prepared for appropriate prosthetic rehabilitation to correct postsurgical defects. If radiation therapy or chemotherapy or both are planned, the treating physician should be aware that the possibilities of oral complications may be increased; furthermore, the degree and type of oral sequelae may affect the patient's compliance with or continuation of cancer treatment.[23–26] Radiation therapy

may directly damage oral mucosa, salivary glands, bone, and oral musculature, resulting in xerostomia, infection, ORN, trismus, dermatitis, extensive dental caries, abnormal bone development and healing, and alteration in taste acuity.[1,17,27,28] Preexisting oral disease may increase the risk and severity of oral complications.[17,25,29,30]

An evaluation of the head and neck, an oral/dental clinical examination, and an intraoral radiographic evaluation should all be performed during the initial visit. Selected dental radiographs are essential in evaluating potential areas of infection that are not obvious on clinical examination (e.g., periapical tooth disease, interproximal caries, residual cysts, and impacted or partially erupted teeth). In addition, the oral oncologist should gather and record the patient's history of present illness, past medical and dental history, social history, review of systems, current medications, and adverse drug reactions, as well as the anticipated cancer treatment plan. From this information, the oral oncologist can plan treatment to meet oral needs in the context of the patient's overall status; however, treatment of malignancy must always take priority over reduction of potential complications.[1,31] Complicated, laborious, and costly prosthetic restoration of teeth should be avoided until after cancer therapy is completed. The overall oral/dental goal is to remove not only current foci of infection but also potential foci of infection as this may increase the risk of ORN and other oral challenges (i.e., teeth that are nonfunctional, noncleansable, and nonrestorable).

The oral oncologist should communicate with the treating physicians to be aware of the diagnosis and staging malignancy, the goals of proposed therapy, the patient's prognosis, the type and dose of therapy to be administered, and the timing of treatment. If radiation therapy is to be used in the head and neck area, the oral oncologist must know the volume of tissue to be radiated, the treatment schedule, the dosimetries, the fractionation scheme, the method of administration (e.g., external beam radiation therapy or brachytherapy), the type of energy (e.g., proton, photon, or electron), and the total dose to be administered.[16,18,32–36]

Oral oncologists should educate patients using tobacco, alcohol, or illicit drugs as to the harmful physical effects of these agents and explain their possible impact on oral health as well as the malignant disease process.[37,38] In addition, the treatment team should immediately discourage further use of these substances and should provide information about and referrals to

cessation programs. The nutritional status of patients should be assessed, and counseling should be provided, if needed, to enable patients to avoid debilitation, which may result in delayed wound healing and increased susceptibility to dental caries.[27,28,39–41]

The oral oncologist's initial examination and early treatment of the patient are directed at documenting and managing any preexisting acute or chronic pathologic conditions, such as dental abscesses, advanced periodontal disease, dental calculus causing gingivitis, partially erupted teeth with the potential for pericoronitis, or soft tissue trauma, which may be factors in the treating physician's selection of an overall cancer treatment strategy.[1,22] Even if the planned cancer treatment is not toxic to the mucosa and is not myelosuppressive, the potential for oral complications remains. Additionally, the cancer may eventually progress, requiring prompt and aggressive therapy; for that reason, the patient's oral and dental status should be optimized to ensure minimal predictable complications. The periodontal status and degree of tooth decay are evaluated, as are the patient's ability and initiative to maintain optimal oral hygiene.[42] Patients must modify their oral care and hygiene techniques to minimize mucosal, gingival, and dental complications that are associated with their specific treatment.[42–44]

One major objective of oral hygiene is to reduce and minimize the formation of plaque—a proteinaceous, adherent, bacteria-laden material on teeth or dental prostheses. Plaque is colonized by normal flora, which is then followed by opportunistic pathogenic organisms. Its accumulation can lead to several harmful conditions, including gingivitis (inflammation of the gingiva), which can progress to periodontal disease (the pathologic loss of supporting bone).[4] Caries is another adverse condition resulting from increased caries-forming organisms and is in itself an important consideration in patients with drug- or radiation-induced xerostomia. Gross caries can result in pulpal involvement and subsequent periapical abscess formation and thus increase the risk of ORN.[4,42,45]

Oral surgery, definitive or intermediate direct restorations, and oral prophylactic procedures may be performed quickly and safely, if needed, under local dental anesthesia, intravenous sedation, or general anesthesia, to expeditiously remove acutely and chronically infected tissues. The oral oncologist must review the patient's medical and hematologic status with the

treating oncologist before initiating any such oral/dental treatment.[46] Prophylactic periodontal procedures and scaling/root planing may be necessary before or during cancer treatment to reduce the oral contamination. Oral hygiene instructions for plaque removal should be emphasized and encouraged, including brushing twice daily with fluoride toothpaste and flossing at least once a day. Oral hygiene procedures may require modification during cancer therapy—for instance, using an extra soft–bristled toothbrush and daily use of topically applied fluoride (e.g., 0.4% stannous fluoride, 1.1% sodium fluoride, or 5,000 ppm sodium fluoride). Customized carriers for fluoride application should be constructed for patients undergoing head and neck radiation therapy and should be used throughout the remainder of the patient's life following radiation therapy.[1,46] Sodium bicarbonate or chlorhexidine gluconate mouth rinses may be beneficial to the patient in reducing microbial and fungal contamination.[47] The prescribed mouth rinse should be carefully selected because some ingredients, such as alcohol and phenol, can be irritating to oral mucosal tissues.

Oral treatment plans should be designed to correct restoration with overhangs, rough or sharp edges on teeth, and any other defects likely to cause soft tissue irritation.[1,48] Patients should be instructed to avoid abrasive foods likely to traumatize soft tissues. Ill-fitting intraoral prostheses should be adjusted to improve fit or not be worn during cancer therapy. Dental implants should be carefully assessed, and their removal should be considered if osseointegration is poor. The implants should not be removed if the implant is stable or if such surgery cannot be performed within 2 weeks before the initiation of cancer therapy.[49–51]

Any potential source of oral infection should be identified and eliminated. Findings of periapical disease, severe periodontal disease, unrestorable teeth with advanced caries, supererupted teeth, and possibly unopposed dentition should be considered for extraction. Endodontic therapy is a viable alternative for infected dentition, provided that the treatment can be expeditiously performed and not delay initiation of cancer therapy.[21,45] To ensure coverage of exposed bone and adequate wound healing, extractions should be performed 2 to 3 weeks before initiation of radiation therapy.[24,52–55] Dental extractions should be performed as atraumatically as possible, and all sharp areas of bone should be removed. This allows for primary closure, which promotes rapid healing.[21,55] ORN can occur in areas

in which teeth were extracted before radiation therapy.[55–57] Sufficient healing time is critical, particularly before radiation therapy is initiated. In general, invasive periodontal surgical procedures should be avoided due to prolonged healing time for the desired results to be achieved.

Patients receiving myelosuppressive or immunosuppressive drugs can develop posttreatment oral or systemic infections, with virus (e.g., herpes simplex virus [HSV]), fungi (e.g., candidiasis), or Gram-positive or Gram-negative microorganisms believed to have originated in the oral cavity.[58,59] As a result, some oncology centers perform microbiologic cultures to assess HIV antibody titers, fungal activity, and microbes with appropriate sensitivity testing as part of the protocol for all oral-related toxicity from cancer therapy. In cases of a positive titer, use of an antiviral agent such as acyclovir, an antifungal agent such as nystatin, or an antimicrobial agent such as clindamycin is common.[60–62]

The following sections describe methods of integrating dental and oral treatment into specific oncologic therapies.

ORAL AND DENTAL ANATOMY

Head and neck surgeons and radiation oncologists should have a thorough knowledge of the oral and dental anatomy to enable accurate communication with the oral oncologist who is responsible for the patient's oral care. It is important to know which teeth will be removed as part of the surgical procedure so the oral oncologist can plan and fabricate an immediate prosthesis. The universal numbering system of teeth is most often used for this purpose. In this system, teeth are sequentially numbered in the adult from 1 to 32, starting with the right maxillary third molar (No. 1), going to the left maxillary third molar (No. 16), then continuing with the opposing left mandibular third molar (No. 17), and ending with the right mandibular third molar (No. 32) (**Fig. 29.1**).[63]

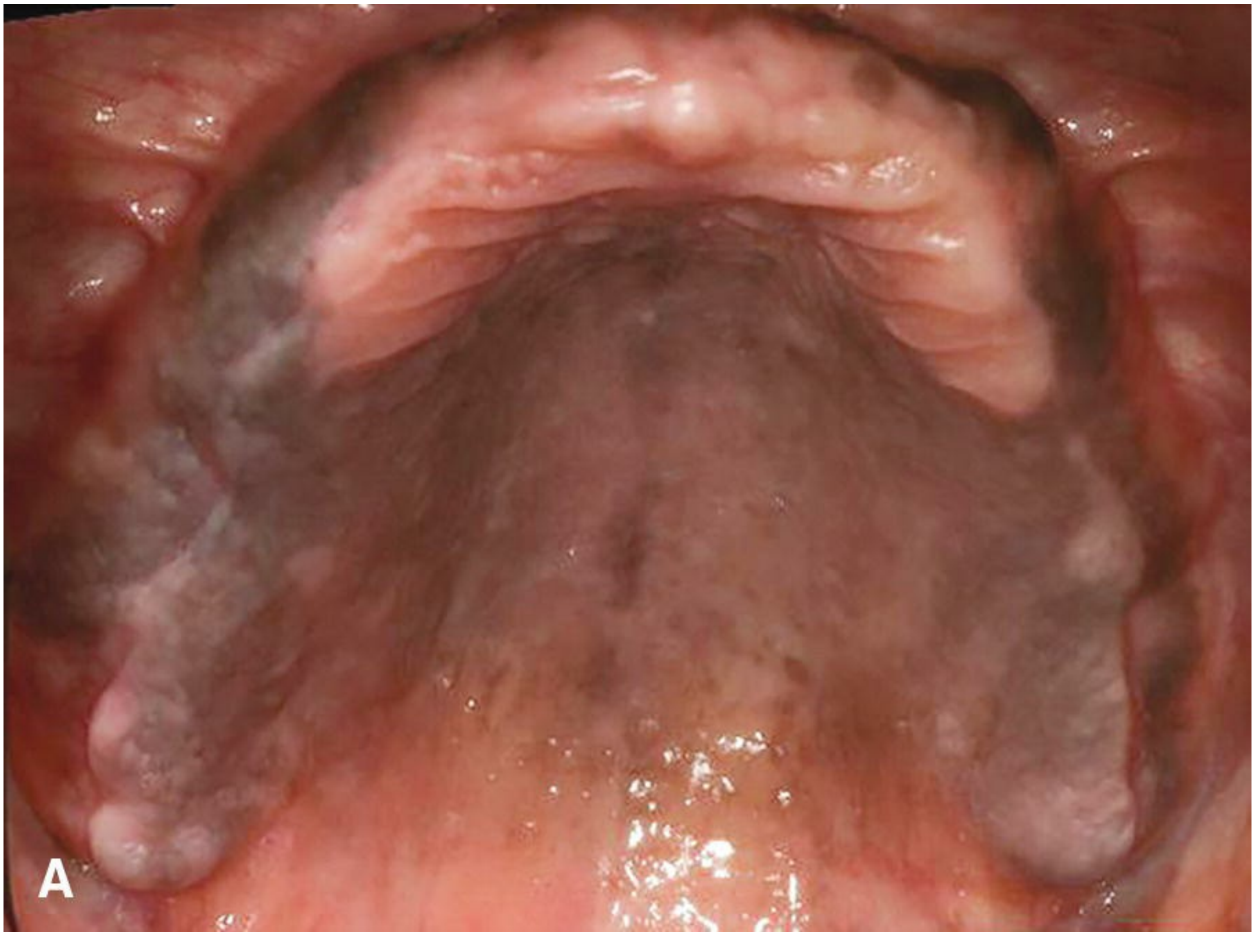
Figure 29.1. The universal numbering system is the accepted method of tooth identification.

Anatomic landmarks important in prosthetic rehabilitation in the edentulous maxillary and mandibular arches are shown in **Figure 29.2**. The stress-bearing surfaces of the edentulous maxilla for a maxillary prosthesis are the tuberosity, rugae, and palatal vault. A maxillary prosthesis is generally retained with suction; if these anatomic regions are not covered appropriately or missing, it is difficult to retain a prosthesis. The mandibular landmarks of importance are the alveolar ridge, retromolar pad, and buccal shelf. The buccal shelf is the primary stress-bearing area for a mandibular complete denture prosthesis. It is important to cover the retromolar trigone to prevent excess resorption of the mandible. Preserving, enhancing, or reconstructing these tissues is important for support and retention of a prosthesis. Teeth that are in good periodontal condition are, of course, essential for the retention and support of the prosthesis. Conservation of the supporting tissues, irrespective of disease removal, should be a priority.[64]



A

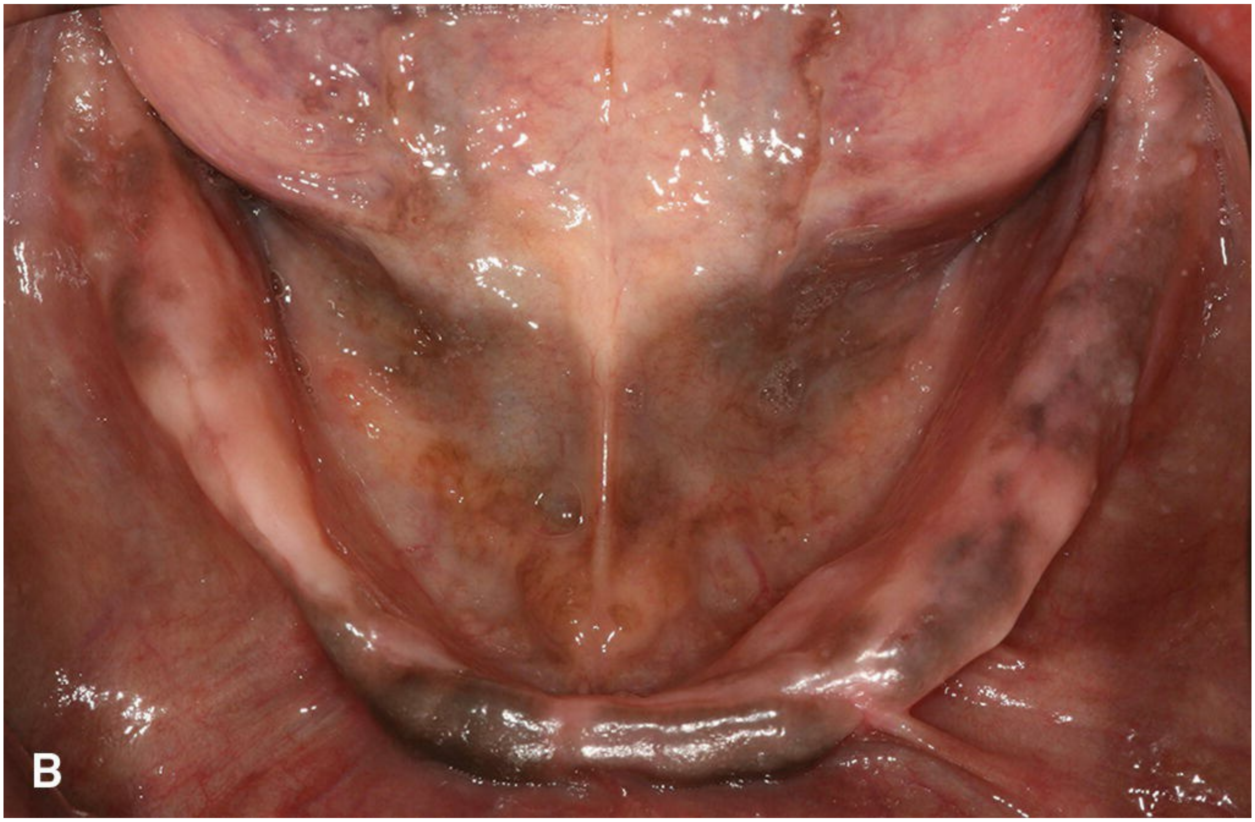


Figure 29.2. Areas that may support prostheses should be conserved, consistent with disease removal. **A:** In the maxilla, these areas include the tuberosity, palatal vault, and rugae. **B:** In the mandible, the areas are the retromolar pad, alveolar ridge, and buccal shelf.

ORAL AND DENTAL EVALUATION

Oral and dental evaluation by the head and neck oncologist should be included in the routine examination of the head and neck. The surgeon should be able to recognize acute or chronic pathologic conditions related to the dentition or supporting structures, such as advanced periodontal disease, gross dental caries, tissue irritation from poorly fitting prostheses, and poor oral hygiene[1] (**Fig. 29.3**). Oral and dental disease should be noted by the oncologist and referred to the oral health provider for evaluation and appropriate treatment.[31]

Figure 29.3. Gross caries, plaque, and calculus formation indicate poor oral hygiene and should be noted in the primary medical evaluation. Mobile teeth indicate bone loss and periodontal disease.

The initial oral–dental examination by the dentist will confirm any preexisting acute and chronic oral pathologic conditions (e.g., dental abscesses, teeth with advanced periodontal disease, or dental calculus causing gingivitis).[1] The dental clinician should obtain appropriate diagnostic radiographs. The most common diagnostic radiographs used in an oral–dental examination are panoramic, periapical, and bite wing radiographs. A panoramic radiograph gives an overall topographic picture of the dentition, maxilla, mandible, sinuses, nasal cavity, and temporomandibular joints.[65,66] These radiographs may be of diagnostic value to the treating oncologist (i.e., diagnosis of bony invasion of the maxilla or mandible by tumor) and are easily obtained in most dental offices (**Fig. 29.4**). Cone-beam computed tomography (CBCT) has become an invaluable tool not only in diagnosis of oral pathology but also in three-dimensional planning for endosteal implants (**Fig. 29.5**).

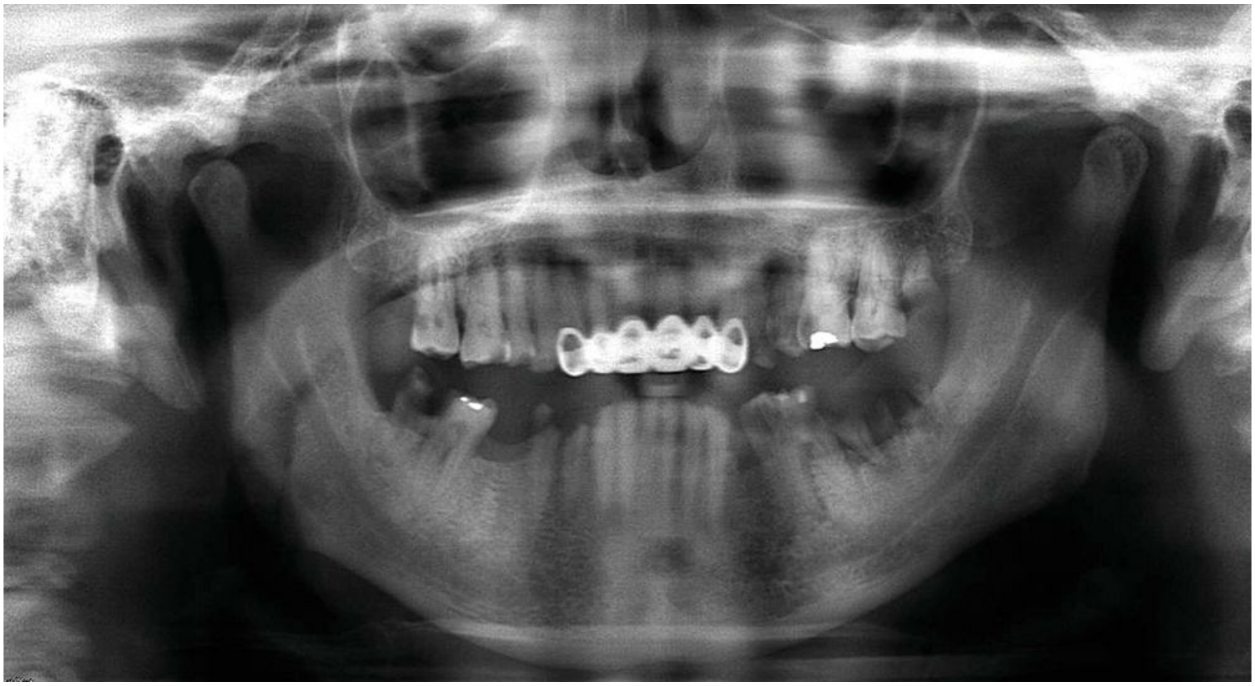

Figure 29.4. A panoramic radiograph is a valuable diagnostic aid that gives an overall impression of the dentition, maxillas, mandible, sinuses, and related structures. Note the broken teeth, rampant caries, and periapical abscesses in this patient, who has received head and neck radiation therapy and has developed multiple oral complications.

The dentition is evaluated with respect to its periodontal, restorative, and hygiene status. The oral oncologist should also determine the ability of the patient to maintain oral hygiene after the cancer treatment. Every effort should be made to eradicate any areas of infection before treatment

associated with the dentition. Nonrestorable teeth can be removed at the time of the ablative surgery. Teeth should not be removed indiscriminately because of their potential to support and retain a prosthesis. Impressions of the maxilla, mandible, or external facial structures are made at the time of initial evaluation; the casts obtained from these impressions may be helpful in fabricating surgical prostheses, if needed (e.g., a surgical obturator for a patient who has undergone a maxillectomy) (**Fig. 29.6**). Patients are instructed on oral hygiene methods and how oral physical therapy will play an important role in the postoperative rehabilitation period. Pertinent findings associated with the oral and dental examination are then presented at the multidisciplinary treatment planning session.[67,68]

Extraction of Troublesome Teeth

The following guidelines are used to identify potentially troublesome teeth for extraction prior to initiating radiation therapy to minimize the risk of ORN. Teeth within the volume of tissue to be radiated that demonstrate moderate or severe periodontal disease, advanced caries, or periapical pathologic conditions should be extracted. Also, partially impacted teeth, unopposed teeth, and teeth that would, if not extracted, oppose a segment of a resected jaw or complicate future prosthodontic rehabilitation should be

extracted. In addition, healthy teeth may need to be extracted if the patient is clinically judged to be unable to maintain adequate oral hygiene following radiation therapy. Fully or deep partially impacted third molars should not be extracted due to extended healing time and risk for permanent damage to the inferior alveolar nerve. Radiologic examination, with either a panoramic radiograph or a CBCT, is the most important diagnostic tool in diagnosing periapical infection, impacted teeth, intrabony cysts, or other hard tissue disease.

Patient Education

The evaluation appointment is the ideal time to present the patient with an oral hygiene protocol designed to minimize or prevent complications associated with radiation therapy to the paranasal sinuses, parotid, nasopharynx, oral cavity, oropharyx, and/or neck. Oral hygiene procedures designed to reduce plaque and oral flora must also be instituted. Because the effects of radiation are permanent, the patient must continue a fluoride protocol throughout his/her life.

Patients who receive radiation therapy to the head and neck area involving the major salivary glands experience reduced saliva flow (i.e., salivary hypofunction or xerostomia).[55] This permanent xerostomia results in dramatic increase in the susceptibility to dental caries, and the severity of the morbidity is dependent on the radiation dose, volume of tissue treated, and the age of the patient when treated.[1] Therefore, patients should be placed on a fluoride regimen as numerous studies have shown that fluoride reduces radiation-induced decay of teeth if used in a systematic, predictable manner.[69,70]

Caries is in itself an important consideration in patients with drug- or radiation-induced xerostomia (**Fig. 29.7**).[1,71] Reducing the potential for dental infection while maintaining optimal oral health can significantly decrease the risk of ORN in a patient who receives radiation therapy or a significant cellulitis in a patient who receives aggressive chemotherapy.[69,72,73] The surgeon should understand the importance of this concept and reinforce compliance at subsequent visits.

Figure 29.7. Radiation-induced xerostomia, as demonstrated by thick ropey saliva, can result in rapid onset and progression of rampant dental caries, which ultimately may result in ORN.

Meticulous oral, dental, and prosthetic hygiene is encouraged as soon as possible after head and neck surgery.[71] In general, patients are hesitant about starting oral and dental hygiene postoperatively because of a fear that the surgical site will be disturbed. Routine oral and dental hygiene can be initiated 2 weeks following surgery. In the immediate postoperative period, within a 2-week period, oral care may be limited to oral lavage and rinses.[1,69,71]

Interincisal opening can be challenging postoperatively, especially following a maxillectomy procedure. Postoperative physical therapy is an additional consideration in rehabilitation, and suitable techniques can be discussed and explained to the patient before surgery and reinforced postoperatively. Stretching can maintain the oral opening and allow the patient better access to the surgical defect and to the remaining oral cavity.[71,74,75] Simple opening exercises using wooden tongue blades or the

fingers may be effective in restoring normal opening after surgery (**Fig. 29.8A**). In more complex cases, devices such as the Therabite or Dynasplint can be implemented (Fig. 29.8B).[69,75]

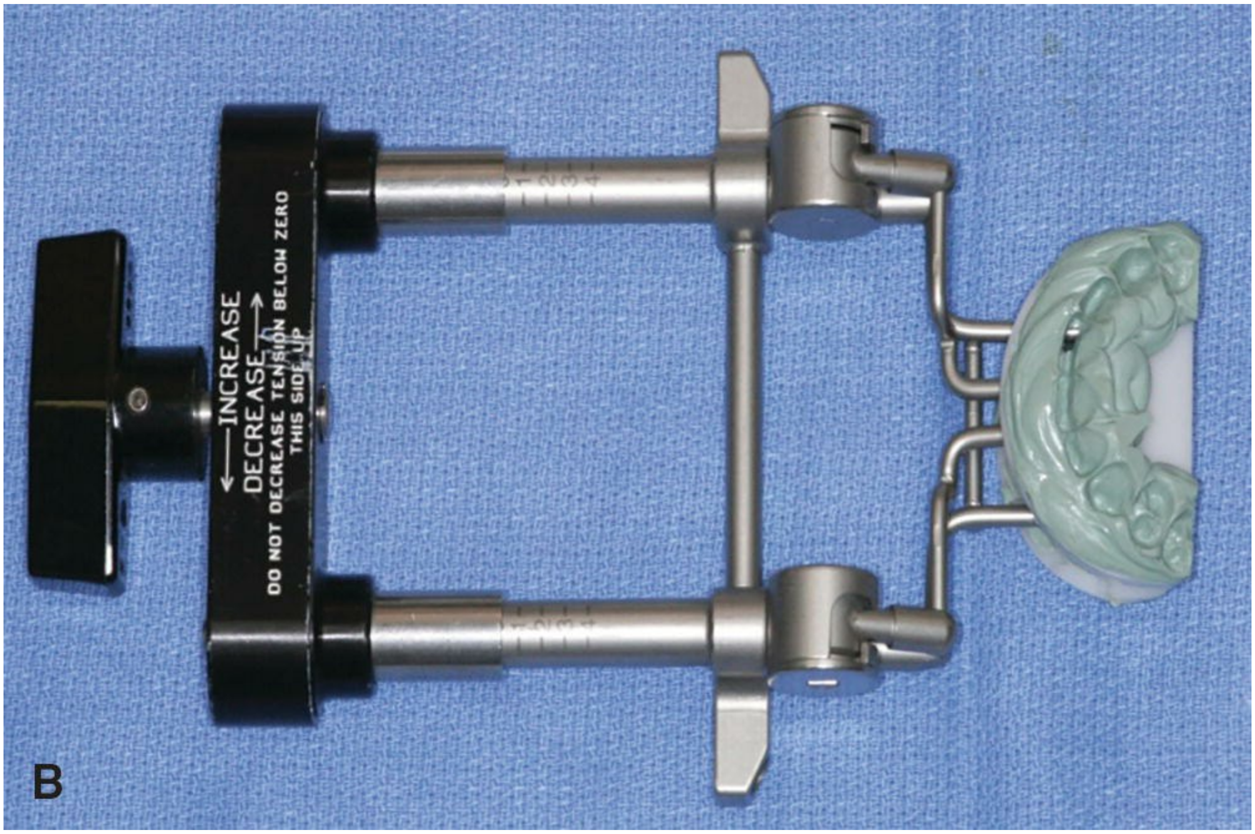

Figure 29.8. A: Physical therapy with active stretching may be helpful for maintaining the oral opening. **B:** A *JDS* device will stretch fibrotic tissues during healing and radiation therapy.

RADIATION THERAPY

More than 80% of patients diagnosed with cancer of the head and neck receive a course of radiation therapy as a component of their treatment.[1,76] Many small or early-stage tumors of the head and neck region can be treated with definitive radiation; more advanced disease often requires a combination of therapies. If surgery is a component of the management strategy for an advanced cancer, radiation may be sequenced so that it is administered either before or after the surgical procedure. Chemotherapy is also used for patients with advanced disease and can be delivered in a neoadjuvant (induction), concurrent, or postoperative adjuvant setting. Studies have revealed that administering chemotherapy concurrently with radiation therapy can improve the therapeutic ratio, resulting in improvement in disease control and survival rates.[9–11,76]

Before a patient receives radiation therapy, the target volume and the surrounding unaffected structures must be defined. The target volume can consist of gross tumor and potential sites of microscopic extension, as well as a volume of tissue to allow for variations in daily patient setup. These volumes are determined by the treating radiation oncologist through physical examination and diagnostic imaging techniques. Treatment planning starts with a simulation—a procedure that is implemented with the use of a special radiographic unit that can reproduce the geometric conditions of a patient on the radiation therapy machine.[36] During simulation, the patient is usually placed in the treatment (i.e., supine) position. Patients are immobilized, usually with a thermoplastic mask, to ensure that the treatment position can be reproduced. Following immobilization, the treatment fields are delineated with the assistance of fluoroscopy and diagnostic radiographs. A CT scan for dosimetry is provided as part of the treatment planning session. The target volume is determined, and normal structures are localized. Treatment portals are designed and verified radiographically. The radiation oncologist prescribes the tumor dose (including fractionation schedules) and, in cooperation with a physicist and a dosimetrist, calculates doses, computes beams, and generates isodose curves.[36] Treatment is implemented by the radiation therapy technician under the supervision of the treating physician and in consultation with the physicist. Periodically, localization films are used and doses on the charts are verified. Tumor response and the patient's tolerance of the radiation treatment are routinely evaluated. The patient is usually evaluated once, weekly by the radiation oncologist.

Radiation Stents

A custom intraoral radiation device, often referred to as a radiation stent, can reduce the radiation dose to unaffected tissue by displacing normal tissue away from the treatment field, minimizing complications and side effects of therapy without compromising total dose to affected area. Patients whose primary tumor is in the oral cavity, oropharynx, paranasal/maxillary sinus, and salivary glands benefit the most by repositioning critical tissue away from the beam of radiation. These radiation stents can be used to depress the mandible and tongue beyond the radiation field, thus minimizing radiation to tissues not at risk or not diseased (e.g., in patients with maxillary sinus cancer, nasopharynx or nasal cancer) (**Fig. 29.9A**).

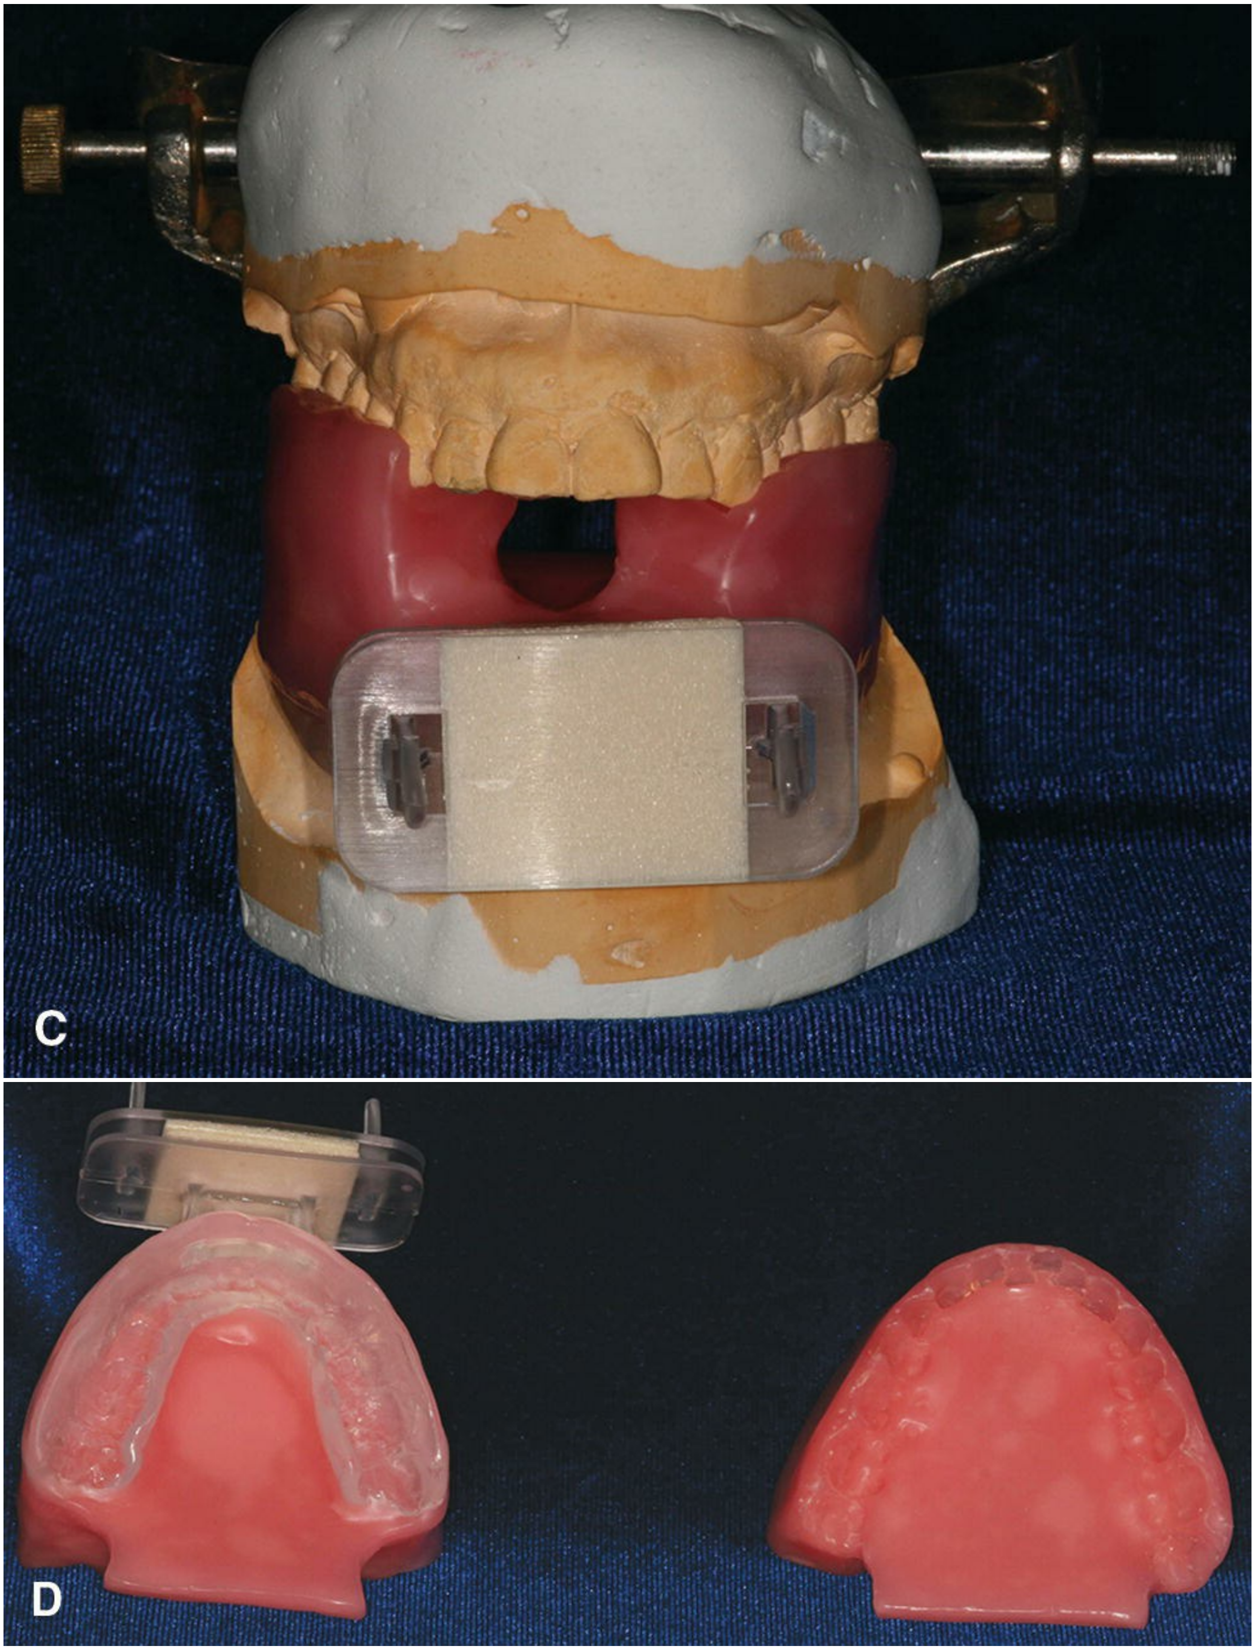

Figure 29.9. A: A CT scan is used for dosimetry purposes in the radiation

treatment planning session. This patient had an olfactory neuroblastoma. Note that the tongue and mandible are completely out of the field of radiation. **B:** Typical records needed for these devices: maxillary and mandibular casts and interocclusal records. **C:** Wax template for final device on mounted casts. **D:** Difference between an IMRT radiation stent and IMPT radiation stent; note the use of the proton bite block. The anteriormost portion of the proton stent is attached to the mask.

These fully customizable devices can be fabricated easily, without complicated prosthodontic techniques. Maxillary and mandibular impressions are required, using a relatively inexpensive material, such as irreversible hydrocolloid. Casts fabricated from these impressions are then placed on a simple hinge articulator with the use of an interocclusal record made at an appropriate mouth-opening distance. The distance is dependent upon the type of device needed, that is, a mouth-opening tongue-depressing stent requires 2 cm opening versus a mouth-opening tongue-deviating radiation stent, which requires 5 mm opening. These devices are also customizable based on the type of radiation to be administered. Proton radiation stents require the addition of a customizable "bite block" (Fig. 29.9B). This bite block attaches to the mask, which allows for a repeatable positioning.

In contrast, the tongue-depressing/mouth-opening radiation device can be fabricated to position the oral tongue and mandible into the field of radiation treatment for repeatable positioning of the oral cavity and tongue during external beam treatment (**Fig. 29.10**).[77] This approach, along with an aquaplast mask, allows for a therapy of exactness and thus eliminates error caused by movement. Such stents are relatively simple to fabricate and are supplied by the oral oncologist.[77,78] If oral oncologic support is not readily available, the radiation therapist or the radiation staff can fabricate a simple device with a tongue blade (composed of Lucite) and a large cork held together with tape, although this measure is not strongly advocated.

A further modification of the basic stent design is required if a maxillectomy, a procedure that results in an oroantral communication, has been performed (**Fig. 29.12**). Incorporation of a cradle-like modification into the stent design allows a water-filled latex balloon bolus (Faultless Balloon Rubber Co., Ashland, Ohio) to be supported within the surgical defect, thus eliminating the air gap.[79] This device, along with placement of a tissue-equivalent material in the defect (i.e., saline), permits a more homogeneous energy distribution.

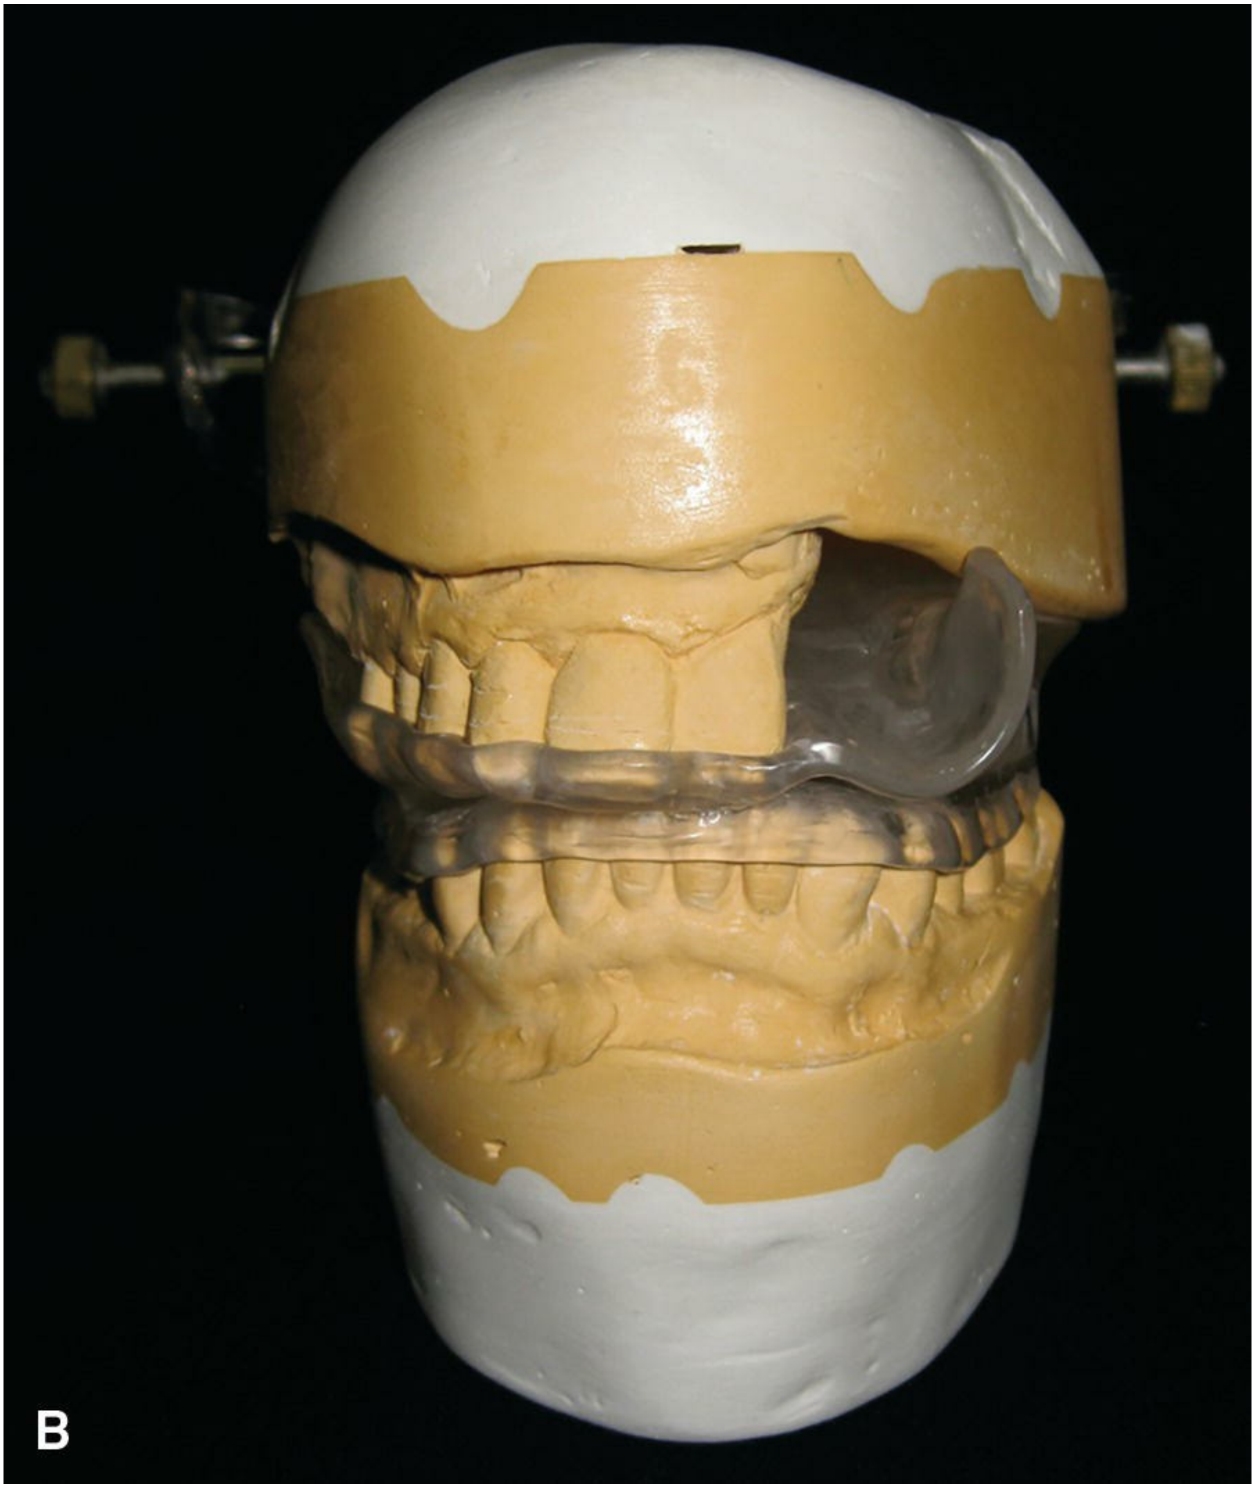

Figure 29.12. A and B: Wax up and final processed balloon-supporting stent. **C:** Lateral aspect of an intraoral stent illustrates the cradle support for the balloon water bolus (tissue equivalent) that is placed into a maxillectomy defect. The balloon is fitted with a No. 12 French catheter to facilitate the injection of water.

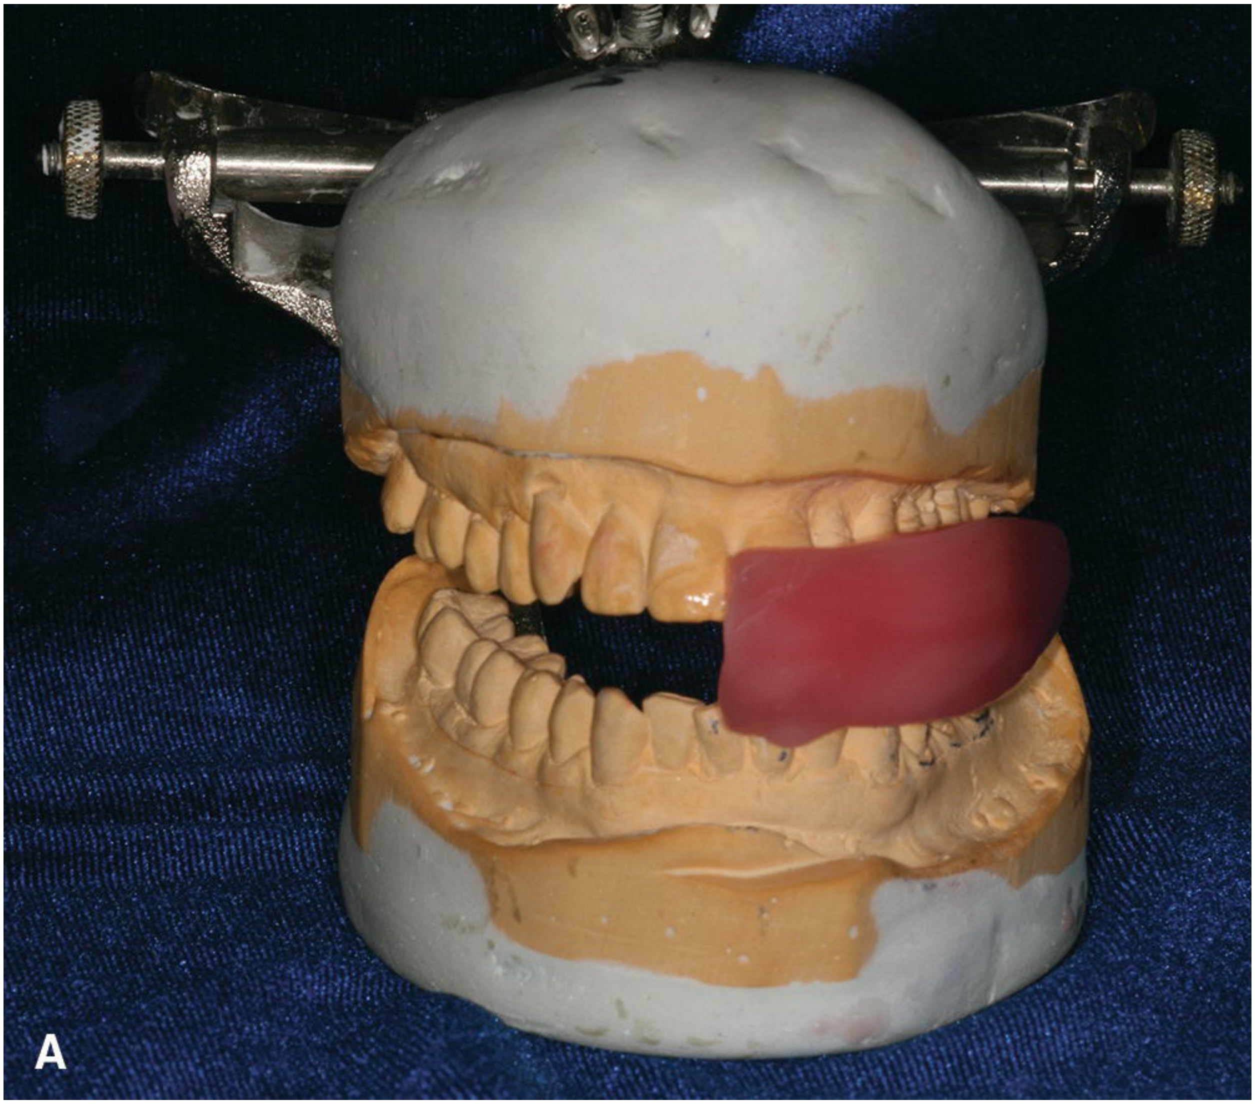
Patients who undergo radiation involving a unilateral treatment field benefit from a unilateral radiation device (**Fig. 29.13**). The device, known as a mouth-opening tongue-deviating radiation stent, deviates the tongue and associated tissues to the contralateral side, thus reducing treatment-related morbidity to the contralateral tissues. A Lipowitz alloy is added to the unilateral radiation stent for added protection when the treated tissue volume receives electron beam energy or combined electron/ photon energy weighted 4:1.



A

The device moves the tongue to the contralateral side of the oral cavity effectively minimizing the dose to the tongue. **B:** Radiation stent in place. Note that the tongue is deviated to the contralateral side, away from field of radiation.

Oral Complications from Radiation Therapy

Good oral health at the onset of radiation therapy minimizes the risk of complications from therapeutic administration of ionizing radiation to the head and neck. These consequences can be categorized as either acute (e.g., mucositis, infectious stomatitis, alteration of taste or smell acuity, dermatitis, pain, inflammation, and difficulty swallowing) or chronic (e.g., xerostomia, caries, abnormal development, fibrosis, trismus, photosensitivity, ORN, and pain).[1,37,45] The severity of treatment-induced morbidity depends on multiple factors, including radiation dose, energy source, volume of tissue treated, pretreatment performance status, and pretreatment periodontal condition.[55] The radiated tissue is susceptible to dermatitis and mucositis, which are often accompanied by salivary gland hypofunction, dysgeusia, dysphagia, odynophagia, hypovascularity of soft and hard tissues, fibrosis, or

trismus.[1,22,54,55] Widespread oral melanotic hyperpigmentation and hypopigmentation have been reported. Developmental abnormalities of the dentition and jaws may occur in children undergoing head and neck radiation therapy.[80–82] In patients of all ages, altered tissues within the volume of tissue radiated are highly susceptible to infectious processes, with fungal organisms such as *Candida albicans* or other *Candida* species; bacterial infections, including streptococci and staphylococci; and viral infections, especially HSV.[59]

Radiation-Induced Mucositis

Oral mucositis generally occurs 5 to 7 days after initiation of external beam radiation therapy. Oral mucosal changes depend on fractionation, energy source, total dose of radiation, and oral and dental status (**Fig. 29.14**).[55] During conventional daily dosing, the rate of destruction of the basal cell layer in excess of proliferation of new cells creates a net deficit of cells resulting in mucositis. During the course of radiation therapy, the mucosa becomes thin as a result of direct cell death and the sloughing off of epithelial cells.[36,83] Subepithelial edema can evoke an epithelial breakdown. By the end of treatment, diffuse erythema, ulceration, spontaneous bleeding, and white or yellow pseudomembrane formation may be present.[84] Late, radiation-induced changes in the oral mucosa are thought to be due primarily to damage of the microvasculature and the connective tissue stromal elements. Telangiectasia, occlusion of capillaries, thickening of blood vessel walls (lack of tonus), and increased hyaline and collagen deposition contribute to thin, atrophic, and relatively avascular mucous membranes.[76,83] Such changes predispose the patient to hypersensitivity to trauma, infection of the oral mucosa, and delayed wound healing, particularly after minor surgical procedures.[1] Dental hygiene procedures may lead to an increased risk of infection or chronic ulceration during this period.[4,23,37]

Figure 29.14. Radiation-induced mucositis, which has been exacerbated by use of an alcohol-containing mouth rinse.

The grade of oral mucositis can be partially controlled by the elimination of all secondary sources of irritation, such as alcohol, smoking, plaque and calculus, coarse or hot foods, alcohol- or phenol-containing mouth rinses, and sodium products that can further dehydrate oral tissues.[21,84] Many physicians recommend that mouth rinses containing alcohol, phenolics, or astringents be avoided owing to the potential of such agents to dehydrate the mucosa and increase oral discomfort.[1,45,55,82] Treatment of mucositis typically consists of palliative pain reduction therapy; however, the Multinational Association of Supportive Care in Cancer (MASCC), in partnership with the International Society of Oral Oncology (ISOO), completed a review of the relevant literature of treatments for mucositis in 2013, which identified low-level laser

therapy (LLLT) as the most promising treatment.[85–89] A new suggestion was made by this group for LLLT (wavelength approximately 632.8 nm) for the prevention of oral mucositis for patients undergoing definitive radiation therapy without concomitant chemotherapy.[86] However, this strategy has yet to be widely practiced in major centers and remains investigational.

Gingival tissues are sensitive to radiation therapy, and increased gingival recession may occur without signs or symptoms of periodontal inflammation.[23] This recession may be due to the hypovascularity induced by the radiation and to the marked reduction of the quality and quantity of salivary secretions following irradiation.[90,91] There is evidence that a limited amount of gingival revascularization may occur over time, provided that the total radiation dosage delivered was relatively low.[35]

Superinfection

Good oral hygiene is essential to improving oral comfort and reducing the risk of oral contamination. Bacterial, fungal, and viral infections can occur as superinfections with mucositis but are less likely to induce septicemia in patients undergoing radiation therapy than in patients receiving chemotherapy.[1] Patients receiving a concurrent regimen of radiation therapy and chemotherapy may be at greater risk of infectious mucositis than patients treated with either therapy alone, due to increased relative dose intensity and immunosuppression secondary to the myelosuppressive effects of chemotherapy.

With fungal infections, such as oral candidiasis, the pathogens can be invasive, refractory to treatment, and potentially systemically disseminated.[59,82] Candidiasis can manifest as pseudomembranous, hyperplastic, or atrophic (erythematous) oral lesions.[25,59] The sites most frequently affected are the tongue, buccal mucosa, hard or soft palate, and commissura labiorum oris (i.e., angular cheilitis). Diagnosis of candidiasis is based on an exclusion of therapy-related toxicity and a clinical evaluation that includes fungal cultures or visualization of organisms using potassium hydroxide stain or Gram stain.[1,92,93] After the diagnosis has been confirmed, treatment consists of topical antifungal agents such as nystatin oral suspension or clotrimazole troches, depending on the degree of xerostomia.[27,53,59] Patients with unresponsive or disseminated candidiasis

may require systemic therapy, such as with ketoconazole, fluconazole, itraconazole, amphotericin B (liposomal), or a combination of antimicrobials with antifungal therapy ideally under the care of a specialist in infectious disease.[27,59]

At times, infections may manifest in the several weeks following the completion of radiation, during the healing phase (**Fig. 29.15**). These types of lesions typically present as a nonhealing ulcers generally within the field of radiation and can be confused easily with mucositis. Long-standing lesions must be cultured and sensitivity tests completed to establish a causative infective agent. Following identification, the appropriate antibiotic, antifungal, or antiviral should be prescribed.

Figure 29.15. Patient radiated for a carcinoma of the base of the tongue with a nonhealing, painful lesion following radiation therapy. Cultures tested positive for Haemophilus species bacteria.

Osteoradionecrosis

Radiation can permanently destroy cellular elements as well as the vascularity of bone and thus limit the potential for wound maintenance and the ability to heal after infection or trauma (e.g., dental extraction, alveoloplasty).[94,95] Further, the risk of complications following trauma or

oral surgical procedures in an irradiated field can be highly significant, depending on a predetermined threshold of radiation, and can result in ORN (**Fig. 29.16**).[54,55,57,95] For these reasons, elective oral surgical procedures, such as soft tissue surgery, are contraindicated within the radiated field owing to the potential for treatment-induced hypovascularity, hypocellularity, and hypoxia; however, noninvasive dental procedures can safely be performed including oral prophylaxis, radiography, and direct restorative (i.e., fillings), endodontic, and prosthodontic procedures (i.e., crowns and dentures).[1,37,45] Optimal oral health must be maintained during and after radiation therapy; however, to avoid soft tissue injury during the postradiation healing period, patients must curtail all but the most basic oral hygiene procedures (i.e., tooth brushing, flossing, and fluoride therapy). It is important after radiation therapy that dental caries or traumatic injury that could lead to ORN be detected and treated; however, ORN can occur spontaneously.[96,97]

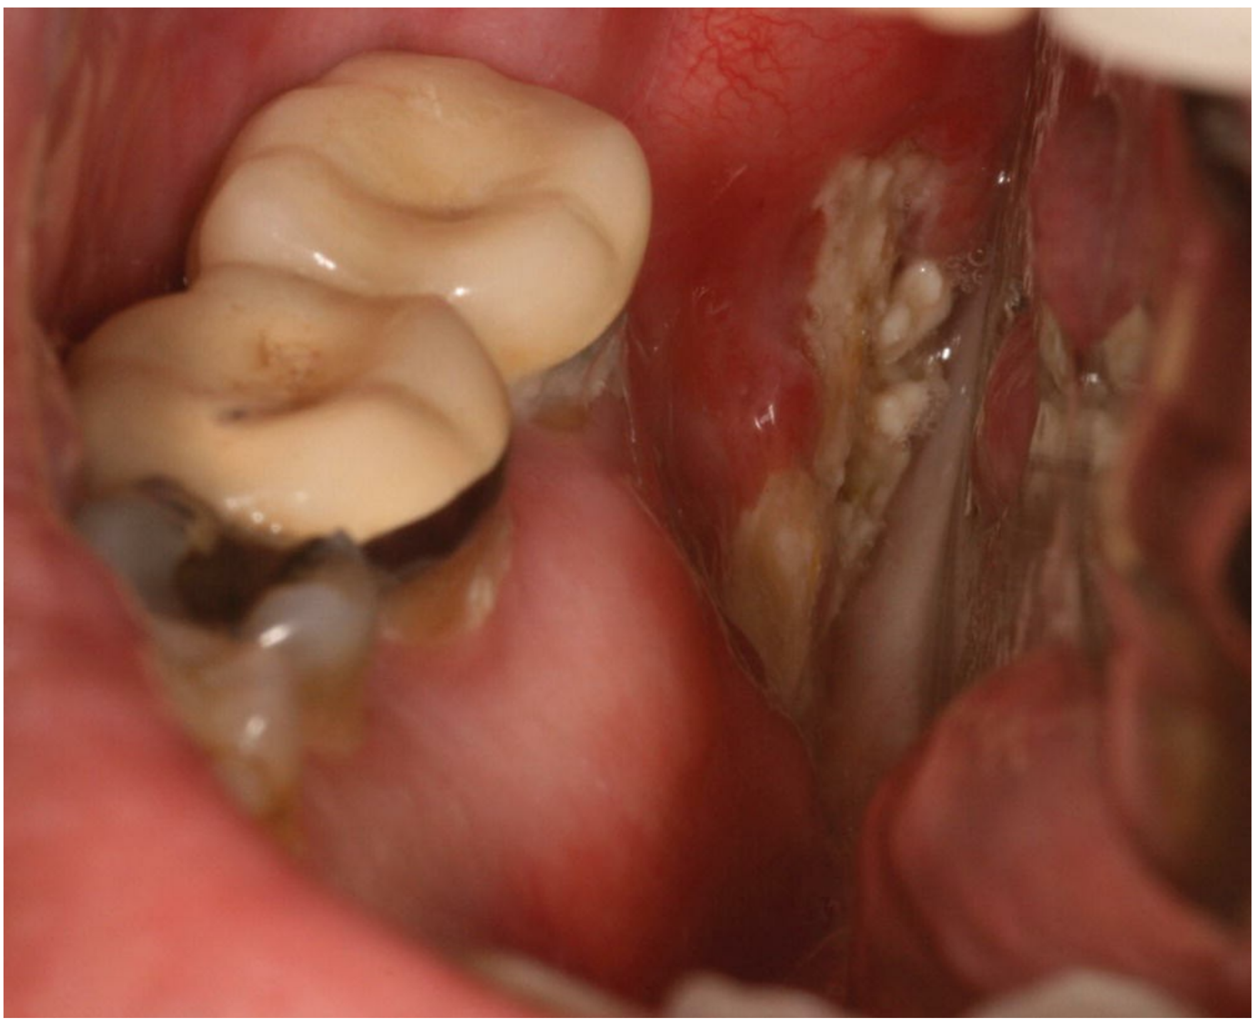


Figure 29.16. ORN following radiation therapy thought to be the result of trauma from intubation.

If oral or periodontal surgical intervention is required after radiation therapy, the clinician should discuss with the treating radiation therapist the volume of tissue radiated and specific treatment parameters and should request a copy of the treatment summary and the dosimetries. Generally, oral surgery, that is, dental extraction or endosseous implant placement, is discouraged in tissue that has received high-dose radiation due to risk of ORN and increased implant failure. Similarly, implants placed into radiated osteocutaneous fibula reconstructions have also shown an increased rate of failure.[98] For teeth that are nonrestorable, conservative measures such as endodontics and crown amputation are preferred over dental extraction. In cases where oral surgery is unavoidable, preoperative hyperbaric oxygen (HBO) therapy administered after radiation therapy is thought to increase the potential for wound healing while reducing the risk of ORN by promoting angiogenesis and osteogenesis, although this remains to be somewhat controversial in the literature.[73,99,100] To date, there are no well-structured, randomized clinical trials to suggest that benefits of HBO therapy. There are contraindications to treatment with HBO, including, but not limited to, pneumothorax and distant metastatic presentation; however, decision to use HBO remains based on empirical judgment and clinician dependent.

HBO therapy can be used as an adjunct to debridement (sequestrectomy) in the treatment of ORN, along with parenteral antibiotics (as dictated by bone culture results).[99,100] Benefits of HBO therapy include improved wound healing in infected ischemic tissue, osteoclastic stimulation, the restoration of normal defense mechanisms responsible for bacterial killing, and the direct killing of anaerobes. Oral oncologists usually prescribe according to the Marx protocol, consisting of 20 preoperative HBO treatments followed by 10 postoperative treatments.[73,101] This prescription may be altered by increasing the number of postoperative HBO treatments to 20 treatments, as decided by the treatment team, to maximize the wound-healing capacity of the patient; however, little benefit was found in patients who received over 40 total treatments. Along with HBO therapy, a specific oral care regimen is indicated to augment wound healing. In such cases, tissues should be managed gently, that is, flapless dental surgery, and antibiotic coverage is required. Local

anesthetics containing epinephrine should be avoided, when possible, to prevent further vascular constriction.[21] Successful placement of endosseous implants in radiated fields with a pretreatment regimen of HBO therapy has been reported; however, there are also reports of initiation of ORN by such elective surgical intervention even when appropriate measures were taken.[96,97]

HBO therapy is time-consuming and expensive and must be performed in an accredited wound care center. When compared with postradiation oral surgical treatment consisting of radical debridement and reconstruction, HBO treatment can be cost-effective if extensive surgery is avoided. HBO may preclude the need for jaw resection and microvascular surgery. In cases in which resection and reconstruction are inevitable, there seems to be minimal benefits from preoperative HBO.

Dental Caries

Dental caries is a common postradiation morbid sequela that is often exacerbated by xerostomia (see **Fig. 29.17A and B**). Radiation of major salivary glands leads to qualitative and quantitative changes in salivary secretions,[1,102,103] thus increasing plaque and mucoid debris accumulation and reducing the salivary pH as a result of a decreased buffering capacity of saliva.[91] These conditions create a cariogenic oral environment, particularly in patients ingesting a diet high in carbohydrates or sucrose.

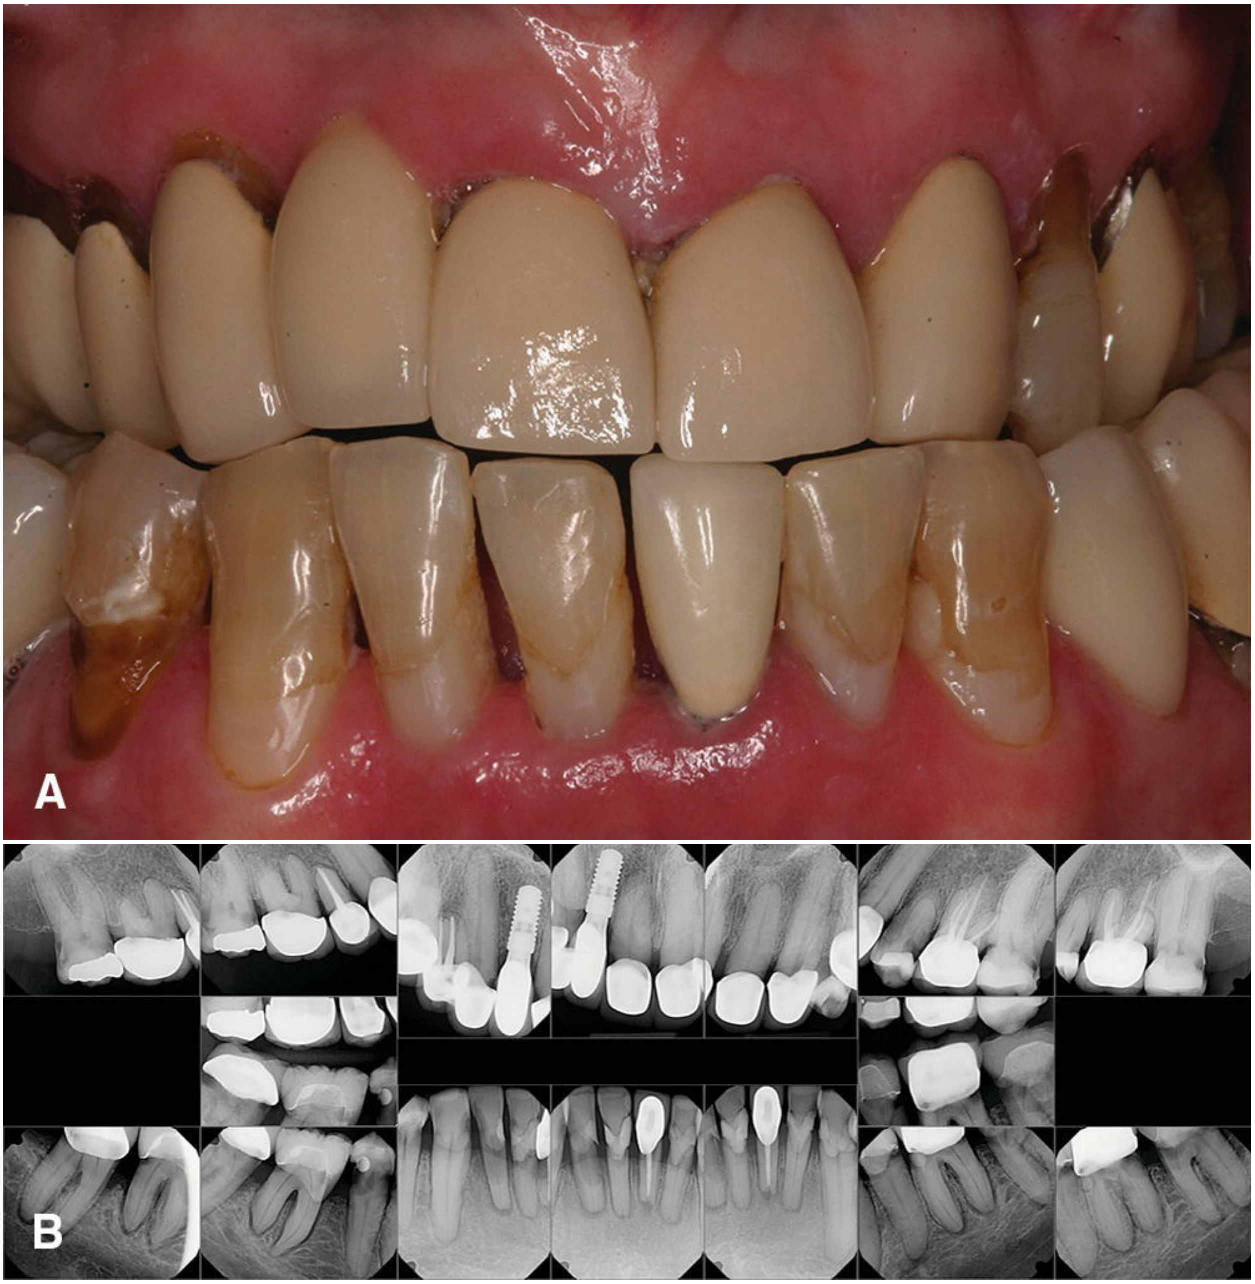

Figure 29.17. A: Rampant caries following radiation therapy for tonsil SCC; note the large carious lesions at the cervical margins of the teeth. **B:** Showing the same patient radiographically; note multiple apical abscess and rampant caries.

The pathogenicity of radiation therapy administered to salivary glands has been attributed to the cytotoxic effects of this treatment on the secretory cells of the glands.[103] Others have attributed salivary gland dysfunction to the direct effects of radiation on the vascular, myoepithelial, and connective

tissues of the glands.[90,102] Saliva is a complex bodily fluid that consists of multiple small organic molecules, electrolytes, and immunoglobulins that defend the oral cavity from contamination and promote healing. Salivary hypofunction can increase the risk for dental caries, compromise mucosal integrity, and impair chewing and swallowing functions.[1] When the salivary glands are within the radiation field, the risk of irreversible damage due to the cytotoxic effects of the radiation is highly likely, as are the clinical manifestations of xerostomia. Dryness of the mucosal tissues may increase susceptibility to oral infections and lead to difficulty in chewing, swallowing, and speaking.[57,103] Susceptibility to caries is not limited to the dentition within the volume of tissue irradiated; all teeth in the oral cavity are a risk.

An effective combination of oral hygiene, frequent dental follow-up examinations, and appropriate prophylactic treatment procedures consisting of flossing, tooth brushing, and fluoride therapy is essential to caries prevention. A daily fluoride program can decrease postradiation dentinal hypersensitivity, remineralize cavitated enamel matrices, and, more importantly, inhibit caries-forming organisms.[1,55] Fluoride treatment should consist of a daily application of 0.4% stannous fluoride or 1.1% sodium fluoride applied to the dentition using a brush-on technique or gel-filled trays (i.e., fluoride carriers) (**Fig. 29.18**).[1,55,90,91] Compared with sodium fluoride, stannous fluoride is slightly more acidic, and as a result, the uptake into the enamel matrices is four times greater.[1,55] Also, the acidic nature of the fluoride may have an antibacterial effect.

Figure 29.18. Fluoride carrier; made of polypropylene. Used to apply fluoride to the teeth. Note the extension beyond the gingival margin of the teeth.

In adults with xerostomia, fluoride leaches out of the enamel within 24 hours; thus, the fluoride regimen must be performed daily for optimal protection. The most efficient method of fluoride application is the use of a custom-made polypropylene fluoride carrier that completely covers, and extends slightly beyond, the tooth surface.[55] Patients fill the carriers ~1/3 full with fluoride gel and place them onto the dentition daily for 10 minutes.[1,55] Patients who receive low doses of radiation and who are expected to have a slight degree of xerostomia can use a toothbrush to apply the fluoride gel.[104] Sensitivity and pain are common adverse effects of fluoride and may necessitate a change in the fluoride concentration or the method of application.

Trismus

When the muscles of mastication are within the volume of radiated tissue, ensuing consequences can lead to restricted mouth opening secondary to

cumulative deposition of fibrous tissues within the muscles, commonly referred to as trismus. There is limited well-structured research surrounding this topic. A limitation in mandibular range of motion, or trismus, can in turn lead to difficulty eating, poor oral hygiene, and impaired speech and limit dental intervention[105] (**Fig. 29.19**).

Figure 29.19. Maximum opening in a patient with severe trismus as a result of maxillectomy and radiation therapy. This patient has difficulty maintaining oral hygiene and inserting the obturator.

Although there is evidence to suggest that the degree of trismus is dose related, detailed correlations between clinical impairment and specific radiation dosages have not yet been established.[106] The incidence of trismus has been reported to range from 0% to 100%.[107] The large variation has been attributed to the lack of uniform criteria and grading scales for trismus, as well as a lack of standardization in assessment style, that is, interincisal measurements versus visual estimation measurements.[107]

Several treatment options for trismus have been proposed; however, there

is limited well-structured research on their efficacy. Most of the regimens include a device to aid in stretching. Devices as simple as tongue blades and unassisted and finger-assisted stretching exercises[108,109] to more complex devices, such as Jaw Dynasplint System[110] (JDS) and Therabite Jaw Motion Rehabilitation System[111] (TJMRS), have been described in the literature. These devices can be generally classified into passive or active motion, depending on whether the muscles of mastication are not involved or involved in opening and stretching of the mandible, respectively. The implementation of an oral physical therapy plan to prevent trismus during and soon after radiation therapy is important to prevent the long-term effects of fibrous tissue deposition in the muscles of mastication, which lead to trismus. Additionally, oral stretching needs to continue lifelong given the cumulative nature of muscle fibrosis after radiation therapy. The effectiveness of oral physical therapy for the treatment of trismus long after radiation has been completed is more limited

A recent study has suggested that trismus is not related to the radiation dose or location but most likely the TGF B1 beta genotype. Development of trismus was significantly related to the presence of the T allele. Although this was a small study of ~60 subjects, this may further the concept of personalized medicine and allow for a predictive model for development of trismus following radiation therapy.[112]

Xerostomia

Radiation therapy can permanently decrease salivary flow. In a study of patients followed for up to 25 years after radiation therapy, Liu and coworkers found that, compared with a nonirradiated group, patients who received bilateral ionizing radiation therapy involving the major salivary gland tissue exhibited, over time, mean decreases of 81% in stimulated and 78% in unstimulated salivary flow.[102] Patients who received unilateral radiation therapy involving only one parotid and one submandibular gland experienced mean decreases of 60% in stimulated and 51% in unstimulated salivary flow.[102] Correspondingly, there is an overall decrease in xerostomia when uninvolved salivary glands are spared during radiation treatment. Patients who underwent cervical with supraclavicular radiation therapy (i.e., mantle field treatment) experienced mean decreases of 43% in stimulated and 32% in unstimulated salivary flow.[102]

Radiation-induced reductions in salivary flow are worrisome because saliva protects the oral mucosa from dehydration and assists in the mechanical lavage of food and microbial debris from the oral cavity.[103] To avoid oral infections and to reduce the mucositis that may arise from radiation therapy, patients must frequently rinse the oral cavity to reduce oral microorganisms and to maintain mucosal hydration. Such oral lavage can be performed by rinsing with a solution of 1 tsp of sodium bicarbonate dissolved in 1 quart of water several times each day to alkalinize the oral cavity and keep the oral and oropharyngeal tissues moist.[1,37]

The traditional treatment for radiation-induced xerostomia is inadequate because no salivary substitute for patients with these conditions can replicate natural salivary mucin and protective salivary components.[48,55] Mouth rinses, saliva substitutes, and gustatory stimulants are frequently abandoned by patients treated with head and neck radiation therapy, but these can aid in palliating xerostomia. Such patients should be encouraged to increase their intake of water, decrease their intake of acidic and carbonated beverages, and decrease their intake of sodium during treatment. Sialagogue therapy, such as with cholinergic agonists (e.g., pilocarpine hydrochloride), has been shown to provide clinically significant relief of symptoms of postradiation xerostomia.[113,114] Healthy oral tissues can be maintained following radiation therapy. Success depends not only on careful oral planning but also on the patient's cooperation and compliance.

Intensity-Modulated Radiation Therapy

One advance in radiation therapy has been the introduction of computed tomography (CT) to define tumor volumes and normal tissues for the development of radiation beam arrangements.[115] The process, known as three-dimensional conformal radiation therapy, enables a higher dose to be directed at the tumor while minimizing the effects on normal tissue. Another advance in technology in radiation oncology is intensity-modulated radiation therapy (IMRT), a technique that delivers radiation more precisely to the tumor while sparing the surrounding normal tissues.[116] IMRT also allows inverse planning and computer-controlled radiation deposition and normal tissue avoidance (i.e., parotid-sparing techniques).[116] IMRT has wide application in most aspects of radiation oncology because of its abilities to create multiple targets and multiple avoidance structures, to treat different

targets simultaneously at different doses, and to weight targets and avoid structures according to their vital importance. IMRT is an approach to conformal therapy in which high-dose radiation is administered to target volumes whereas lower-dose radiation is delivered to sensitive structures. With certain head and neck treatment schedules, IMRT may reduce the total dose to major salivary glands, thereby decreasing the incidence and severity of postradiation-induced xerostomia.

Intensity-Modulated Proton Therapy

Intensity-modulated proton therapy (IMPT) was recently introduced for the treatment of head and neck cancer. It is thought to be superior to IMRT given the proton's physical property to stop at the targeted range of the tumor, thus limiting the amount of normal tissue radiated (i.e., Bragg peak).[117] By reducing the dose intensity to normal tissues, IMPT is associated with a reduction in the oral morbidities associated with radiation therapy contributing to an overall increase in quality of life during and following treatment.[117] Randomized blinded clinical trials are currently underway to further determine the differences between IMPT and IMRT in regard to radiation treatment–associated oral morbidities, including salivary flow (both stimulated and unstimulated) and oral opening.

CHEMOTHERAPY

Today, many patients with cancer of the head and neck receive chemotherapy as a single- or multiple-drug regimen, either alone or in combination with other therapies.[76,118–121] The duration of treatment ranges from several months to years, depending on how long the therapy remains effective or how long the patient can tolerate it. Most chemotherapeutic agents are designed to kill multiplying tumor cells but also target mitotically active normal tissue cells, and therefore, chemotherapy often induces toxicity in the hematopoietic cells, skin/mucosa, and aerodigestive tract.[37,76] Such toxicity may cause treatment-induced complications in the oral cavity, especially if myelosuppression has occurred. Many of the sequelae of chemotherapy are similar to those induced by radiation therapy, but sometimes, they are more episodic in relation to the chemotherapy regimen owing to the dosing schedule or agents administered.

Oral Complications from Chemotherapy

Treating oral conditions resulting from chemotherapy is interesting and challenging for the oral oncologist. The medical team often experiences anxiety over precipitating oral problems during therapy, and patients, after reading the literature addressing the sequelae of chemotherapy, are sometimes overtly fearful of the complications (e.g., fear that brushing the gingival tissues can result in a septic condition).[1,37,122] Thus, a regular regimen of dental visits and good hygiene practices is replaced with suboptimal oral care practices.

Acute oral conditions detected during the oral and dental evaluation of patients with cancer must be treated before chemotherapy if the patient's health or hematologic values permit or, if not, when the opportunity arises between treatment cycles and an appropriate performance status has been established. Chronic problems should not go unattended but should be treated strategically as the patient continues with chemotherapy.[37] With appropriate coordination, acute problems can be treated promptly. If left untreated, chronic conditions may become acute at a time when the patient's physical well-being or hematologic parameters will not allow oral treatment intervention.

Dental practitioners must not lose sight of the long-term medical and oncologic goals for patients with cancer; additionally, they must not implement elaborate restorative plans or treat periodontal conditions that would have a guarded prognosis in patients without cancer.[121] During oncologic therapy, the oral treatment plan for patients with cancer should be simple, practical, and functional in relation to the patient's oral or dental health and should not be in the realm of cosmetic dentistry; extensive, complex fixed prosthodontics; or advanced periodontal therapy.[37,123] Dental specialists face an almost overwhelming temptation to give esthetic possibilities undue consideration while failing to recognize the difficulty patients face in coping with their cancer diagnosis and undergoing drug therapies that have serious adverse effects.[1,37,45]

Oral Infection

Even before the initiation of chemotherapy, individual malignancies can predispose individuals to infectious risks, with neoplastic processes of either

bone marrow or lymphoid tissue (i.e., lymphoma) having the greater potential for infection.[124–126] The risk for infection further increases after treatment has started and is compounded for patients at more advanced stages of the therapeutic regimen or with more advanced stages of disease.[37]

Oncologic therapy designed to control or cure disease and to prolong survival can severely weaken the immune system, creating excellent conditions for infection to develop locally or to become a septic focus.[127,128] Despite major preventive practices such as prophylactic antibiotics, isolation techniques such as protected environments, and treatments such as immunologic leukocyte growth factors, the immune system can be immensely impaired by both the malignancy and the therapeutic regimen used to control infection. Even more challenging is the potential or presence of an existing infection that can be manifested by a broad spectrum of clinical signs and symptoms owing to a severely impaired immune response or the common use of prophylactic rather than therapeutic antibiotic, antifungal, or antiviral agents during treatment. Oral complications associated with cancer and its therapy have been well documented and are broadly categorized as infection, mucositis, or bleeding problems.[23,129]

Given the immunosuppressive effects of malignancy and its treatment, empirical use of an oral decontamination agent, that is, 0.12% chlorhexidine gluconate and 1.1% sodium fluoride toothpaste, may substantially lower the risk of infection of the oral cavity and alter the presenting signs and symptoms of infection during chemotherapy.[37] Oncologists and treatment centers vary in their treatment philosophies on the use of such anti-infectious agents. The dentoalveolar complex should be thoroughly evaluated for microbial reservoirs (e.g., plaque, calculus, or periodontal pockets), and these infectious foci should be eliminated before the start of chemotherapy (**Fig. 29.20**).[23,37] A compromised periodontal status increases risk of infection.[130,131] Clinically, however, the risk of infection depends on multiple interacting factors, such as oral hygiene status, immune-myelosuppressive status, chemotherapeutic agents used, prophylactic or therapeutic antimicrobial agents used, and the degree of periodontal disease.

Figure 29.20. Severe gingivitis causing significant inflammation and increased risk of bleeding. These inflamed areas are portals of entry for bacteria potentially causing systemic infections and are bleeding risk sites.

Oral Care.

To minimize the risks of oral infection, it is important that simple and practical guidelines be developed for maintaining oral health and for diagnosing, preventing, and treating oral–periodontal infection during therapy.[1,37] Patients with cancer should make regular dental visits for overall dental and periodontal assessment. Patients receiving chemotherapy can undergo a dental treatment provided that they meet the following hematologic conditions: (1) an absolute neutrophil count of ~1,000/mm^3 (white blood cell count times percent neutrophils equals the absolute neutrophil count), a level at which the risk of developing an infection is minimal, and (2) a platelet count above 50,000/mm^3 with a normal coagulation profile.[79] The administration of prophylactic antibiotics is essential owing to the induced bacteremia, immunocompromised status, and potential for hypofunctioning white blood cells introduced by chemotherapy. The American Heart Association recommends that a viable antibiotic regimen to prevent subacute bacterial endocarditis be administered before periodontal procedures.[132,133]

Patients with an uninfected dentition and good periodontal health do not pose a treatment challenge, nor do patients with mild periodontal disease that

does not mandate immediate surgical intervention. However, patients with increased loss of attachment from resultant bone loss with root exposure or periodontal pocket formation pose a treatment dilemma.[37] Patients in whom pocket depth is normal (between 1 and 4 mm) can be treated with regular periodontal care and maintenance, even though there has been a history of periodontal disease. Extraction should be considered only for patients with pathologic mobility of dentition or fulminant periapical abscess.[1,37]

Patients with moderate to advanced periodontal disease present a greater challenge and would, under usual circumstances, receive instructions for infection prophylaxis and dental hygiene, as well as surgical intervention; however, the feasibility of such comprehensive therapy during chemotherapy can be limited by several factors, including performance status, type of malignant disease, cycling of chemotherapy, and hematologic competence. The clinician should strive to provide a thorough scaling/root planing and to encourage maintenance through exceptional plaque control (i.e., tooth brushing, flossing, and use of antimicrobial mouth rinse).[37,134,135]

To reduce the risk of septic foci, extractions should be considered for patients with an exacerbated or acute periapical infection. This oral surgical correction should be performed at the appropriate time in the treatment cycle or when the patient's cancer is in remission. If chemotherapy is on hold, oral–periodontal surgery could be considered provided that the hematologic status is appropriate. The oral oncologist must discuss with the treating medical oncologist about the patient's oral status, treatment plan, and contraindications to surgical intervention, as well as the appropriate timing of oral procedures.[37,76,118]

Periodontal Care.

Tooth brushing and flossing should be the standard of dental care. As in the general population, many patients with cancer either do not floss or floss only infrequently; therefore, clinicians may either instruct patients to floss or stress its importance. If the clinician identifies an area in which food continually lodges, the patient should be encouraged to floss the area to reduce the risk of gingival inflammation.[45]

Patients who floss regularly are instructed to modify the flossing technique in certain clinical situations: First, patients are instructed to floss gently when the lining of the oral cavity starts to become sensitive to thermal

changes or food substances, indicating mucosal thinning due to suppressive effects of chemotherapy on the normally proliferative epithelium.[82] Second, patients are instructed to floss only to the gingiva when the platelet count is above 50,000/mm^3. This technique removes most of the debris from the teeth. By not flossing at all, about half of the teeth are not cleansed.[37]

Brushing the teeth is imperative for plaque control. The patient should be instructed to brush after each meal. In certain clinical situations, such as increased mucosal sensitivity to food or thermal changes, increased sensitivity to toothbrush bristles, irritation of the gingival tissues by the toothbrush, or profound thrombocytopenia (<20,000/mm^3), patients should change from a soft to an ultrasoft-bristled or sensitive-bristled toothbrush.[1,37,45,59]

In controlling plaque accumulation, it is important that the risk of gingival inflammation be minimized, along with the oral bacterial load and the potential for infection.[136] Along with routine brushing and flossing, rinsing with chlorhexidine gluconate should be initiated when patients begin chemotherapy. Such rinsing is an adjunct to ideal oral–periodontal care and can also be used when indications arise, such as oral mucosal changes secondary to chemotherapy and subsequent increased soft tissue sensitivity.[37,134,135] Patients undergoing chemotherapy should be encouraged to rinse with a dilute saline and sodium bicarbonate solution (5%) to reduce adherent mucoid debris on oral soft tissues, to lubricate oral mucosal and oropharyngeal tissues, and to elevate the pH of oral fluids.[45] Patients who experience nausea and anorexia should be encouraged to rinse with the sodium bicarbonate and salt water solution several times throughout the day to reduce oral acidity and minimize the mucosal insult.[137,138]

Another challenge cancer patients face is the risk of local infection or septicemia associated with dental implants. If an implant with its restorative component poses a risk of infection for patients under normal circumstances, this risk will be intensified during chemotherapy. Interventional antibiotics and aggressive hygiene have limited ability to control infection caused by a poorly integrated endosseous implant, whereas a well-integrated implant should not pose problems if its integrity is maintained with effective dental hygiene practices.[49–51]

Aggressive anticancer therapy severely undermines the integrity of the

mucosal epithelium of the oral cavity. In addition, the oral cavity is a focused area for trauma from teeth, denture prostheses, and hot or cold dietary substances.[4] Many patients are at risk for infection from resident microflora or opportunistic pathogens sequestered in sanctuary areas (**Fig. 29.21**). Furthermore, cancer patients share with the general population common problems of the oral cavity, such as poor hygiene, poorly maintained dentition, periodontal disease, prostheses in poor repair, as well as the associated mucosal disease.[37] With all these interactive injurious influences in such close proximity, even small alterations in the area can cause a problem. Each course of chemotherapy introduces this threat of oral complication, and the risk of developing complications with subsequent courses increases as local or systematic resistance is challenged. Appropriate evaluation of the oral cavity and correction of existing oral and dental pathology can minimize, and in some cases eliminate, treatment-limiting toxicities such as mucositis, oral infections, and bleeding that necessitate dose reduction or termination of chemotherapy.[4,76,139]

Figure 29.21. Patient undergoing chemotherapy; significant pain is noted due to an overgrowth of Candida. Diagnosis is confirmed with culture and sensitivity testing.

Chemotherapy-Induced Mucositis

The oral mucosal response to chemotherapy is varied and unpredictable. Some patients undergo the most aggressive treatment regimens with no problems; others experience increased mucosal sensitivity to food and thermal changes due to the thinning of the mucosal epithelium or profound ulcerative lesions. These soft tissue mucosal reactions can confuse treating physicians, leading to inappropriate local oral treatment parameters and substantially influencing whether chemotherapy is continued.

Diagnosis.

Oral mucosal reactions must be identified as either stomatitis or mucositis;

the distinction determines the treatment and provides insight into the overall effectiveness of the chemotherapeutic regimen.[1,37,43,45] A diagnosis of oral stomatitis should be made when the integrity of the mouth has been altered by traumatic events, such as a coarse diet, an ill-fitting denture prosthesis, or infectious agents (i.e., viral, bacterial, and fungal). In contrast, a diagnosis of oral mucositis should be reserved for oral tissue changes that are the direct cytotoxic effects of chemotherapy. All other factors must be ruled out before a condition is diagnosed as mucositis. An incorrect diagnosis of mucositis could cause unnecessary delay, reduction in dose, or complete discontinuance of potentially effective chemotherapy. Incorrect mucosal assessment can also lead to improper care and treatment and thus to the persistence of the mucosal disease.[37] This problem can be further compounded by superinfection, pain, decreased nutritional intake, bleeding, or a focus for sepsis, effects that increase the treatment morbidity, treatment costs, length of hospital stay, need for additional antibiotic therapy, and need for parenteral nutritional support. Stomatitis is preventable, and the condition can be corrected or significantly reduced with antimicrobial or dental therapy such as correction of a plunger cusp causing frictional irritation of the lateral tongue and subsequent ulceration and marked discomfort.

Etiology and Progression.

Patients vary considerably in their tolerance of various chemotherapy agents and the development of mucositis. Chemotherapeutic agents (e.g., antimetabolites, alkylating agents, and vinca alkaloids) known to produce mucositis may not produce a mucosal reaction when given at the appropriate dose and duration, whereas other agents not known to produce mucositis, if given at an intensified dose or for a sufficient duration, can produce mucosal toxicity, thus necessitating dose reduction.[22,82,140]

Mucositis, the most common acute complication of chemotherapy, has a specific, defined mechanism of progression: Mucosal erythema progresses to oral sensitivity and then to mucosal denudation.[3,22,82,140] Several grading scales for oral mucositis have been developed to assess the severity of the mucosal reaction during each course of chemotherapy. Grading scales range from the simple to the complex.[23,141–144] A universal grading system for mucositis has not been established and accepted by the profession.

The most commonly used scale to assess mucositis severity was the

World Health Organization (WHO) classification (1 = soreness, erythema; 2 = erythema, ulcers, can eat solids; 3 = confluent ulcers, requires liquid diet only; 4 = oral alimentation not possible, hemorrhage) although it is used in less than one-half of all studies. The RTOG oral mucositis grading system incorporates both a patient-graded component and an assessment by a medical professional (1 = erythema; 2 = patchy mucositis; 3 = greater than one-half of the mucosa affected by a fibrinous mucositis; 4 = necrosis and hemorrhage, functional component graded by patient). Validity and reliability have yet to be established with this grading scales and this, in turn, may lead to difficulty in interpreting result of clinical trials or systematic reviews. The National Cancer Institute (NCI) first created the Common Toxicity System (CTC v1.0) in 1983 to aid in the recognition and grading of adverse chemotherapy events. Since that time, several versions have been introduced. The CTCAE 4.0 scale is the most updated version of their Adverse Events (AE) (1 = erythema; 2 = patchy ulcerations or pseudomembranes; 3 = confluent ulcerations, bleeding with minor trauma; 4 = issue necrosis, significant spontaneous bleeding, life-threatening consequences; 5 = death). Validation studies are currently being undertaken.

In cases of appropriately diagnosed mucositis, the emergence of mucosal toxicity would be expected to coincide with the administration of chemotherapy. However, mucosal HSV infections occurring early in the chemotherapy cycle can mimic mucositis. Failure to collect diagnostic cultures with each mucosal reaction can lead to a misdiagnosis of mucositis, in which the infection goes untreated.[145–149] Culturing at this early stage of therapy is essential for differentiating mucositis from infectious stomatitis, which can be caused by a bacterial, fungal, or viral agent and which is usually associated with a low neutrophil count.[1,37] Oral mucosal infectious agents must be correctly identified and treated because the loss of mucosal integrity creates a portal of entry for systemic infection in immunocompromised patients.[129]

Chemotherapeutic Agents Associated with Mucositis.

Chemotherapy-induced pancytopenia, combined with mucositis, can cause oral infection and bleeding events. Severe thrombocytopenia (platelets < 20,000/mm^3) and neutropenia (neutrophils < 500/mm^3) may be present despite normal-appearing oral mucosa. Serious complications, such as

hemorrhagic diathesis or sepsis, can occur if hematologic parameters are not considered in the treatment of the oral cavity. Thus, clinicians should conduct a benefit-versus-risk analysis of the intended therapy and should thoroughly assess the hematologic values before each treatment intervention. Treatment guidelines based on such assessments have been established.[1,3,23,37,150]

Drug-related mucositis can be severe, with onset occurring within 7 days after initiation of chemotherapy and with duration varying from several days to weeks. Compared with single-agent therapy, combination drug therapy or chemoradiation therapy is more likely to intensify mucosal morbidity. Maximal myelosuppression can induce thrombocytopenia, thereby causing gingivitis and gingival bleeding.

Drugs most frequently associated with mucositis and myelosuppression include Cytoxan, etoposide, cyclophosphamide, doxorubicin, dactinomycin, daunorubicin, 5-fluorouracil, bleomycin, melphalan, and methotrexate.[3,16,25,32,76,80,118,121,138] Chemotherapy is usually administered over 3 to 5 days, and recovery intervals of 21 to 28 days are usually provided between chemotherapeutic sessions.[37,123] Drug-induced myelosuppression renders patients susceptible to hemorrhage and increased infectious potential.[138]

Targeted Therapy.

As cancer becomes more targeted and personalized, new systemic therapies have evolved; these agents are specific to pathways and molecules involved in carcinogenesis. Because of their specificity, some of the oral complications and myelosuppression are less than those with traditional cytotoxic chemotherapy. Epidermal growth factor receptor (EGFR) inhibitors are one of the recent additions to this class of drugs. The most common adverse reaction with EGFR inhibitors is cutaneous reaction, usually treated with antibiotic creams. Cetuximab is an EGFR inhibitor that is currently approved for locally advanced cancer of the head and neck and has been found to be superior to definitive radiation therapy alone when used in combination with radiotherapy.[151] Oral mucositis associated with cetuximab presents with generalized erythema and is less ulcerative than is typically seen with traditional cytotoxic chemotherapy.[152] When a targeted therapy and cytotoxic agents are used together, a combined presentation of oral mucositis is seen in which the classic presentation is aggravated by a generalized erythema

extending to the labial mucosa (**Fig. 29.22**).[152] Bonner et al. in 2006 found similar oral toxicities with radiation therapy alone versus concurrent chemoradiation with cetuximab, whereas a retrospective review with a meta-analysis found an increased prevalence of mucositis in patients receiving concurrent radiation therapy with cetuximab versus concurrent radiation therapy with traditional cytotoxic therapy. Further assessment is required given that oral toxicities are often not mentioned in clinical trials.

Figure 29.22. Patient undergoing concurrent chemoradiation with cetuximab for nasopharyngeal CA. **A:** Note the generalized facial rash associated with EGFR inhibitors. **B:** Note the mucositis present with generalized erythema, which is less ulcerative than what is typically seen with traditional cytotoxic chemotherapy.

Treatment.

Unlike the approach to oral stomatitis, effective therapy for oral mucositis has not been standardized. The MASCC, in partnership with the ISOO, in 2013, extensively reviewed the literature on treatments for the chemotherapy-induced mucositis. Cryotherapy (cooling therapy) was found to be effective for bolus chemotherapy regimens with short half-lives.[87] Keratinocyte growth factor-1 (KGF-1) was found be successful in autologous stem cell transplantation if given 3 days before the conditioning regimen.[88] There was insufficient evidence to support the use of amifostine in the prevention of oral mucositis.[89] Most interventional agents are aimed at either the prevention/reduction or the palliation of toxicity caused by chemotherapy. The many agents used vary widely in their mechanisms of action.[140] In cases of mucositis that can be controlled, chemotherapeutic agents, alone or in

combination regimens with mucositis medication, are escalated to higher doses to achieve the ultimate goal of cure of cancer. Gingival hemorrhage can usually be controlled by local measures such as the application of pressure, cool water, periodontal dressings, topical thrombin, gelatin sponges, oxidized cellulose, prefabricated stents lined with a hemostatic agent, or tranexamic acid.[1] Persistent hemorrhage may require platelet support.[16,21,37]

Antibiotic and Diet.

Any emergent oral treatment given while patients undergo myelosuppressive chemotherapy requires prophylactic antibiotic coverage, and all patients with indwelling central venous catheters require prophylactic antibiotic coverage for procedures likely to induce bacteremia.[45] The oral oncologist should consult with the patient's treating oncologist for the selection of the most appropriate antibiotic.

Although grossly overlooked, diet profoundly influences the stability of the oral tissues and can cause mucosal problems when a patient is undergoing chemotherapy.[1,118] During the myelosuppressive phase of therapy or when the mucosa is thinned owing to chemotherapy, the diet should consist of nontraumatizing, soft foods that reduce the risk of puncture, abrasion, or damage to the compromised mucosal epithelium. Hard or abrasive food items can lead to increased pain, infection, or bleeding episodes. All sources of trauma should be minimized or avoided completely.

Patients at Higher Risk.

Viral reactivity may lead to severe oral or disseminated infection during periods of immunosuppression. In particular, HSV infections are often associated with severe, painful, and prolonged ulcerations atypical of those found in immunocompetent hosts (**Fig. 29.23**).[26,145–148] Suspected HSV lesions should be treated with antiviral agents such as acyclovir administered orally or intravenously and should be managed as described earlier for irradiated patients. The diagnosis should be established with the use of viral cultures, direct immunofluorescence, or other rapid diagnostic tests, as well as histologic assessment of the lesions.[26,145–148]

Figure 29.23. Culture-positive HSV oral infection is treated with antiviral systemic and topical medications.

Bacterial infection following chemotherapy can cause localized mucosal lesions, sialoadenitis, periodontal abscesses, pericoronitis, or acute necrotizing ulcerative gingivitis.[37,121] Because systemic infection is a serious complication in neutropenic patients, constant vigilance must be maintained

to prevent or manage oral infection of any type.[1,11,37,45] Oral infection should be treated with selected antibiotic combinations (broad-spectrum antibiotics), including an agent effective against anaerobic Gram-negative bacilli such as *Pseudomonas* species, *Klebsiella* species, or enterobacteria, which are often found in the oral cavity of immunocompromised individuals.[37,45,121] Oral microbial culture testing should be used to ensure antibiotic sensitivity and resistance selection and to assist in identification of causative organisms.[37]

PROSTHETIC REHABILITATION AFTER HEAD AND NECK CANCER TREATMENT

Self-confidence can be decreased in patients that have undergone head and neck cancer therapy, particularly those who have undergone ablative surgical resection. Intra- and extraoral prostheses restore form and function, in turn, lessening the challenges associated with cancer therapy and improving patient's overall quality of life.

Maxillary Defects

The oral–nasal defect resulting from a maxillectomy procedure leads to unintelligible speech, impaired swallowing, and nasal regurgitation, unless oral–nasal separation can be reestablished. This can be accomplished surgically, with a flap reconstruction, or prosthetically with an obturator. An obturator is a removable prosthesis that replaces the missing portion of the palate that has been resected during the tumor-ablative surgery.[153] The obturator functions primarily as the partition between the oral cavity and the sinonasal cavity and secondarily to recreate the palatal contours for appropriate speech sounds.[154,155] Size and location of the surgical defect and presence and condition of remaining teeth are considerations for prosthetic rehabilitation.[154] As the size of the defect increases, the number of remaining teeth and amount of residual palatal decreases, which, in turn, reduces stability, retention, and support of the obturator prosthesis.[154–157] This, then, decreases functionality overall and thus patient satisfaction.[157–159]

Osseointegrated endosseous implants placed in edentulous areas provide

retention and stability to prostheses that otherwise would be compromised due to lack of tissue-bearing surface.[155,160,161] Important factors in the successful implant prosthetic rehabilitation following radiation therapy are similar to that of nonradiated patients, that is, fixture and abutment length and appropriate selection of implant sites. However, in a patient with a history of radiation therapy, radiation dose to proposed implant sites and time from radiation therapy to implant surgery requires significant consideration.[72,155,156] As the amount of radiation increases to a proposed implant site, the risk of ORN also increases. It has been suggested that HBO therapy reduces this risk; however, the use of implant-born prostheses in radiated patients remains controversial and is actively being studied.[162]

Difficulties in prosthetic rehabilitation can be minimized, or even eliminated, with careful surgical planning. Dental casts are usually fabricated presurgically and used for discussion between the head and neck surgeon and the maxillofacial prosthodontist. The proposed surgical margins should be established so that an appropriately sized prosthesis can be fabricated. The overall oral condition should be addressed, that is, oral surgical needs and dental restorations that may be required. Teeth that are nonrestorable or have questionable prognoses require extraction, ideally at the time of surgery.[155]

Several surgical enhancements can be incorporated in order to improve the outcome of the prosthesis.

1. Osteotomies between teeth should be avoided; rather, it should be made through either an edentulous area or the socket of an extracted tooth in order to prevent bone/tooth loss.[155]
2. A split-thickness skin graft (STSG) should be placed in the maxillary defect over any exposed bone and at the cut edge of the buccal mucosa. This will allow for formation of a scar band, which will provide retention of the obturator and create a prosthesis-bearing surface.[72,155–164]
3. Removal of the inferior turbinates, even if unaffected but tumor, is recommended to allow for adequate superior extension of the prosthesis. The respiratory epithelium surrounding the turbinates is friable and will become a constant source of bleeding and irritation.[72,155,156,160]
4. The amount of remaining maxilla will directly influence the support and stability of the prosthesis. Sparing prosthesis-bearing areas, that is, the tuberosity bilaterally and the premaxilla, will increase functionality of

prosthesis and most likely patient acceptance.[72,155,156,160] The remaining palatal mucosa can be wrapped around the palatal aspect of the osteotomy to provide a denture-bearing surface.

5. An intraoral approach is recommended when possible, as opposed to a Weber-Fergusson incision. This allows for ease of manipulation of the lip and cheek postoperatively during the interim phase of obturation.[160,163]

Surgical Reconstruction of Maxillary Defects

Current microvascular techniques have facilitated surgical reconstruction of a maxillectomy defect, thus effectively restoring function and cosmetics. However, depending upon bulk, type of graft, and location of reconstruction, it may preclude future prosthetic rehabilitation. If the flap invades the space where the prosthetic teeth should be, prosthetic rehabilitation may not be possible without revising the flap (**Fig. 29.24A and B**).

Figure 29.24. A: Maxillary defect immediately following reconstruction; note lack of restorative space and lack of vestibule. **B:** Same patient following revision and implant placement. Note sufficient space for prosthetic teeth.

An osseous element is often necessary for successful prosthetic rehabilitation following surgical reconstruction of the maxilla. This bone provides support for the prosthesis and provides an area for implant placement. The free fibula graft is well suited for this type of reconstruction. The vertical height of a fibula has been found to range from 13.1 to 16.7 mm, with an average of 15 mm.[164–166] The adequate stock of bone, along with bicortical configuration, is ideal for placement of endosseous implants (**Fig. 29.25**). Many bone defects in the head and neck are considered suitable for fibula reconstruction and functional rehabilitation can be optimized in these patients. With the addition of CAD/CAM technology, osteocutaneous reconstructions can be planned virtually to include endosseous implants. CAD/CAM implant placement guides can be fabricated allowing implants to be placed into the fibula prior to transfer into the head and neck region. This allows for predictable prosthetic restorations that are implant supported/retained, potentially delivered immediately in some cases.[167–170] Patients who receive implant-retained maxillary prostheses placed into fibula reconstructions have near optimal mastication and speech.[169]

Figure 29.25. Model of endosseous implants placed into a fibula. Note the bicortical stabilization.

Soft tissue flaps, without an osseous component, often lack the ability to support a prosthesis, making for a nonretentive and potentially nonfunctional prosthesis. Alveolar or bone support and relatively immobile soft tissue are key elements in a functional prosthesis. These flaps are thought to best serve patients who are not interested in postsurgical prosthetic rehabilitation and those, possibly, unable or unwilling to care for a traditional obturator.[154]

Prosthetic rehabilitation using obturator prosthesis is divided into three phases: surgical, interim, and definitive.

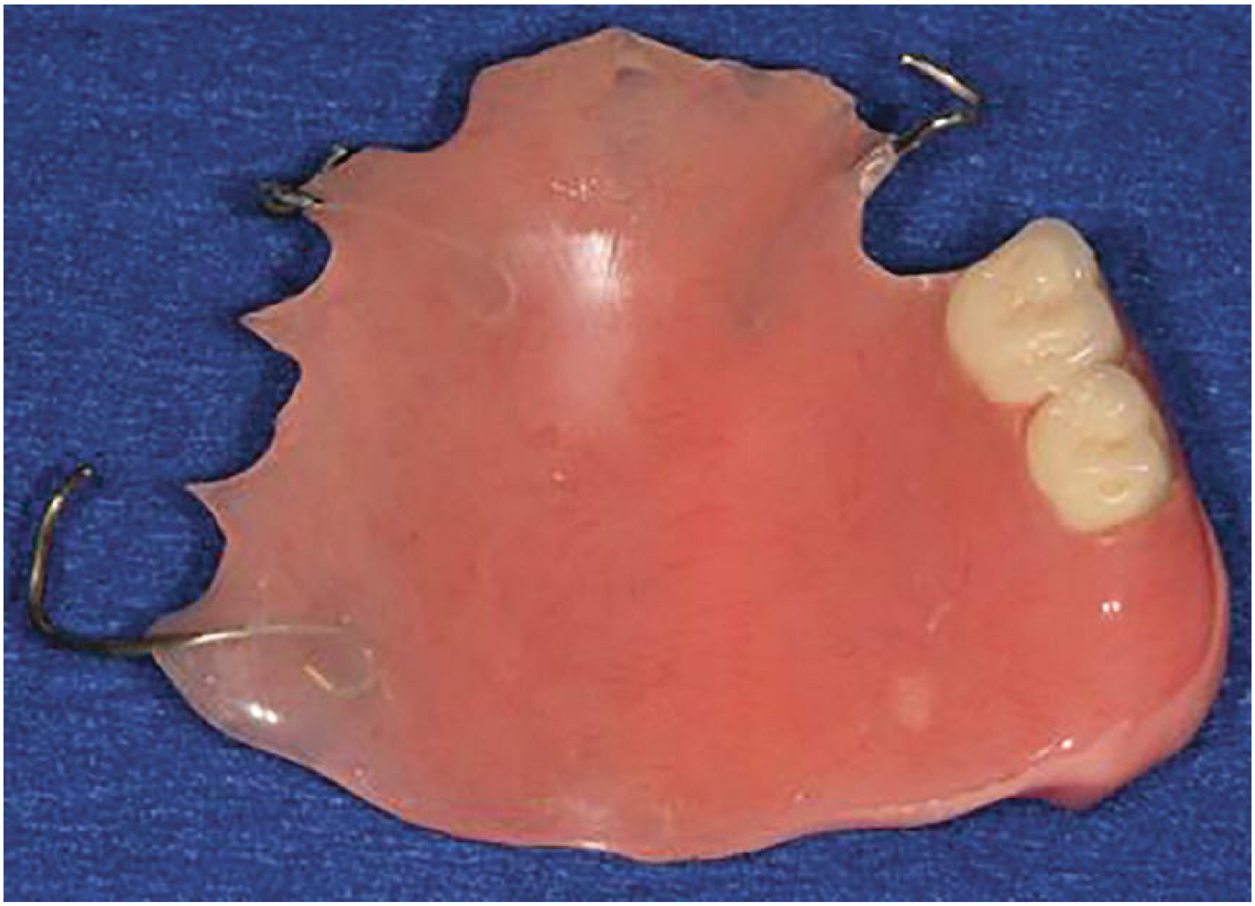
Surgical Obturator

A surgical obturator is a prosthesis, often without prosthetic teeth, placed at the time of surgery. The primary objective of this prosthesis, along with restoring the palatal continuity, is to support the surgical packing, holding the STSG in place. It also reduces risk of postoperative bleeding. Surgical obturators enable early postoperative oral alimentation and, therefore, often bypass the need for a nasogastric feeding tube and decrease the duration of postoperative recovery. Maintaining the patient's ability to eat and speak immediately postoperatively improves patient's psychological status.[154,155,163,168] The surgical obturator most often will not have prosthetic teeth, depending on the situation. It is usually retained by stainless steel orthopedic screws in the edentulous patient and by interdental wrought wire in the dentate patient. For patients who wear prostheses, it is sometimes possible to modify an existing maxillary removable partial denture or complete denture to be used as a surgical obturator.[14] A surgical obturator remains in place for ~5 to 10 days; however, it can remain in place for up to 14 days without problems.

Interim Obturator

An interim obturator prosthesis is placed following removal of surgical obturator/packing, generally 5 to 10 days later. During normal healing, the maxillectomy defect will continue to remodel, leading to ongoing challenges of nasal regurgitation and hypernasality. In order to accommodate these

changes, the interim obturator is modified with resilient polymethyl methacrylate material (**Fig 29.26**). At this point, prosthetic teeth are added to establish appropriate lip and cheek support during healing, increase function, and reduce contracture of scar tissue.[154,155,163,168] A well-contoured, intimately fitting interim obturator can be converted to a definite obturator once the defect becomes dimensionally stable. This prosthesis is worn throughout the cancer treatment phase, that is, postoperative radiation therapy and chemotherapy.



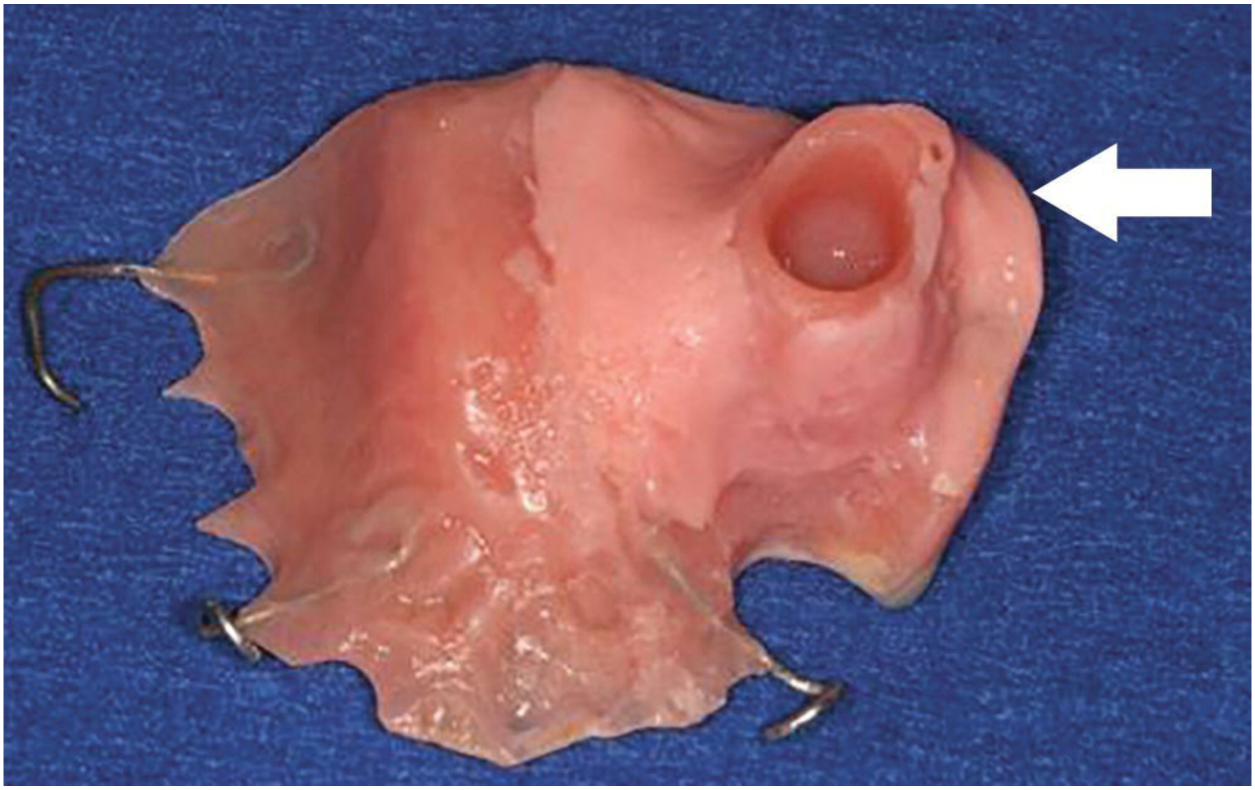


Figure 29.26. Polymethyl methacrylate obturator; the *arrow* indicates soft reline material that is modified to accommodate the healing defect.

Definitive Obturator

A definitive obturator should be fabricated 3 to 4 months following completion of treatment, once the defect is dimensionally stable; however, multiple factors may affect timing of fabrication, that is, size of defect, the use postoperative radiation, prognosis of tumor, severity of oral complications, or progress of healing.[153,154] Missing teeth are replaced to improve oral function and esthetics and restore facial symmetry. These prostheses can be fabricated with a metal framework, fabricated from chrome cobalt, depending upon contours and condition of remaining teeth and patient expectations (**Fig 29.27**). Often, a metal framework is not possible without substantial prosthetic modification to the remaining dentition. As with any maxillofacial prosthesis, the remaining dentition is critical to the functionality of the prosthesis. Every effort should be made to maintain and enhance the dentition.[71,155]

Figure 29.27. Definitive obturator with a metal framework. The definitive phase begins when the defect becomes dimensionally stable. The definitive prosthesis maximizes stability, support, and function.

Information given to the patient regarding prosthetic rehabilitation must be tempered by the experience and judgment of the clinician. Questions concerning the diagnosis and prognosis of the disease should be referred to the primary surgeon in charge of the patient’s overall care. The patient should also be informed of any variables beyond the control of the clinician that may compromise an ideal result. Members of the treatment team should not lead the patient to believe or expect that the maxillofacial prosthodontist will be able to completely restore original appearance and function.

Hygiene of the Maxillary Defect

The surgical defect can be rinsed and cleaned following pack removal with the use of a gravity irrigation system (Oral Irrigation Kit, Mentor Corporation, Health Care Products, Santa Barbara, CA) consisting of a holding tank and hose with a plastic nozzle.[171] Powered lavage systems, such as the Waterpik (Teledyne Dental, Buffalo, New York) and the SurgiLav 201 (Stryker Co., Kalamazoo, MI), can also be used and are commercially available for patient use. After the surgical obturator and packing are removed, the patient is instructed to use the irrigation system to rinse three times a day with a saline solution. This solution is made by adding 1 tsp of salt and 1 tsp of sodium bicarbonate to 16 oz of water. The irrigation system must provide enough pressure to ensure that the prepared saline rinse reaches all parts of the surgical defect. Because there are some concerns that the patient may injure the surgical defect and skin graft if a power-spray lavage system is used during the initial healing period of the first 3 weeks, the patient should be instructed in the proper use of the lavage system.

Routine dental hygiene (i.e., tooth brushing and flossing) should be resumed when the surgical pack is removed. Most patients are apprehensive about resuming tooth brushing and flossing owing to concerns that doing so may harm the surgical site, and patients must be specifically instructed to resume oral hygiene. Oral hygiene is one of the most important aspects of postoperative care and cannot be stressed too much.

During the fourth week of postoperative healing, rinsing with a 1:1 dilution of 3% hydrogen peroxide in water can be added to the routine. This mixture is helpful in loosening dried crust and debris in the surgical defect before the patient rinses with the salt and sodium bicarbonate mix. A piece of gauze measuring 4 × 4 inch or a washcloth can be wrapped around the index finger and used to clean the skin graft portion of the defect. A sponge-tipped applicator may also be used for this purpose. After the surgical site has been cleaned, the entire oral cavity, including the tongue, cheek, and remaining hard palate, should be rinsed.

The use of commercial and prescription mouth rinses during the initial healing period is discouraged because the alcohol and phenol in these products may irritate the tissues. These products may also irritate the oral tissues in patients who have received chemotherapy or irradiation as adjunctive treatment.[171,172] The extent of decreased oral opening, loss of innervation, and facial deformity secondary to maxillectomy vary according

to the extent of surgery and adjunctive treatments such as radiation therapy and chemotherapy. When the clinician anticipates these problems, oral opening exercises should be initiated as soon as the patient can tolerate them with regimens previously prescribed in this chapter.

Soft Palate

The soft palate acts as a separator between the oropharynx and the nasopharynx, similar in function to the hard palate. Unlike the hard palate, however, the soft palate moves significantly in function. When the soft palate is involved in the surgical procedure, functionality of the soft palate should be considered. A partial or completely nonfunctional soft palate is difficult or nearly impossible to restore. It is easier to rehabilitate a patient's speech and swallowing if the entire soft palate is removed.[69] Sometimes, however, in cases of limited prosthesis-bearing surface, a thin strip of soft palate can be useful for retention and support of the prosthesis.[64,74]

Primary irradiation of the soft palate may cause palatal incompetency resulting from fibrosis and tumor necrosis. Patients with a radiated soft palate may regurgitate liquid and food through the nose and may have speech impairment.[69] In this situation, prosthetic rehabilitation may be difficult or near impossible because of poor access to the oropharynx.

Mandible

Defects of the mandibular secondary to tumor ablation creates functional and esthetic challenges. Defects of the mandible that are not reconstructed often present with substantial challenges; speech, effective mastication, lip posture, bolus control, and dental malocclusion are common challenges associated with this type of procedure. Most notably, the mandible will deviate to the side of the defect thus compromising occlusion (**Fig. 29.28**). Prosthetic rehabilitation with a mandibular resection prosthesis can often reduce these challenges. As with any prosthesis, retention and stability of the mandibular resection prosthesis can be improved with the remaining mandibular teeth and endosteal implants. A nonmobile soft tissue base is critical to prosthetic success. A flap reconstruction of the mandibular defect has improved the quality of the prosthetic rehabilitation.[45]

Figure 29.28. Patient following segmental mandibular resection, without reconstruction, in maximal intercuspation. Upon opening, the mandible will deviate to the side of the defect (*right*) and dental intercuspation is minimal.

Free-tissue transfer has revolutionized mandibular reconstruction because of its predictability and improved prosthetic outcomes. The most commonly used flap to repair mandibulectomy defects is the fibula free flap. Similar to repair of a maxillary defect, the fibula flap appears to be the most adaptable graft providing adequate bone length and quality to repair any defect of the mandible.[167] The fibular flap is an excellent choice for dental implant placement and support of a prosthesis.

Most patients who have had reconstruction of the mandible can present with an inadequate vestibular depth, and a bulky, load-bearing tissue base over the reconstructed alveolar ridge, making prosthetic rehabilitation difficult or impossible. Often, flap revision surgery, that is, liposuction of the soft tissue component of the flap and placement of dental implants, is necessary for adequate prosthetic rehabilitation[69,74] (**Fig. 29.29**).

Figure 29.29. Fibula flap reconstruction after segmental mandibulotomy followed by postoperative radiation therapy. Note the tongue is tethered by the flap, making prosthetic rehabilitation challenging. Revision of the flap is needed in order to prosthetically rehabilitate this patient to create space for prosthetic teeth; note the indentations from the maxillary teeth on the distal aspect of the flap.

If the normal association of the mandibular segments with the glenoid fossa and maxilla is not maintained, prosthetic rehabilitation may be limited or even impossible. The posterior maxillary teeth, particularly the third molars, opposing the mandibular reconstruction may need to be removed to prevent trauma to soft tissue flaps. When reconstruction is not indicated in a patient who has had a mandibulectomy, removal of the condyle and ramus on the affected side prevents migration of these structures toward the maxilla, thereby facilitating prosthetic rehabilitation.

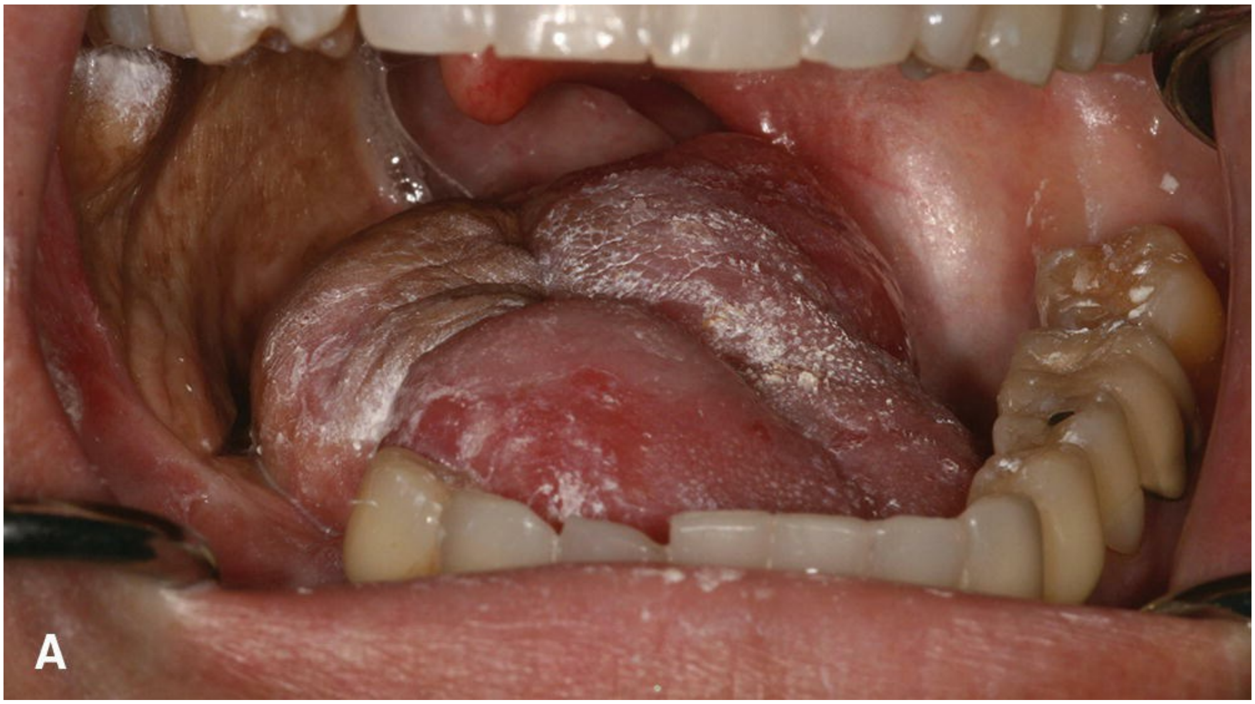
Marginal mandibulectomies (alveolectomies) can be reconstructed primarily with an STSG. Primary closure of these defects, when the tongue/floor of mouth is sutured to the buccal mucosa, often leads to

difficulty with prosthetic rehabilitation because the prosthetic space has been invaded and the tissue is substantially mobile decreasing prosthetic stability (**Fig 29.30**). Skin grafts provide a sound prosthesis-bearing surface and also separate the floor of the mouth from the buccal mucosa.[74] As with the maxilla, conservation of the supporting tissue in the mandible is important when possible.

Figure 29.30. Primary closure of the buccal mucosa, native tongue, and free flap reconstruction. This obliterates the prosthetic space necessary for mandibular resection prosthesis making successful prosthetic reconstruction difficult.

Palatal Augmentation Prosthesis

Speech and swallowing dysfunction are common problems in patients after glossectomy without or with flap reconstruction. Palatal augmentation prostheses modify the contours of the palate to allow for adequate tongue contact during speech and swallowing (**Fig. 29.31**). Articulation is accomplished, in part, by precise positioning of the tongue against the palate, teeth, and other oral structures.[154] Deglutition requires maximal contact of the tongue to the palate. Reduced tongue contact will impair speech and swallowing and recontouring the hard palate with a prosthesis allows for improved lingual contact.[154]



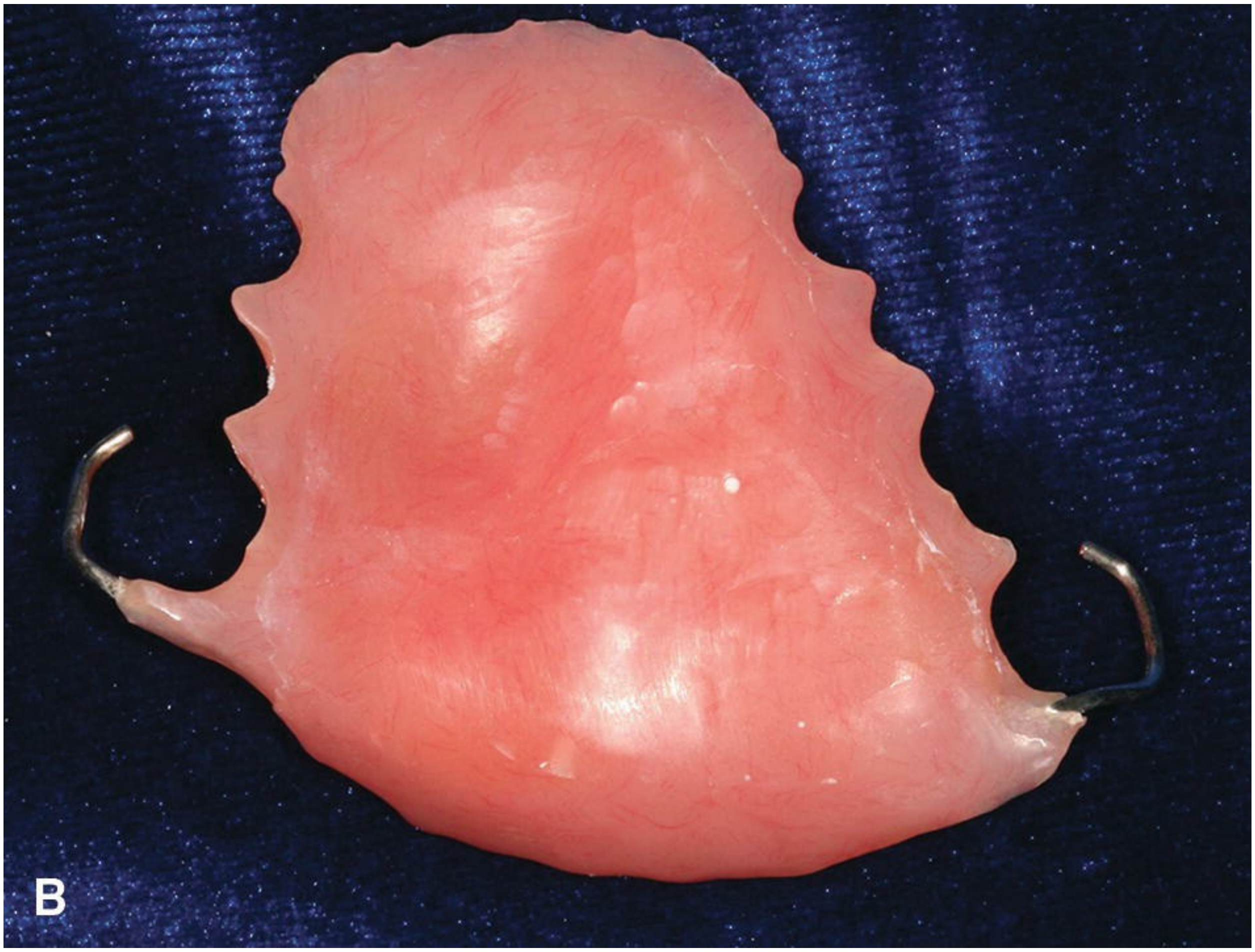


Figure 29.31. A: The limited range of motion of the tongue following partial glossectomy and radiation therapy. **B:** Palatal augmentation prosthesis that allows for appropriate lingual contact maximizing intelligible speech and adequate swallowing.

A direct correlation has been established between the amount of lingual tissue removed and impairment of articulation.[154] Patients who have speech and/or swallowing challenges postoperatively, regardless of flap reconstruction, may benefit from this type of prosthesis. A review of the studies has shown that patients with severe restrictions in tongue–palate contact following resection had an improvement in speech (86%; 36 of 42 subjects) and swallowing (86%; 32 of 37 subjects).[173]

PROSTHETICS FOR FACIAL DEFECTS

Preoperative Evaluation

Traditional facial prostheses include the nasal, orbital, and auricular prostheses. Multidisciplinary care is integral to successful prosthetic rehabilitation and can directly impact timing of prosthesis fabrication, overall cost, and overall success of the prosthetic rehabilitation. This will better prepare the patients not only physically for prosthetic rehabilitation but also psychologically for the changes that they will experience.[67] The preoperative appointment is felt to be a critically important aspect of prosthetic rehabilitation, as this appointment is reserved for setting realistic expectations and explaining risks and benefits of prosthetic rehabilitation and potential complications, which will better prepare the patients for the changes in lifestyle and appearance that they will experience. Comfort, ease of placement/removal, cleansability, and pleasing esthetics are the primary goals of any facial prosthetic rehabilitation.

During the preoperative evaluation, the maxillofacial team should also discuss: the design of the prosthesis, process of fabrication, time frame for fabrication, types of prosthetic materials available, prosthesis longevity, and associated costs. It is imperative to discuss facial and prosthetic hygiene as well as appropriate prosthetic maintenance. The esthetic expectations should be met with an honest discussion of realistic outcomes. Viewing examples of facial defects and prosthetic restoration is often most helpful to patients. Preoperative photographs of the patient can be taken to provide a record of facial features and aid in visualizing the size and contours of the future prosthetic. In some cases, where there is minimal anatomic distortion, a facial moulage (impression) can be made of the affected area before surgical resection. The dental stone cast created from the moulage can be a guide for future prosthetic rehabilitation.

Cases involving osseointegrated craniofacial implants also require preoperative assessment. Factors such as bone quality and volume, soft tissue thickness, and need for radiation therapy may affect the outcomes of craniofacial implant rehabilitation and must be appropriately evaluated prior to surgical intervention.[174–182] Surgical templates, made by the prosthetic team, are recommended to ensure proper placement of the implant(s) in the available bone and to facilitate implant placement.

General Surgical Guidelines and Prosthetic Rehabilitation

Retention is a primary component in the success of any prosthesis, particularly a facial prosthesis.[183] Prostheses can be retained by engaging anatomic undercuts, adhesive, double-sided tape, osseointegrated implants, or a combination of these methods. An appropriate prosthesis-bearing surface is also integral to success of the prosthesis. The ideal postsurgical site characteristics vary depending on type of facial prosthesis. An ablative procedure performed without an understanding of maxillofacial prosthodontic principles may provide a cure but leave the patient orally and esthetically handicapped. Facial defects can be optimized for prosthetic rehabilitation through preoperative discussion between the ablative and reconstruction surgeons and the maxillofacial prosthodontist and consideration of several simple, surgical principles.

These general principles are as follows:

1. Bony margins should be smoothed and rounded to minimize the risk of bony exposure and allow for the comfortable use of prosthesis.
2. Placement of an STSG on exposed bone or periosteum not covered with free tissue or a pedicled flap will resist the abrasive forces of prostheses and decrease mucous secretion in the defect. Prosthesis hygiene and retention are improved by providing an adequate gluing surface.
3. Unsupported tissue tags should be removed, as this tissue is difficult to capture during a moulage procedure. Prostheses fabricated over tissue tags frequently are overcontoured and, due to facial movement, difficult to retain.
4. Donor tissue, ideally, should match the recipient bed adequately and be relatively hairless. Excessive hair growth will interfere with prostheses retention; laser hair removal may be necessary postoperatively.
5. Excessively bulky flaps can obliterate the prosthetic space, making prosthetic rehabilitation difficult or impossible. Revision of the flap may be necessary to provide adequate space for a better outcome.

Postsurgical Evaluation

The patient should return to the maxillofacial prosthetic team postoperatively to evaluate healing and the extent of anatomical loss. At this point, the time frame for fabrication of the prosthesis will be decided. Factors deciding this

time will be dependent on the presence of exposed bone, infection, or bulky soft tissue flaps and the need for adjuvant therapy. These complications will delay prosthetic rehabilitation and should be discussed with the surgeon to discuss possibility of revision. Gentle palpation of the prosthesis-bearing surface can identify areas of tenderness, edema, friable/bleeding tissue, tissue tone, and mobility.[184] Hypermobile tissue can significantly decrease prosthesis retention and thus poses a significant challenge.

Implant position can be evaluated at this point and thus determine the future retentive mechanism. Prosthetic components are varied. Implant-retained facial prostheses are often retained by magnets or, at times, dental components, for example, locator attachments can be used to retain a substructure. If osseointegrated implants are used, 6 months is recommended for adequate osseointegration prior to prosthetic rehabilitation. Prior to prosthetic rehabilitation, the prosthesis-bearing tissue ideally should be dimensionally stable to ensure an accurate fit of the prosthesis.

Biomaterials

The success of any facial prosthesis is dependent on the physical and mechanical properties of the biomaterial used. Since the 1960s, elastomeric material, that is, silicone rubber, has been the most commonly used biomaterial in facial prosthesis fabrication.[185] The ideal mechanical properties of silicone include durability, ease of manipulation, and flexibility similar to that of skin. This material can also be colored to mimic human skin shade and texture relatively easily; coloration of this material can be easily accomplished by either intrinsic or extrinsic coloring with simple oil-based paints and pigments.[186,187] Limitations of silicone rubber include poor edge strength, limited material longevity, discoloration over time, and the ability to support fungal growth; because of these limitations, the average lifespan of the prosthesis is 1 year. Exposure to ultraviolet light, daily application, and removal of adhesive are also thought to decrease longevity.[188,189]

Acrylic resin is often utilized in facial prosthesis, particularly for substructures with samarium cobalt magnets. These substructures help guide the prosthesis into place as well as house the retentive components needed for prostheses for both conventional and implant-retained prostheses. Additionally, acrylic resin is used to fabricate an ocular prosthesis used in an

orbital prosthesis.

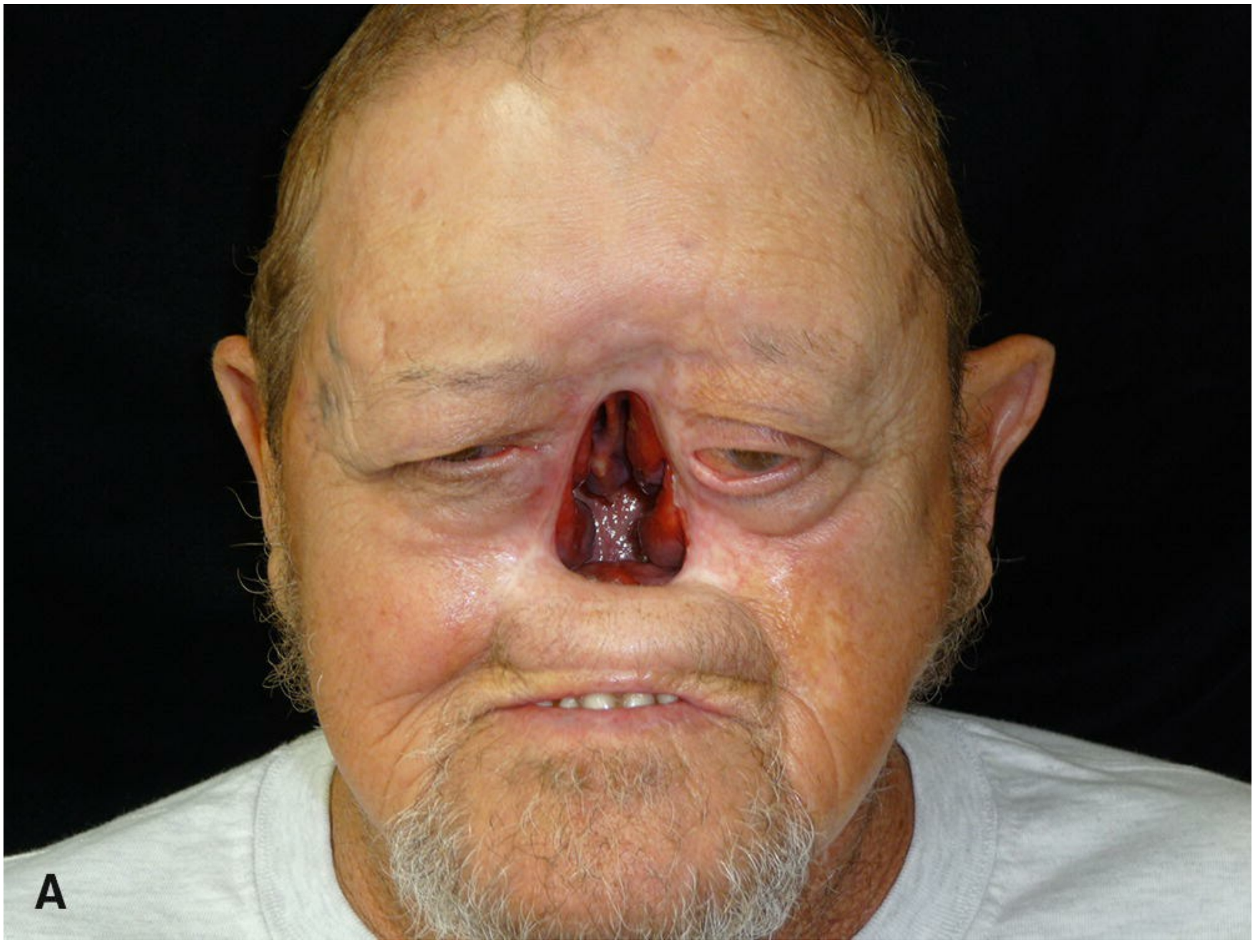
Prosthetic Retention

Multiple retentive mechanisms are available for facial prosthetic rehabilitation. Engagement of anatomic undercuts is useful in retaining a prosthesis, although, depending on location, or tissue friability, these undercuts may not always be available. The type of prosthetic retention is generally directed by the patient's defect site and contour, the quality of the underlying hard and soft tissue, and tissue movement with facial expressions. Medical-grade adhesive and double-sided tape are most often used to retain facial prostheses. Prostheses can be extended to provide adequate gluing surface; however, facial movement is the limiting factor. Adequate adhesion cannot be achieved on friable, weeping, or thin tissue. Adhesive interaction with the skin can affect the longevity of the bond, decreasing prosthesis retention, and lead to dermatologic sensitivity/irritation.[24] Maintenance of the skin and prosthesis requires considerable daily effort and dexterity by the patient. Patient acceptance and confidence with the prosthesis relies upon predictable retention of the prosthesis. Endosteal implants are becoming more common in patients requiring facial prostheses; however, this may not preclude the need for adhesive retention as adhesive may still be required to disguise the margins of the prosthesis.

Nasal Prosthesis

Malignancies involving the nose may require complete or partial rhinectomy. When nasal bones and the anterior nasal spine are preserved, local flaps produce excellent results. However, if these structures cannot be preserved, a prosthesis is often the most esthetic option. Saving even a portion of the nasal bone allows vertical support for the prosthesis and, if necessary, for eyeglasses. Reducing the profile of the distal end of the nasal bone allows for a prosthesis to be overlaid without increasing nasal projection. This procedure also gives the clinician greater control in determining the final dimensions of the nasal prosthesis, which may need to be decreased to avoid unfavorable alteration of lip contours following rhinectomy. Unsupported tissue tags, such as an alar remnant, should be resected.[190,191] The borders of the resection and any exposed bone, such as the nasal bone or the anterior nasal spine, should be lined with an STSG to provide prosthetic support for

the prosthesis as well as help reduce secretions (**Fig. 29.32**).[190] If the septum is preserved, the anterior border should be reduced to increase the space for a properly contoured prosthesis. Contracture of the graft at the periphery of the surgical site decreases the amount of muscular action during facial movements (e.g., smiling and eating) and makes the prosthesis more stable.



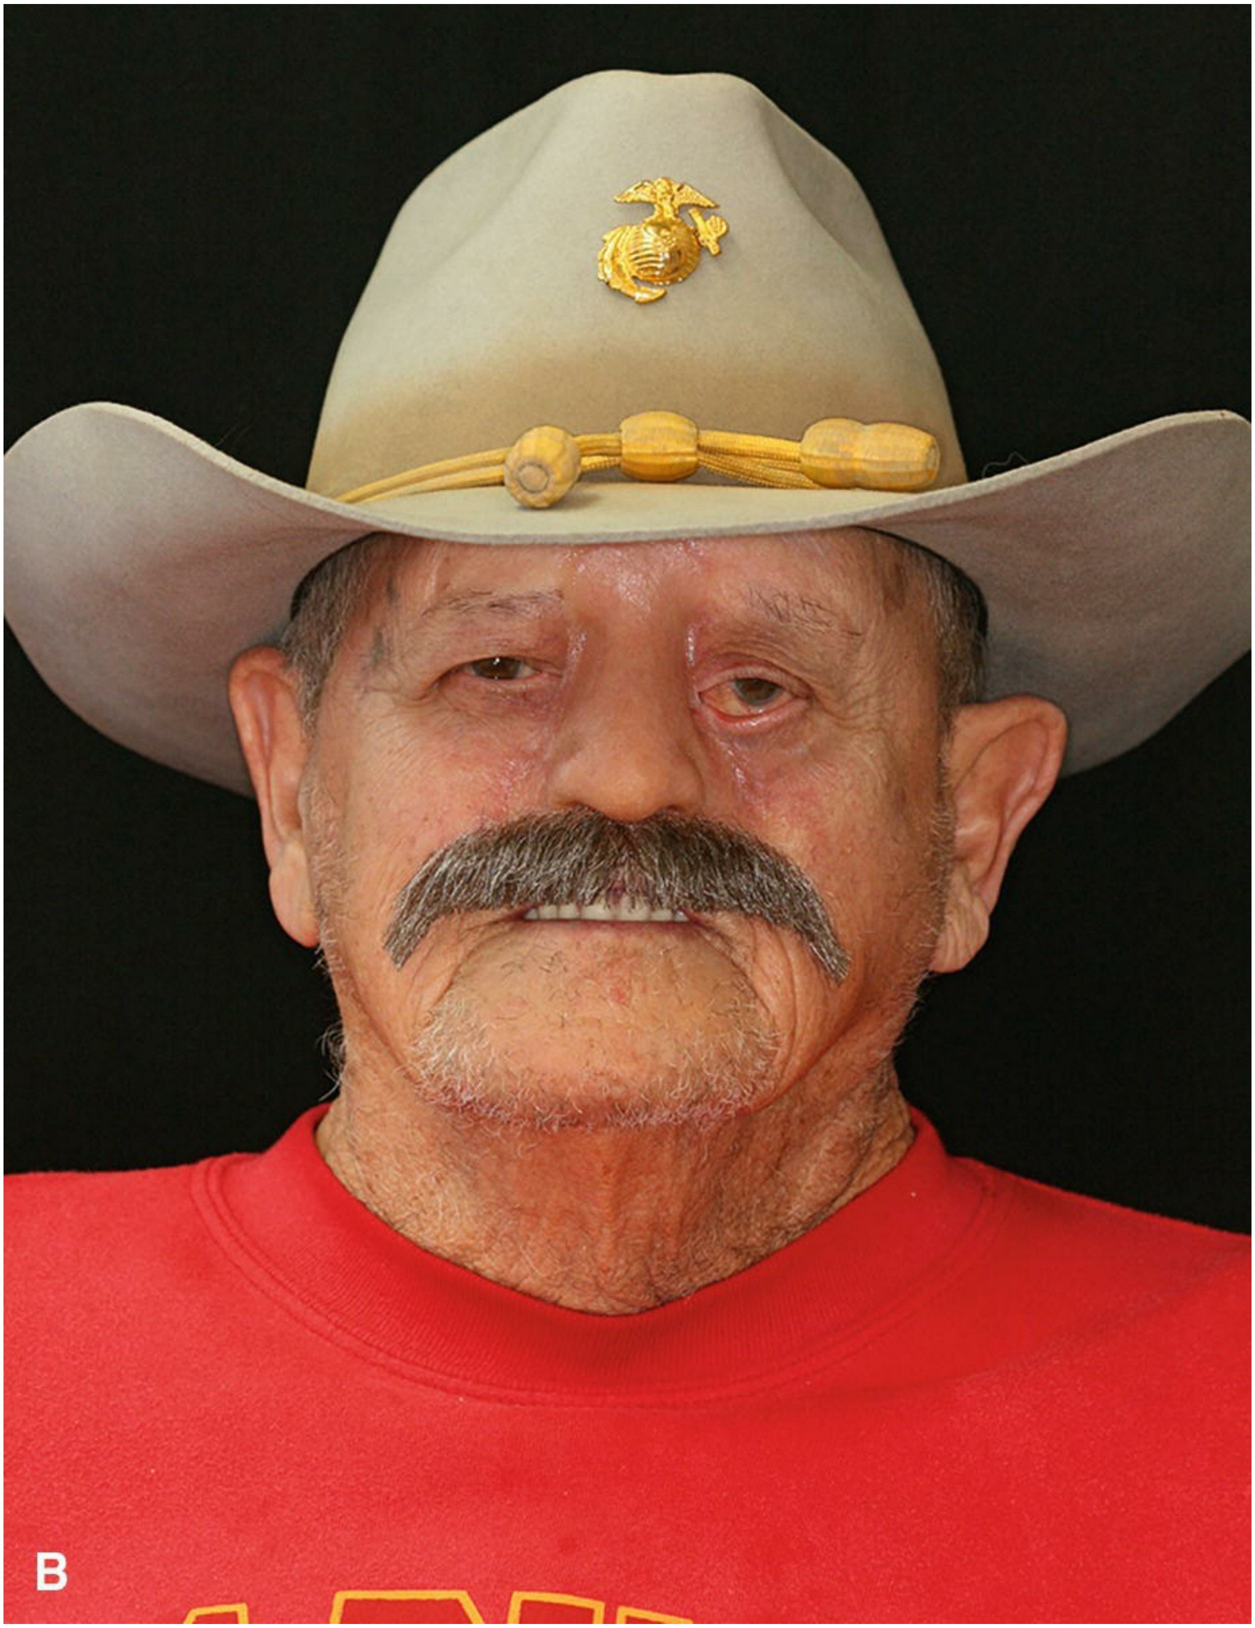


Figure 29.32. A: The skin graft on the superior aspect of the defect enhances adhesion of the liquid water-based adhesive used to retain the nasal

prosthesis. **B:** Moustache masks superiorly placed lip.

Following a rhinectomy procedure, the upper lip tends to contract superiorly despite the surgeon's efforts to maintain a normal intraoperative position, and therefore, every attempt should be made to maintain normal lip position.[191] When this contraction occurs, the lip is everted and raised to expose the anterior dentition. With preservation of the nasal spine, however, the superior lip attachments remain in its normal position (**Fig. 29.33**).

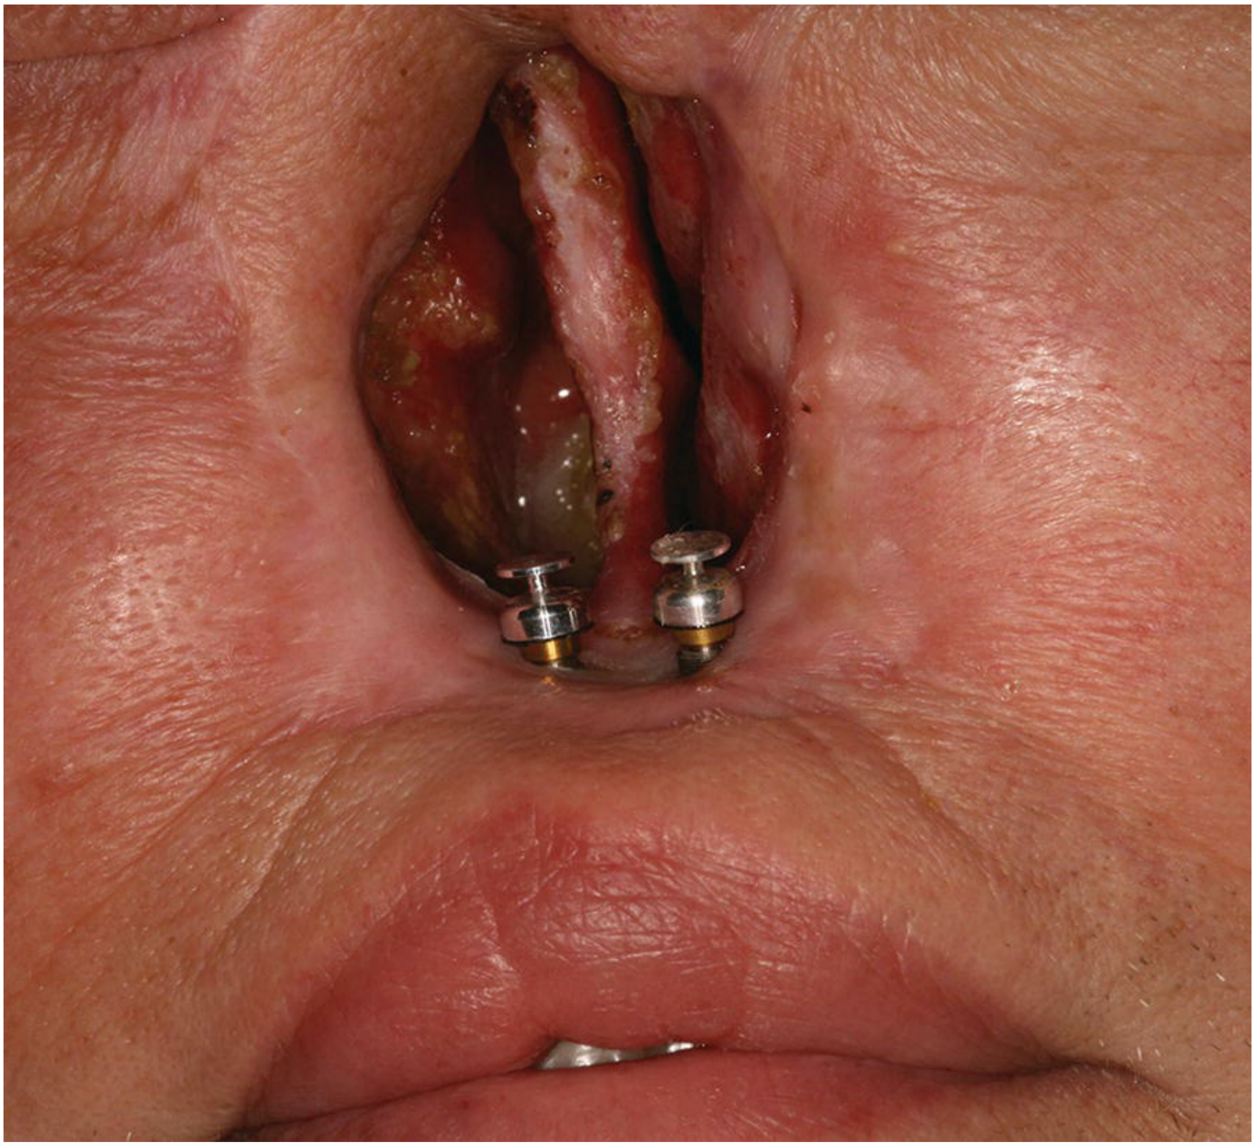

Figure 29.33. Patient following rhinectomy for SCC of the nasal cavity. Notice the upper lip has everted superiorly. Implants were used with locator attachments in order to retain a facial prosthesis.

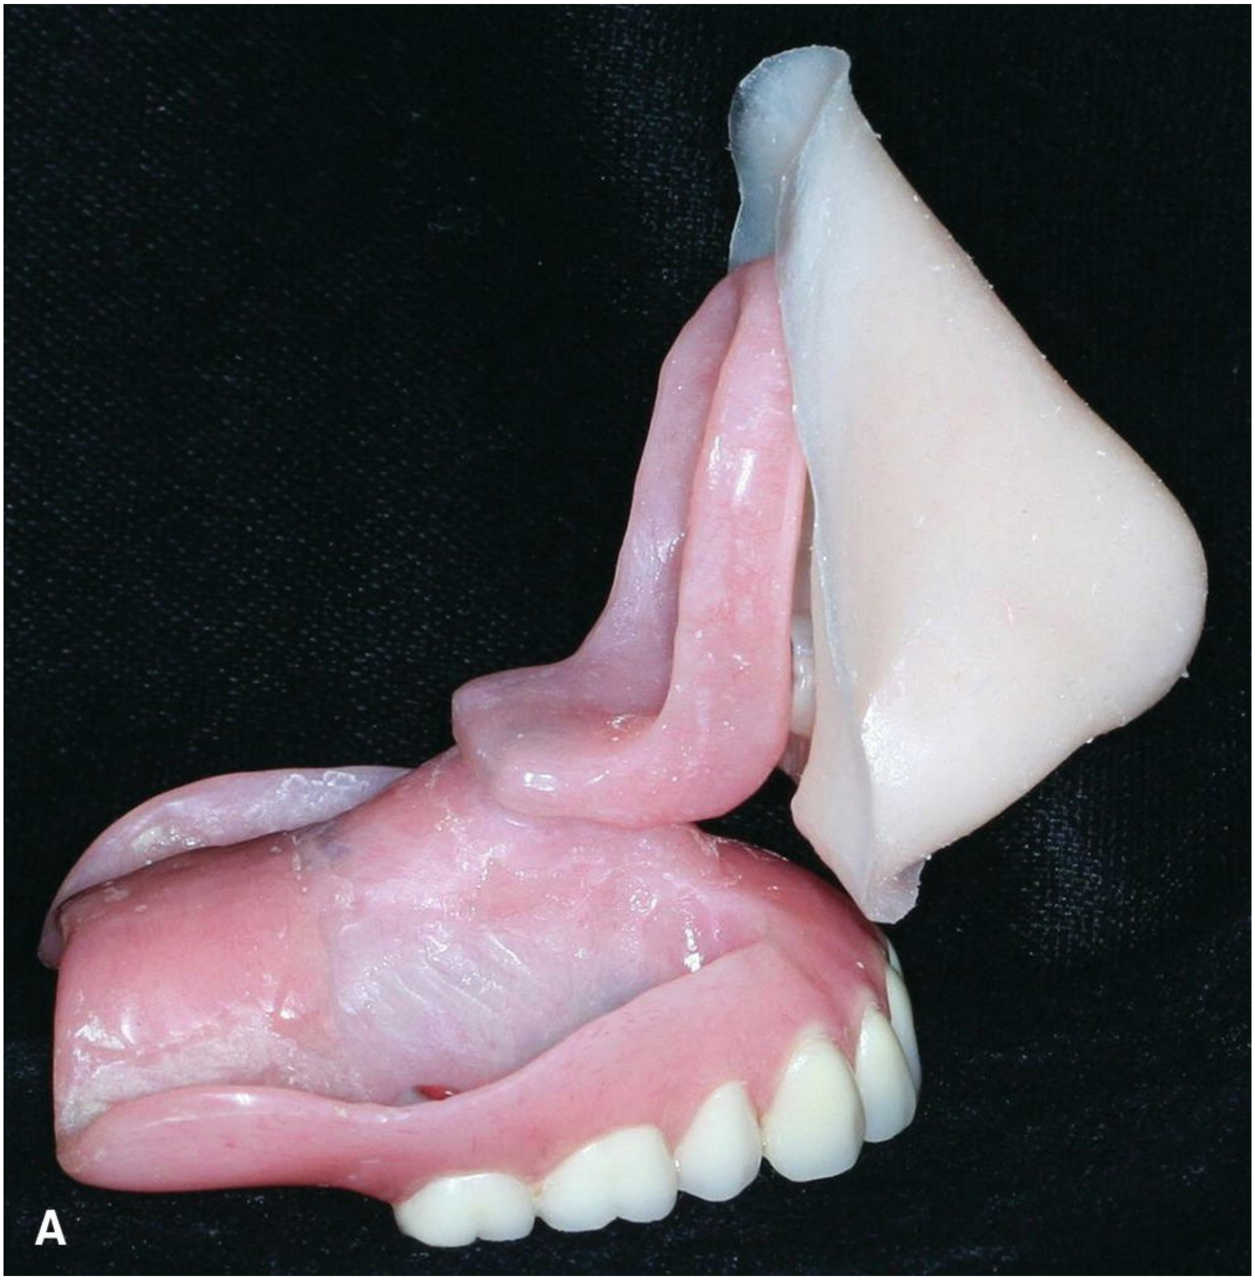
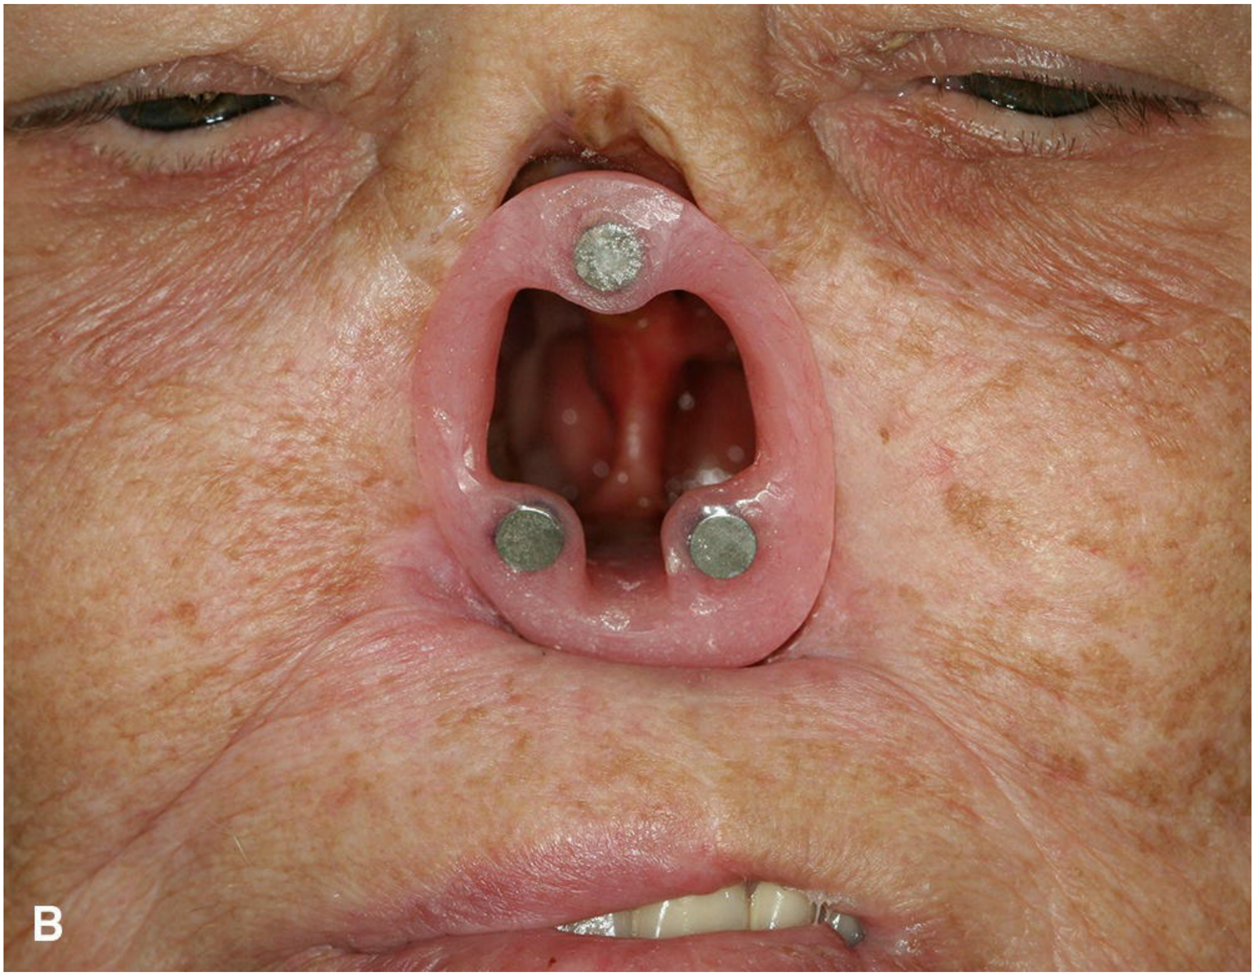
Combined Defects

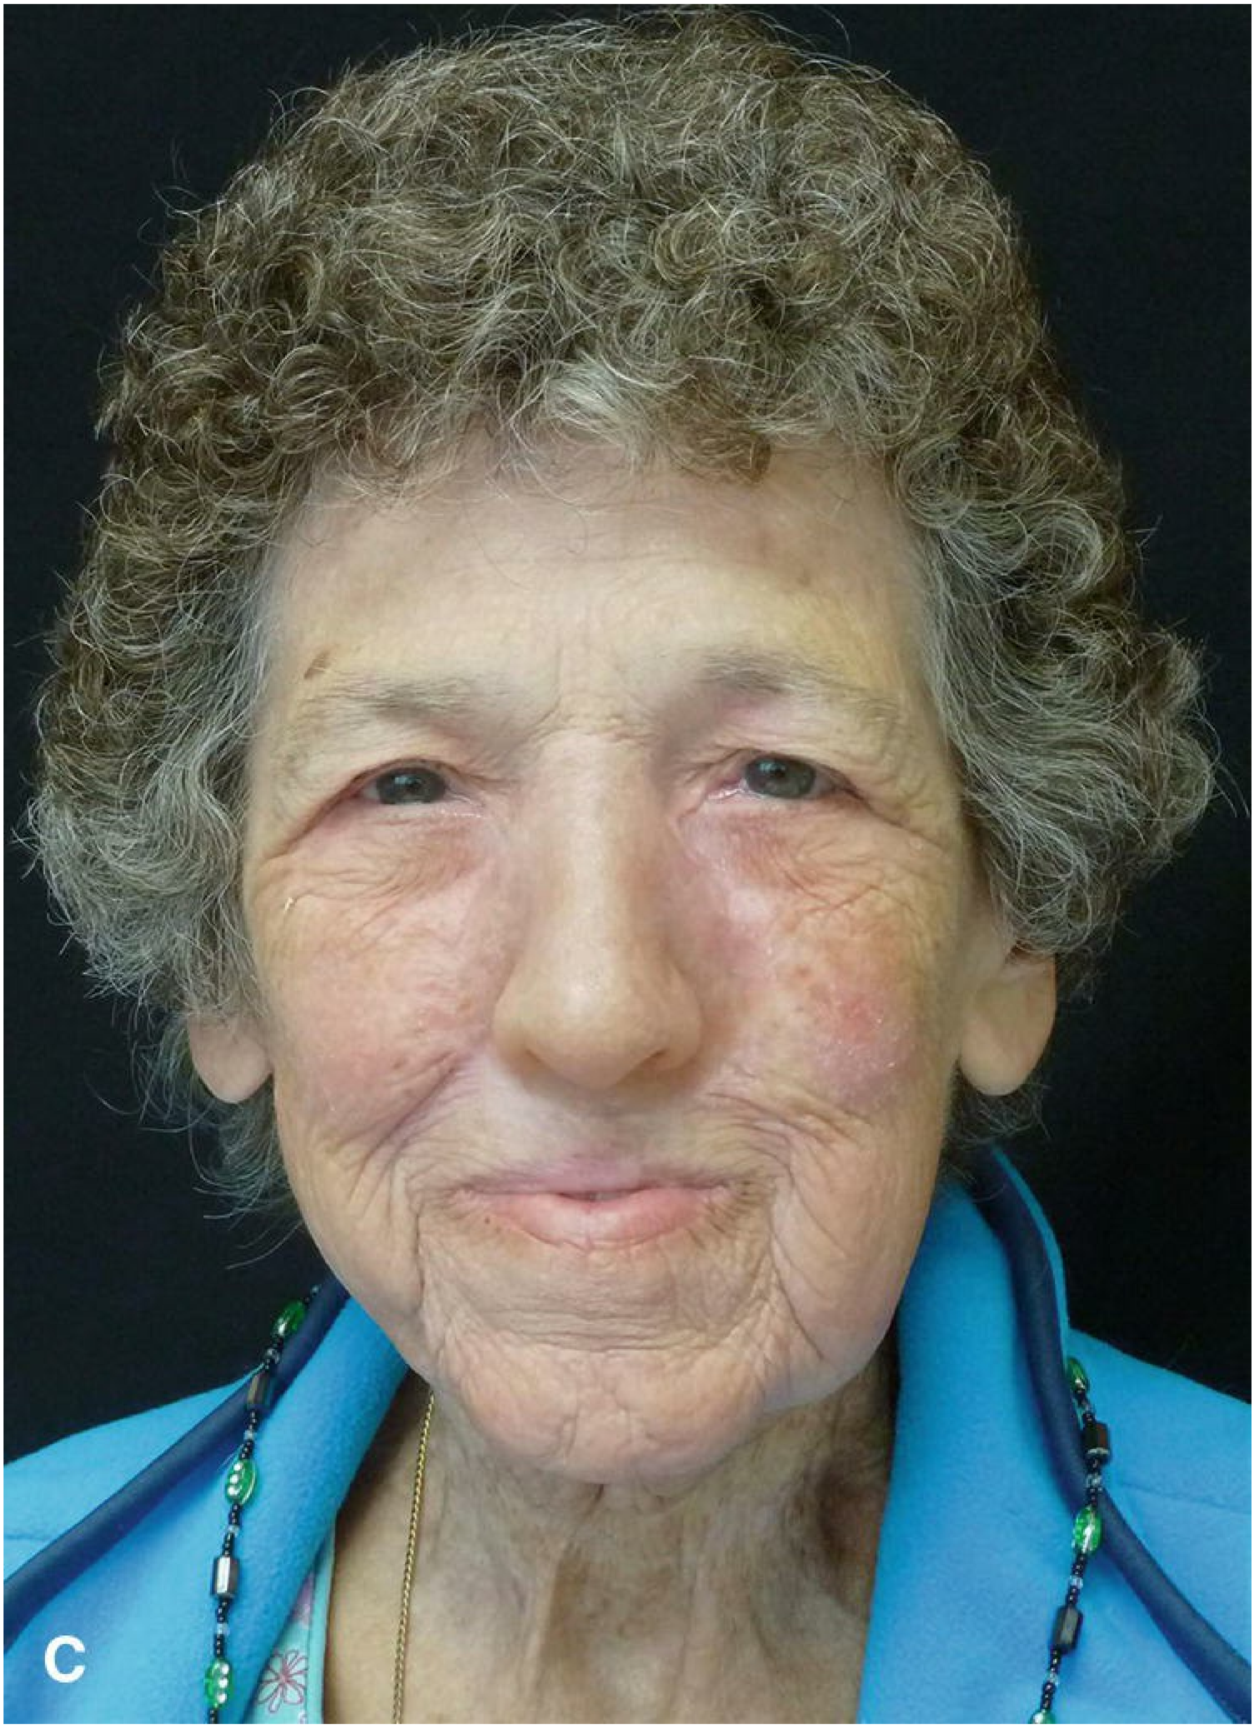
In cases when a nasal defect extends into the oral cavity, a stable intraoral prosthesis can increase retention of a facial prosthesis. This is achieved by extending the oral prosthesis into an anatomic recess within the midface defect, mechanically connecting the intraoral to the facial prostheses (**Fig. 29.34**). Most commonly, magnets serve as an attachment.[192,193] A large defect of the midface can be reconstructed by microvascular free flap, effectively closing the sinus cavity; however, if a patient desires a prosthesis after this type of reconstruction, the flap should be positioned to allow adequate space for development of proper contours of the prosthesis. Concave flap contours generally produce a better esthetic result.



A



B



C

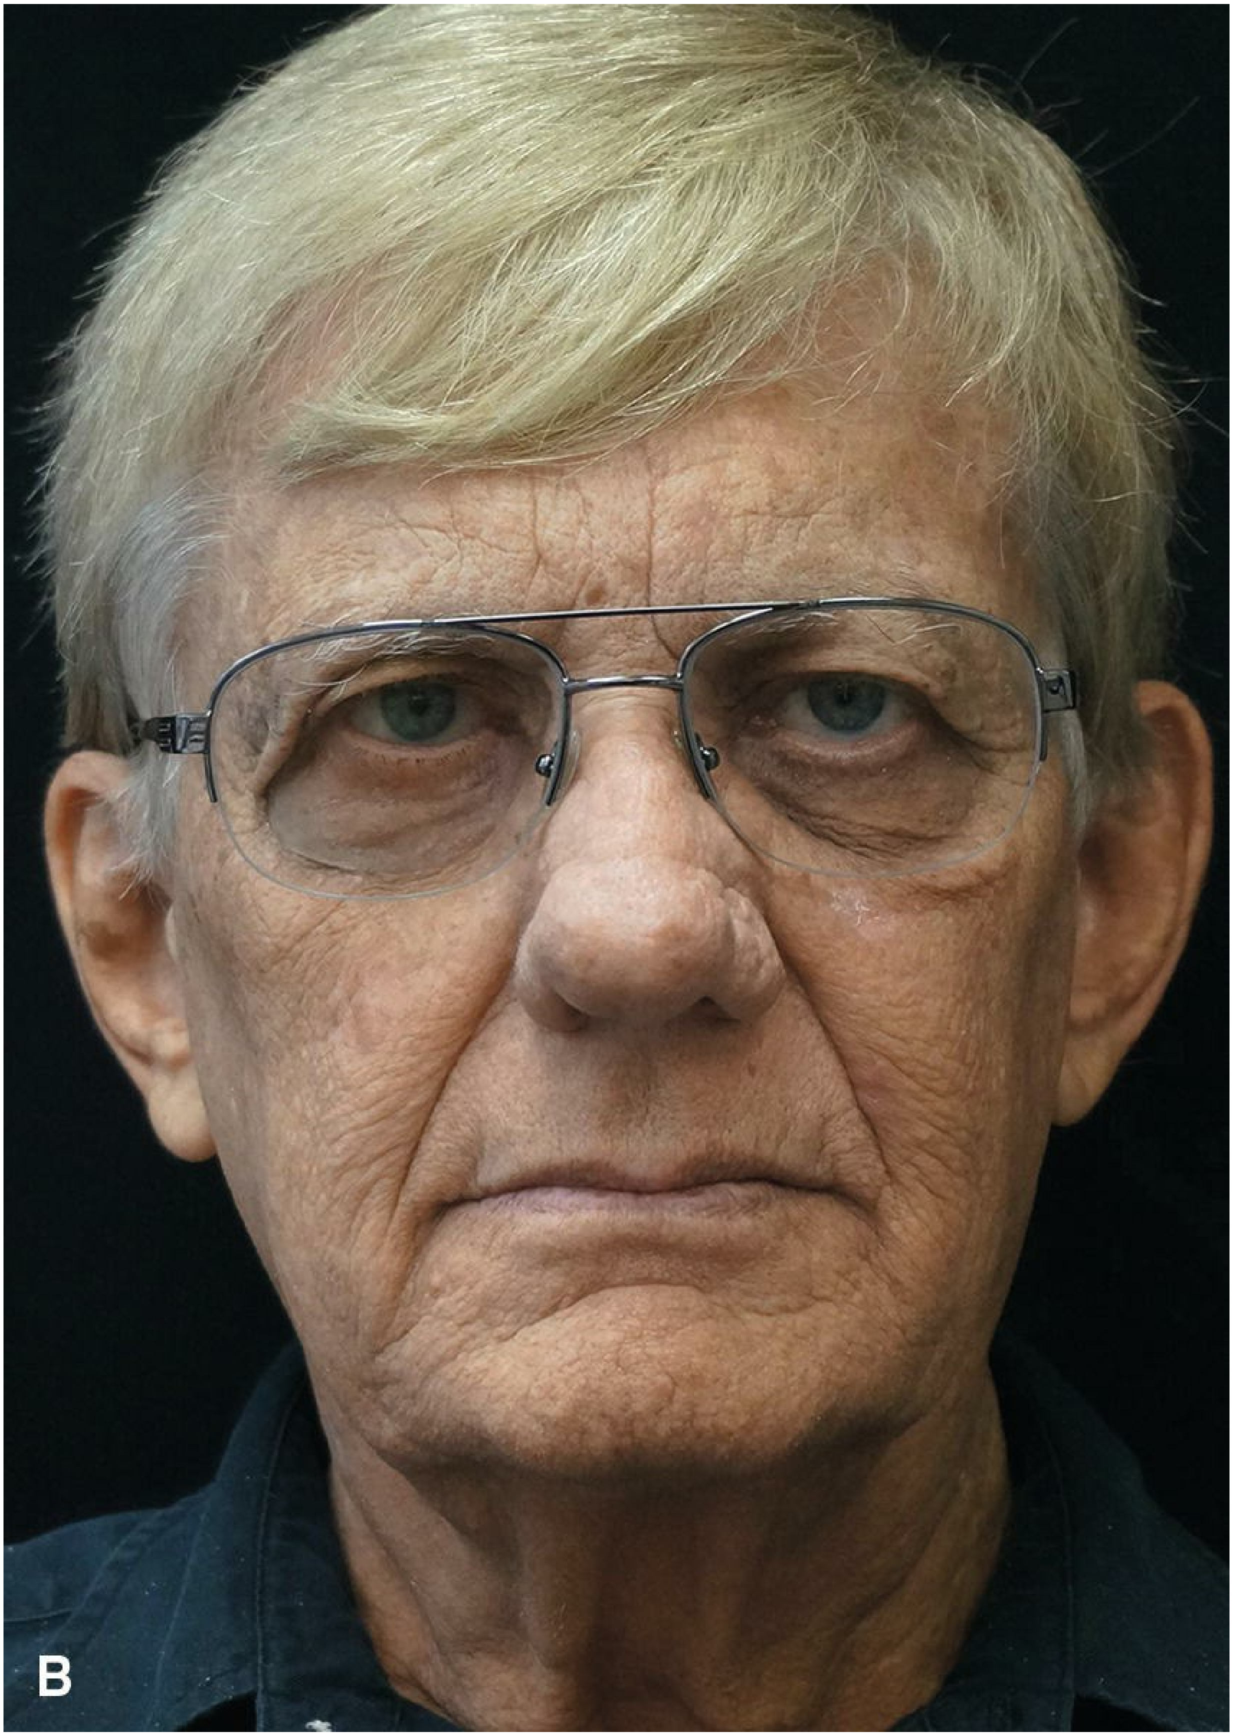
Figure 29.34. A: Nasal prosthesis prior to extrinsic coloring. Note that maxillary obturator is connected to the acrylic substructure for the nasal prosthesis. **B:** Acrylic substructure in place. **C:** Final prosthesis in place.

Orbital Prosthesis

The design and fabrication of an orbital prosthesis following an exenteration is thought to be one of the most esthetically challenging restorations. The difficulty lies in the fact that the prosthesis must mirror image the existing eye and its unique contours of the eyelids and surrounding tissues exactly. Minor inconsistencies are easily noticeable to the casual observer. The perfect recipient site is needed to achieve an esthetically acceptable orbital prosthesis.

The eyelids should be resected while the position of the eyebrow is maintained. An STSG is placed to the depth of the defect, covering any exposed bone allowing for adequate hygiene (**Fig. 29.35**). This STSG also allows the prosthesis to be extended into the defect for greater orientation and stability.[194] Occluding the orbit with bulky flaps should be avoided (**Fig. 29.36**). A concave bony orbit lined with an STSG is the ideal recipient site for an orbital prosthesis, providing an immobile tissue foundation, the depth required for mirror imaging, and a good adhesive platform.

A



B

Figure 29.35. A and B: The patient is a 63-year-old male with a history of recurrent squamous cell carcinoma of the right bulbar conjunctiva, caruncle, and lower palpebral conjunctiva who underwent a right orbital exenteration. The concavity of his defect provides ample space for an ocular prosthesis to be correctly positioned within the orbital prosthesis resulting in excellent esthetic results. Eyeglasses aid in disguising the borders of the prosthesis.

Figure 29.36. Prosthetic restoration of an orbital defect is one of the most difficult defects to restore. Bulky flaps that occlude the orbit make restoration difficult. Note the flap invades the space for ocular prosthesis. A concavity defect lined with an STSG is preferable whenever possible.

Auricular Prosthesis

As with the nose, surgery of the ear can vary from subtotal resection to a total auriculectomy. With a total auricular prosthesis, the clinician has more freedom to determine the shape, size, and location of the prosthesis, allowing for easier fabrication than a partial auricular prosthesis. Unlike the orbital prosthesis, direct comparison of the natural ear to the prosthetic ear is almost impossible. The recipient area should be flat or concave; convexities from excessive tissue bulk can hamper esthetic results; however, tissue concavities assist in the orientation and stability of the prosthesis and allow the margins to extend in a 0-degree emergence profile.[174]

The tragus is a stabile prosthetic landmark and, therefore, should be preserved whenever possible.[194] The tragus allows the anterior margin of the prosthesis to be hidden behind the posterior flexure and facilitate prosthetic placement. The inferior half of the soft tissue pinna is of little or no value. The lobe of the auricle lacks cartilaginous support and therefore is normally drawn down and away from the head, also of little value prosthetically. The lobe is difficult to capture in an impression, and bilateral symmetry usually cannot be achieved. The superior half of the auricle has better cartilaginous support but tends to distort postsurgically. Preserving a portion of the root of the helix provides a good landmark and support for eyeglasses. This area may help later in vertical support of the prosthesis. The anterior superior helical rim should remain if possible. Posterior regions may be grafted (**Fig. 29.37**).

A

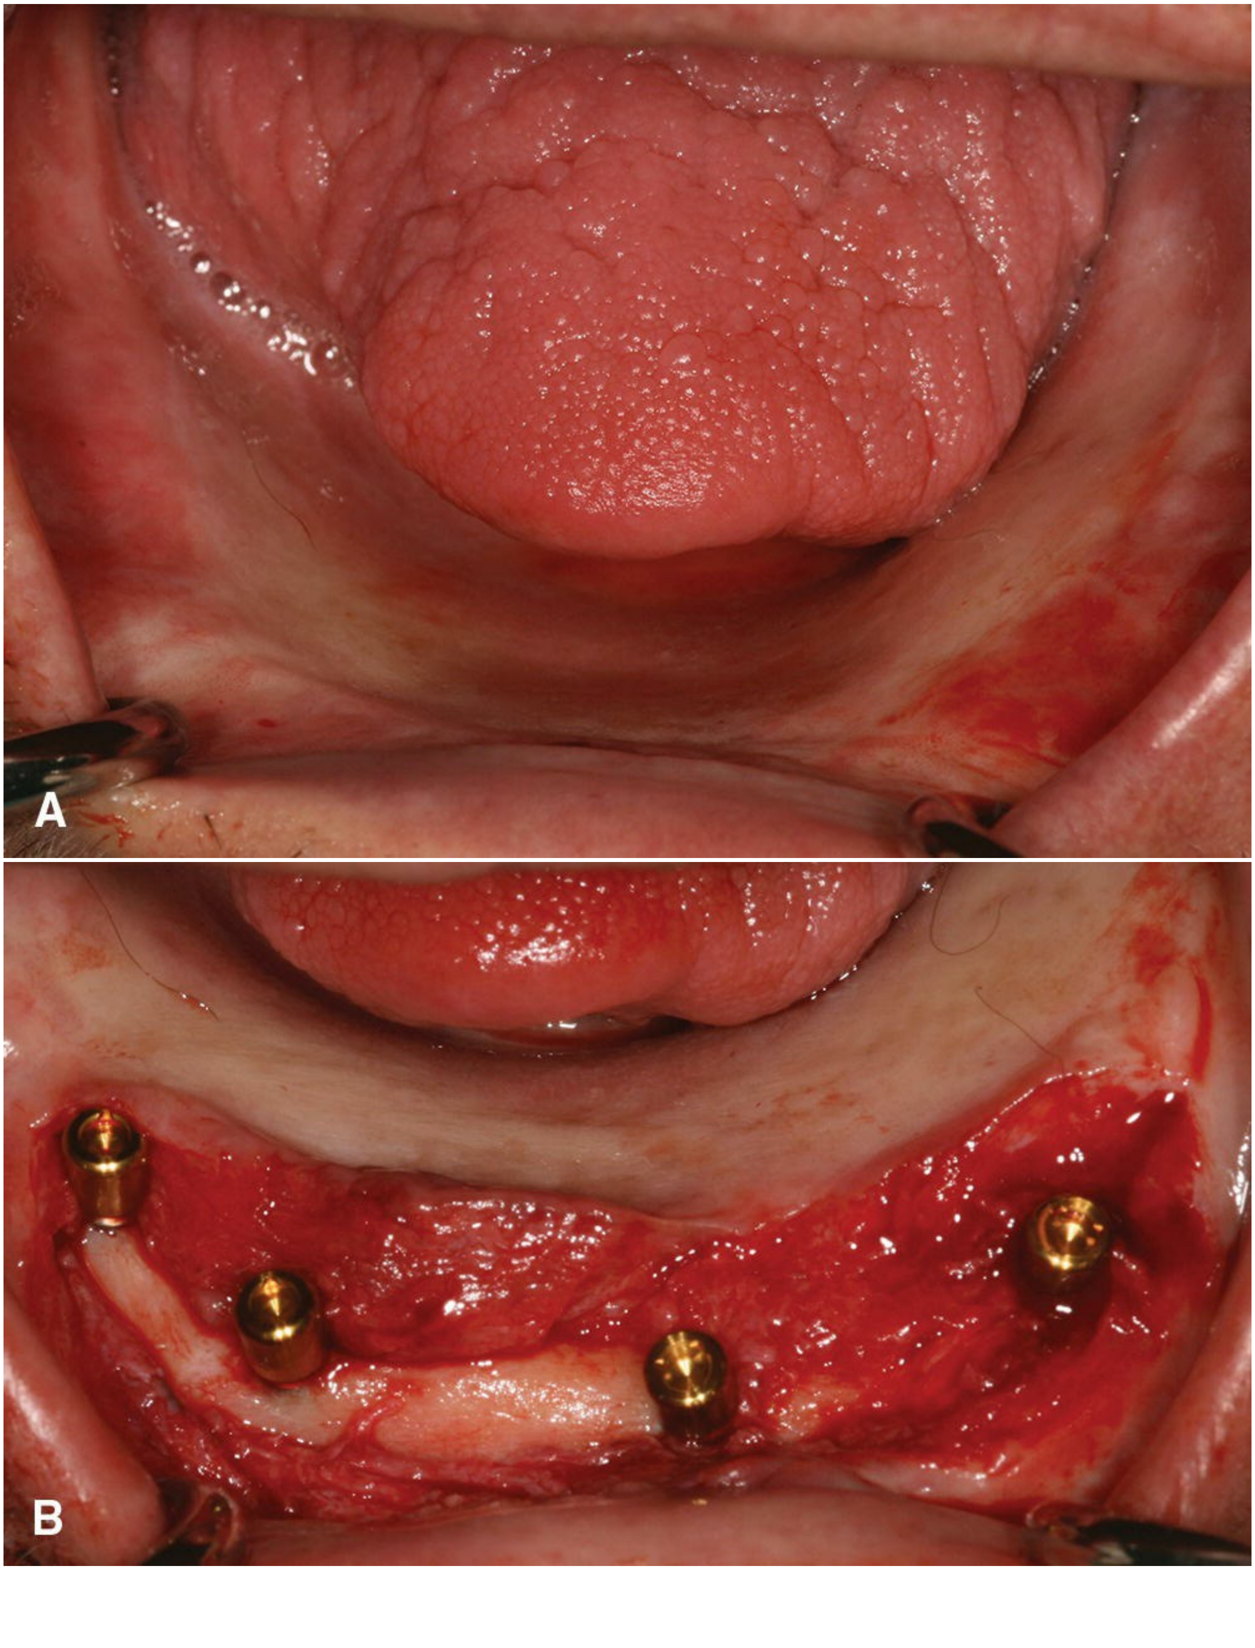
Figure 29.37. A: Patient is with a history of recurrent squamous cell and basal cell carcinoma of the right external auditory canal. The flat contour of the skin paddle of a microvascular flap absent of a stable anatomical

landmark (such as the tragus) is a challenge for repeatable correct positioning of the auricular prosthesis. Retention of the prosthesis achieved with the use of a medical-grade double-sided tape. **B:** Final prosthesis.

Prosthetic replacement of missing facial tissues has several advantages over surgical reconstruction. The process allows for periodic evaluation and cleaning of the surgical site and is an alternative to surgery in unsuitable candidates. The fabrication process is relatively short, and the dental clinician has complete control of the color, shape, and position of the prosthesis. Disadvantages of prosthetic rehabilitation include possible irritation of the tissue site, the need for periodic remakes, and the need to rely on some form of retention. Furthermore, the patient may view the prosthesis as a mask and not as part of his or her body.

OSSEOINTEGRATED IMPLANTS

A variety of implant systems are available, and each has its own characteristics. Most of these systems have similar placement and restoration procedures that are usually done in two stages. Stage 1 is the surgical placement of the implant in the recipient bone. The surgical sites are prepared in bone by techniques designed to prevent soft and hard tissue damage at the cellular level.[68] Initially, the soft tissue is reflected to expose the bone. The recipient site of the bone may need to be flattened to provide proper surface adaptation of the implant. An air-driven, slow-speed handpiece (15 to 20 rpm) with copious amounts of irrigation is then used in preparing the recipient site and preventing overheating of the bone.[68] Implant sites are enlarged in small increments with the use of increasingly larger burrs and are then tapped to receive the threaded implants. Following placement of the implant, a cover screw is placed, and the surgical site is readapted by primary closure of the tissue flap. The implants are not disturbed for 3 to 4 months to allow for osseointegration, especially for implants placed into a fibula (**Fig. 29.38**). Following this period, stage 2 can be initiated. The implants are uncovered and the abutments placed. An abutment is positioned onto the implant and secured in place to allow for interlocking attachments that will connect and support an overlying prosthesis.



A
B

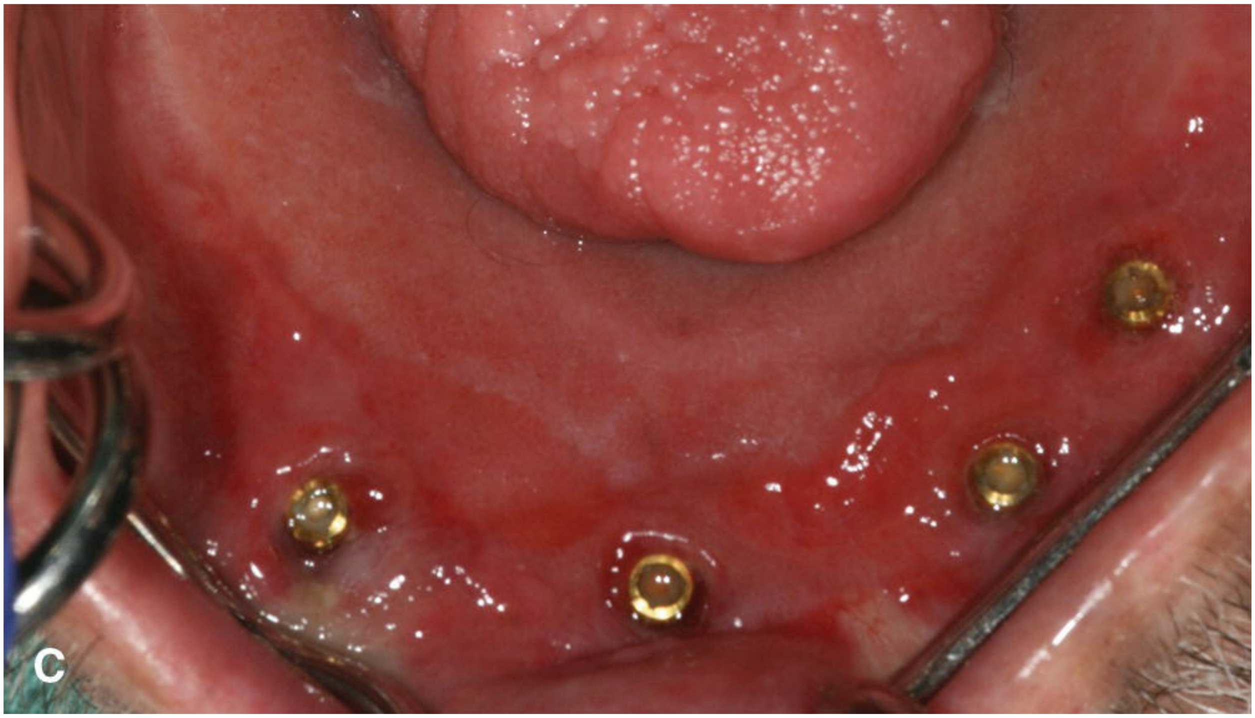


Figure 29.38. A: Mandibular reconstruction using a fibular free flap. With the flat architecture of the reconstructed mandible, a conventional prosthesis without implants is difficult to retain. **B:** Implants into a fibula following stage II (uncovery). **C:**Final healing; tissue ready for fabrication of the prosthesis.

Immediate loading of implants, when the prosthetic abutment is placed at the time of the implant placement, is a common practice. Multiple publications have discussed immediate loading. The authors concluded that immediate loading is successful in select patients, although there is increased risk of failure associated with immediate loading versus conventional loading.[192,194,195] A survey of prosthodontists revealed that just over half of the surveyed prosthodontists (61%) use immediate loading in their practices.[193] Despite positive, high-level research, immediate loading remains a somewhat controversial practice in dentistry, given that 39% report not using this technique. The most commonly cited reason, according to this study, was that they don't believe the loading philosophy.[193]

PROSTHETIC REHABILITATION AFTER RADIATION THERAPY FOR

HEAD AND NECK CANCER

The primary concern of the prosthodontist in fabricating a prosthesis for a patient who has been treated with radiation of the head and neck is the risk of traumatizing extremely friable tissue. In addition to adhering rigidly to proven prosthodontic principles, the prosthodontist must exercise special caution in designing the prosthesis to avoid causing trauma to tissues previously subjected to surgery and/or radiation. For example, the portions of an obturator that are adjacent to surgical margins should be fabricated of acrylic resin to permit easy adjustment. Tooth gingival margins should be avoided, and all surfaces in contact with tissue must be thoroughly polished to minimize the exposure of these tissues to plaque buildup on the prosthesis.

Radiation therapy permanently impairs the healing capability of the treated tissue volume. For this reason, prosthodontic rehabilitation of previously radiated patients requires radiation treatment details.[150,196–198] The geometry of the treatment volume, energy source, total dose, and daily fraction are the most desirable details. In some instances, this information may not be available directly from the treating radiation oncologist; however, careful examination of the patient, together with information the patient can provide, usually suffices for the experienced maxillofacial prosthodontist. Certain characteristics are evident in patients who have previously received therapeutic radiation; for example, the skin within the treatment area is often permanently hyperpigmented, epilation is particularly noticeable in men, and the skin texture is often significantly altered. Telangiectatic changes are common in previously radiated skin and mucosa. If major salivary gland tissue was within the radiated tissue volume, xerostomia is often very apparent.

Prosthodontic rehabilitation for patients who have received radiation therapy requires that the restorative dentist pay particular attention to detail. Radiated tissues do not necessarily become less sensitive with time and can readily change in contour. Therefore, a regular recall schedule is highly recommended for evaluation and possible adjustment of the prosthesis or modification in previously radiated patients.

A problem frequently encountered after maxillectomy by a patient who has had postsurgical radiation therapy is a definite decrease in interocclusal distance or trismus. Instituting a physical therapy program designed to

overcome surgically induced fibrosis in the immediate postsurgical period can help to prevent this reduction of the oral opening. Because surgically traumatized muscle fibers are extremely susceptible to radiation-induced fibrosis, a near-normal intermaxillary opening may not be attainable unless it is achieved by the time radiation therapy begins. Radiation also produces changes in the capillaries and arterioles, thereby further reducing an already surgically reduced blood supply to the muscles of mastication. Failure to treat this problem after radiation therapy results in continuing progressive muscle fibrosis and a further decrease in oral opening.

CONCLUSION

The oral cavity should be thoroughly evaluated in all patients diagnosed with head and neck cancer. Preventing and treating the oral complications of cancer and its therapy are important responsibilities of the dental oncologist or maxillofacial prosthodontist, and anticipating primary and secondary mucosal insults and recognizing oral complications promptly in this setting can decrease the incidence of such complications or ameliorate their morbid adverse effects. By fostering communication and compliance among the multidisciplinary team, the prosthodontist can ensure the quality of preventive and prosthetic treatment, as well as maintenance care, for patients with cancer of the head and neck.

30 General Principles of Radiation Therapy for Cancer of the Head and Neck

Randall J. Kimple Bhishamjit S. Chera, Paul M. Harari

Treatment of cancer of the head and neck continues to evolve through our improved understanding of head and neck cancer biology and risk factors, as well as the emergence of promising new treatment approaches. More than ever before, the close collaboration of the head and neck surgeon, radiation oncologist, and medical oncologist (in addition to ancillary experts) is critical to optimize outcome for patients with cancer of the head and neck. Our expanding knowledge of human papillomavirus (HPV)-associated cancer of the head and neck along with steadily improving surgical, radiation, and chemotherapy techniques is affording new opportunities to increase tumor control rates and diminish normal tissue toxicities. Maintaining a modern and balanced perspective regarding the respective strengths and weaknesses of each treatment modality enables each practitioner to advocate most effectively for head and neck cancer patients. The primary purpose of this chapter is to provide a broad overview of “radiation for head and neck cancer” in an effort to strengthen the practitioner’s knowledge base on behalf of the patients that they serve who have cancer of the head and neck.

In this chapter, we provide an overview of head and neck radiation oncology. We start by reviewing important clinical trials that have shaped the management of patients with cancer of the head and neck and describe several recent advances that are likely have significant impact in the years to come. We then provide an overview of typical radiation workflow from pretreatment assessment through posttreatment follow-up. We provide several simple definitions to clarify modern approaches in radiation

oncology. We provide a brief overview of radiation physics and radiation biology with the goal of helping the reader understand important contributions of these fields to the care of the head and neck cancer patient. Finally, we offer comments addressing the importance of multidisciplinary care for patients with cancer of the head and neck.

Key Studies Impacting Radiation Oncology Practice

The role of radiation therapy in cancer of the head and neck first emerged in the early 1900s with single fraction, and thereafter, multifraction treatment schedules developed in Europe (for detailed discussion, see Thames and Hendry's *Fractionation in Radiation*[1]). The field advanced to incorporate radiation in the postoperative setting in the 1950s [Fletcher and colleagues at MD Anderson Cancer Center (MDACC)] with further expansion to the definitive setting by Million and colleagues (University of Florida) and Wang (Harvard) in the 1960s to 1980s. Over the past 25 years, there have been a series of landmark clinical trials (Table 30.1) that have influenced the practice of radiation oncology in treating patients with cancer of the head and neck. Several but not all of these studies are briefly discussed here.

Table 30.1 Sampling of Trials with Impact on Current or Future Head and Neck Radiation Oncology Practice

Landmark Trial	Treatment Arms	Summary of Results	Impact
VA Larynx Trial[2]	Phase 3 randomized control trial comparing neoadjuvant chemotherapy + radiation vs. surgery and postoperative radiation in squamous cell carcinoma of the larynx	2-year survival was 68% in each arm with 64% of patients in the chemoradiotherapy arm maintaining larynx preservation at early follow-up	Established chemoradiotherapy as an organ-preserving option for patients with cancer of the larynx
EORTC HPX Trial[3]	Phase 3 randomized control trial comparing neoadjuvant chemotherapy + radiation vs. surgery and postoperative radiation in squamous cell carcinoma of the larynx and hypopharynx	3-year survival was 43% in surgical arm and 57% in chemoradiotherapy arm	Established chemoradiotherapy as an organ-preserving option for larynx and hypopharynx cancer patients
RTOG 91–11[4,5]	Phase 3 randomized control trial comparing (1) neoadjuvant chemotherapy and radiation, (2) concurrent chemotherapy and radiation, or (3) radiation alone	Survival was similar across all three arms, but laryngeal preservation was highest for the concurrent arm (88%), neoadjuvant (74%), and radiation alone (70%)	Established concurrent chemotherapy as a nonoperative standard of care with radiation
MACH Meta-analysis[12]	Meta-analysis of 15 trials (6,515 patients) evaluating altered fractionation vs. conventional fractionation (no chemotherapy)	Altered fractionation improved survival (3.4% at 5 years) and local–regional control (6.4% at 5 years)	Established that with radiation alone regimens, altered fractionation is better than conventional fractionation
RTOG 0129[29]	Phase 3 randomized control trial comparing altered fractionation + chemotherapy vs. conventional fractionation + chemotherapy. Post hoc analysis of HPV as prognostic factor	Arms were equivalent. 3-year overall survival was 82% in the HPV-positive vs. 57% in the HPV-negative patients. OPSCC patients can be categorized into low-, intermediate-, and high-risk groups	Altered fractionation can be used with concurrent chemotherapy. Treatment of OPSCC patients will be tailored according to risk group
GORTEC 99–02[118]	Phase 3 randomized control trial of (1) standard fractionation and chemotherapy, (2) hyperfractionation and chemotherapy, and (3) hyperfractionation alone	Two chemotherapy arms had similar and significantly better outcomes compared to radiotherapy alone. Acute toxicity was worse in the two hyperfractionated arms	Altered fractionation should be used with caution with concurrent chemotherapy. Altered fractionated radiotherapy alone showed inferior outcomes
MACH-NC8[13,14]	Meta-analysis of 87 trials (16,485 patients) that evaluated the efficacy of definitive chemoradiotherapy	The addition of chemotherapy to radiation improved survival by 4%–5%. Concurrent chemotherapy had the greatest impact on survival. Neoadjuvant and adjuvant chemotherapy did not significantly affect survival	Established that concurrent chemotherapy can be given with radiotherapy for the definitive treatment of stage III–IV head and neck squamous cell cancer
EORTC 22931 and RTOG 9501[17–19]	2 phase 3 randomized control trials of postoperative radiation vs. postoperative radiation + chemotherapy	The addition of chemotherapy improved local–regional control and survival in patients with + margins or extranodal extension	Established that chemotherapy can be given with radiotherapy after surgery in patients with high-risk pathologic features
Bonner et al.[26,27]	Phase III randomized control trial of radiation vs. radiation + cetuximab. First of its kind study in head and neck cancer, allowing for the evaluation of molecular targeted therapy in combination with radiation	The addition of cetuximab to radiation resulted in an absolute improvement in survival of 10% without increased toxicities (except acneiform rash)	Study was the first of its kind in head and neck cancer, allowing for evaluation of molecular targeted therapy in combination with radiation
RTOG 1016	Phase III randomized control trial of radiation + cisplatinum vs. radiation + cetuximab in HPV-associated OPSCC, closed to accrual	Primary end point is noninferiority and less toxicity in the radiation + cetuximab arm	If the radiation + cetuximab arm is noninferior and less toxic, this regimen would offer a deintensified option for patients with HPV-associated OPSCC
ECOG 3311	Ongoing phase 2b randomized study of transoral surgery followed by observation (low risk), chemoradiotherapy (high risk), or randomization to 50 Gy vs. 60 Gy (intermediate risk) in HPV-positive OPSCC	Primary end point is 2-year PFS. Secondary end point is 2-year functional outcome	Study opened in 2014

Curative Role for Radiotherapy

Historically, surgery was the primary treatment of choice for cancer of the head and neck, whereas radiotherapy was reserved for the postoperative setting. In the 1960s to 1980s, several institutions (University of Florida, Harvard, MDACC, among them) advanced a nonsurgical treatment approach by treating selected larynx, hypopharynx, and oropharynx patients with definitive radiotherapy. In the early 1980s, the Department of Veterans Affairs (VA) Laryngeal Cancer Study Group conducted a prospective randomized clinical trial (the VA Larynx trial published in 1991) evaluating whether nonoperative therapy (induction chemotherapy and radiotherapy) could provide equivalent survival compared to surgery and postoperative radiation in local–regionally advanced squamous cell carcinoma of the larynx.[2] The 2-year survival was 68% in each arm with 64% of patients in the chemoradiotherapy arm preserving their larynx in early follow-up. In parallel, the European Organization for Research and Treatment of Cancer (EORTC) conducted a similar study in patients with advanced cancer of the larynx and hypopharynx and observed similar results.[3] The Radiation Therapy Oncology Group (RTOG) and Intergroup performed a follow-up study (RTOG 91–11) for which patients with local–regionally advanced cancer of the larynx were randomized to (1) induction chemotherapy and radiation, (2) concurrent chemotherapy and radiation, or (3) radiation alone. Overall survival was the same across all three arms, but preservation of the larynx was highest in the concurrent chemoradiotherapy treatment arm (88% vs. 74% and 70%).[4] The 10-year update showed similar results.[5] These important studies helped to establish the role of radiation as a curative option in appropriately selected patients with cancer of the larynx and hypopharynx.

Altered Fractionation

The most commonly used fractionation schedule in the United States for head and neck cancer is 1.8 to 2 Gy per fraction given once a day for 35 to 39 treatments 5 days a week for 7 to 8 weeks. Altered fractionation schedules were developed to compensate for rapid and accelerated repopulation (see section “Basic Radiation Biology” below) observed in head and neck squamous cell carcinoma. Clinically, this phenomenon manifests as reduced

local/regional control in patients who have treatment delays extending their overall radiation treatment time[6]–[9] or who have a prolonged interval between surgery and beginning their treatments. Intensifying the radiation dose delivery by treating "faster" is a method to compensate for accelerated tumor cell repopulation.

Several clinical trials have been conducted to evaluate whether intensification of the radiation dose with altered fractionation schedules could improve local–regional control and survival in patients with cancer of the head and neck. Numerous altered fractionation schemes have been used. Hyperfractionation refers to the delivery of multiple smaller fractions per day, whereas accelerated fractionation commonly delivers more than 10 Gy per week. Both hyperfractionation and accelerated fractionation can result in the completion of radiation in <7 weeks but deliver the same (or slightly higher) total dose as standard fractionation schedules. As examples, twice daily radiation (1.15 Gy per fraction × 70 fractions = 80.5 Gy) was compared to once daily radiation (2 Gy per fraction × 35 fractions = 70 Gy) for patients with cancer of the oropharynx by the EORTC. In this randomized trial, hyperfractionation improved local control with a strong trend toward improved survival and no difference in late effects.[10] The Danish group has studied accelerated fractionation in over 1,000 patients randomized to 5 fractions per week (66 to 68 Gy in 33 to 34 fractions) versus 6 fractions per week (same total dose), with the 6th fraction given either on the weekend or as a second daily fraction during one of the weekdays. Local control at 5 years was improved by 10% (70% vs. 60%) for patients treated with 6 fractions per week.[11] Again, no difference in overall survival was seen. The published meta-analysis of these clinical studies showed that altered fractionation regimens delivered without chemotherapy significantly improved local–regional control (6.4% at 5 years) and survival (3.4% at 5 years).[12]

Definitive Chemoradiotherapy

The addition of chemotherapy to radiation has been studied in many clinical trials since the 1970s. Chemotherapy may be given before (neoadjuvant), during (concomitant), and after (adjuvant) radiation or a combination thereof. Pignon et al. conducted a meta-analysis of 87 randomized trials and 16,485 patients (stage III to IV with no prior treatment for cancer of the head and

neck) that evaluated the efficacy of chemoradiotherapy (*m*eta-*a*nalysis of *c*hemotherapy in *h*ead and *n*eck *c*ancer or MACH-NC).[13,14] The addition of chemotherapy conferred a 5-year, 4.5% absolute survival benefit (HR 0.88, 95% CI 0.85 to 0.92). Concurrent chemotherapy was observed to have the most pronounced benefit for survival: 5 years, 6.5% absolute benefit (HR 0.81, 95% CI 0.78 to 0.86) versus 2.4% for neoadjuvant (HR 0.96, 95% CI 0.90 to 1.02) and −1% for adjuvant (HR 1.06, 95% CI 0.95 to 1.18) delivery of chemotherapy.[13] The MACH-NC analysis solidified the addition of chemotherapy (most commonly cisplatin) to radiation as a standard of care approach for the definitive treatment of stage III to IV squamous cell carcinoma of the head and neck, with the preferred sequence being concomitant administration of drug with radiation. It should be noted that this added efficacy is accompanied by increased acute toxicity and possibly some late toxicities including fibrosis and dysphagia although several groups have suggested that these late toxicities are more closely related to radiation dose to critical structures than to the use of concurrent chemotherapy.[15,16]

Postoperative Chemoradiotherapy

Historically, the standard of care for advanced cancer of the head and neck was surgery followed by radiotherapy. For high-risk patients, this still resulted in less than desirable survival outcomes. With the observation that adding chemotherapy to radiation could improve outcome in the definitive setting, the RTOG and EORTC conducted randomized studies that evaluated the addition of concurrent cisplatin chemotherapy to radiation in the high-risk postoperative setting.[17–19] The eligibility criteria differed slightly for both studies and the EORTC study showed a survival benefit to postoperative chemoradiotherapy,[18] whereas the RTOG study showed a marginal benefit.[19] In both studies, positive margins and extranodal extension were common eligibility criteria. A combined analysis of both studies showed that patients with positive margins and/or extranodal extension had improvement in local control, disease-free survival, and overall survival with the addition of cisplatin to postoperative radiotherapy.[17] Patients with other pathologic risk factors (i.e., perineural invasion, ≥ 2 positive nodes, lymphovascular space invasion) did not show a clear outcome benefit from the addition of chemotherapy. These studies established a favored recommendation (in patients deemed fit to receive cisplatin) for the use of concurrent

chemotherapy with radiation in the postoperative setting for those patients with high-risk pathologic features including positive margins and/or ECS.

Recent Advances in Head and Neck Cancer

Over the last 15 years, several new developments promise to advance the evaluation and management of head and neck cancer patients. We discuss several of these that are having an important impact on the care of patients with cancer of the head and neck.

Targeting the Epidermal Growth Factor Receptor

High-level epidermal growth factor receptor (EGFR) expression is reported to occur in ~90% squamous cell cancers of the head and neck and is correlated with reduced survival outcomes and response to radiotherapy.[20–22] Preclinical studies indicate that molecular inhibition of EGFR can enhance radiosensitivity (see below) and that the combination of EGFR inhibition with radiation is synergistic.[23–25]

A phase III trial testing the role of the EGFR inhibitor cetuximab in combination with radiation (compared to radiation alone) was initiated in 1999. Enrolling patients with locally advanced cancer of the head and neck, this study demonstrated that cetuximab led to both improved local control and improved overall survival when compared to radiation alone, and this approach was not associated with increased acute or late toxicity with the exception of acneiform rash.[26,27] This study was the first of its kind in treating cancer of the head and neck, allowing evaluation of a molecularly targeted therapy in combination with radiation in the curative treatment setting. This study did not stratify patients on the basis of HPV status as this distinction was not appreciated at this time.

Following the radiation/cetuximab trial, the RTOG evaluated whether the addition of cetuximab to the standard chemoradiotherapy backbone of 70 Gy and cisplatin could further improve outcome (RTOG 0522). This phase 3 randomized trial of 70 Gy/cisplatin versus 70 Gy/cisplatin/cetuximab showed

no additional benefit over chemoradiotherapy alone and the addition of cetuximab was associated in this setting with increased overall toxicity.[28]

A current trial run by the RTOG (RTOG 1016, and similar studies in other countries) is addressing the question of whether cetuximab is effective in patients with HPV-positive cancer of the head and neck. This study randomizes patients with HPV-positive cancer of the head and neck to radiation + cisplatin versus radiation + cetuximab. Results of this prospective study will help define whether cetuximab can safely and effectively replace cisplatin in the treatment of HPV+ patients.

Human Papillomavirus

HPV-positive cancers arising in the oropharynx have been identified as a unique clinical, biologic, and epidemiologic entity that is associated with a significantly better prognosis than HPV-negative oropharynx cancers.[29–41] These significant differences have led to great interest in tailoring therapy to reduce treatment-related toxicity (i.e., deintensification).[42] A secondary analysis of the RTOG 0129 trial evaluated the prognostic implication of HPV in cancers of the oropharynx. The 3-year overall survival was 82% in the HPV-positive versus 57% in the HPV-negative patients.[29] A recursive-partitioning analysis classified patients with squamous cell carcinoma of the oropharynx into categories of low, intermediate, or high risk of death based on the following prognostic factors in decreasing order of importance: HPV, number of tobacco pack years, N stage, and T stage.[29] As noted above, RTOG is conducting a clinical trial randomizing HPV-positive patients between 70 Gy in 6 weeks with concurrent cisplatin versus 70 Gy in 6 weeks with concurrent cetuximab (RTOG 1016, NCT01302834).

Transoral Surgery

Transoral surgical approaches [i.e., transoral laser microsurgery (TLM) and transoral robotic surgery (TORS)] are garnering increased interest for the treatment of cancer of the head and neck.[43–45] A potential benefit of primary TLM and TORS for selected patients is a reduction in the intensity of chemoradiotherapy without compromising oncologic outcome. It is hoped that primary surgery will provide pathologic information to guide adjuvant therapy recommendations such that radiotherapy and chemotherapy may be

selectively omitted or reduced in intensity or that surgery will aid in treatment intensification for higher-risk patients.

There are several new clinical studies evaluating the use of TLM/TORS to alter treatment intensity. The Eastern Cooperative Oncology Group (ECOG) is enrolling early-stage HPV-positive oropharyngeal patients (ECOG 3311, NCT01898494). All patients undergo transoral resection (TLM or TORS) and then, based on pathologic features, receive risk-based adjuvant therapy: (1) patients with T1–T2 N0–N1 disease (negative margins, no extranodal extension) are observed, (2) patients with positive margins or extranodal extension receive 66 Gy with weekly cisplatin, and (3) intermediate-risk patients are randomized to 50 Gy or 60 Gy without chemotherapy. The primary end point is 2-year progression-free survival (PFS). This trial (and others under development) will help to provide standardization of methodology for transoral surgery in head and neck cancer and may have significant implications for the future clinical management of patients with oropharyngeal cancer.

The Basic Steps of Radiation Therapy Workflow

In this section, we provide an overview of the radiation oncology work process from pretreatment evaluation through posttreatment follow-up. Throughout this process, the radiation oncologist works with a team of specialists ranging from dentists to social workers to speech language pathologists to radiation therapists.

Pretreatment Assessment

The majority of patients with cancer of the head and neck are referred to radiation oncology by a head and neck surgeon. Multidisciplinary evaluation by head and neck surgery, medical oncology, and radiation oncology is an important initial step in the evaluation of patients with head and neck cancer. In our clinics, patients meet with the radiation oncology nursing staff prior to beginning radiation to discuss management of toxicity, oral hygiene, and skin care. They are provided a booklet containing recipes for oral rinses,

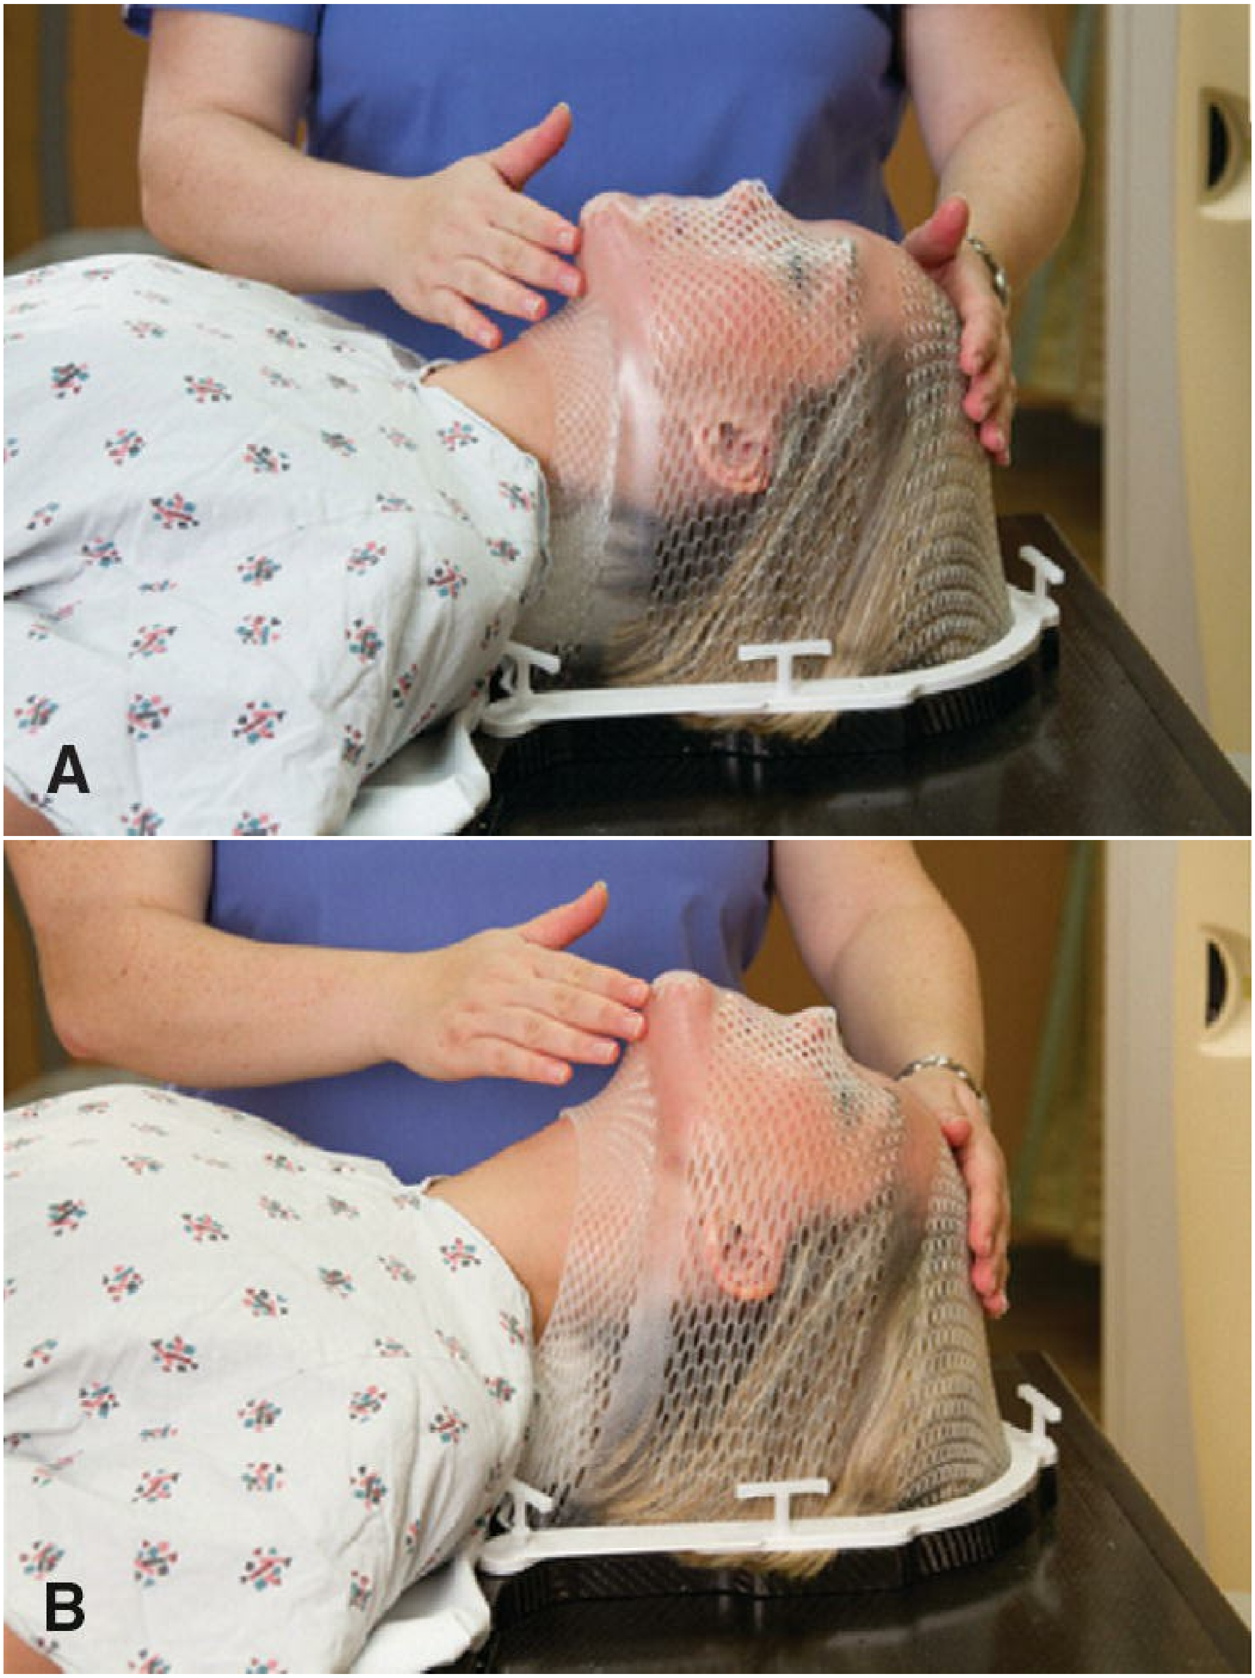
suggestions for skin care, and to address common questions.

It is our practice to routinely have patients seen for a dental evaluation prior to undergoing radiation. Radiation causes alterations in salivary function and oral microflora, which puts patients at increased risk for the development of radiation caries.[46,47] In addition, radiation can place patients at risk for the development of osteoradionecrosis, a potentially serious complication following dental extractions.[48,49] Dental evaluation may recommend fluoride trays to be used after radiation or prophylactic dental extractions should be considered before radiotherapy is initiated. In general, several days are allowed following dental extractions prior to the radiation planning computed tomography (CT) scan to allow for resolution of procedure-related edema. Radiation commences ~2 weeks after extractions to allow for adequate healing.

Patients undergoing radiation of the head and neck may develop odynophagia and/or dysphagia during treatment. These common side effects, if not caused by the cancer itself, often develop during the 2nd to 3rd week of radiation and progress until several weeks after the completion of radiation. Thus, for many patients, there is a 5- to 6-week period during which they have significant challenges maintaining adequate oral intake. Pretreatment evaluation by a speech/language pathologist with assessment of current swallowing function and a prescription for a series of exercises may decrease the long-term morbidity associated with radiation of the head and neck.[50–52] Still, a significant number of patients undergoing radiation for cancer of the head and neck or chemoradiotherapy will require supplemental nutritional support by way of a percutaneous endoscopic gastrostomy or nasogastric feeding tube placement. There exists considerable variation in tube placement with some centers routinely recommending prophylactic placement and others advocating a reactive approach. It appears that no difference in cancer outcomes is seen based on when feeding tubes are placed, that complications may be slightly higher for reactive placement, but that up to 30% to 50% of patients who undergo prophylactic tube placement will have minimal need to use it.[53–56] Most patients also meet with a nutritionist to discuss caloric needs, food choices, and the use of liquid nutritional supplements.

Simulation/Setup

The first step in the radiation treatment-planning process is to perform a simulation of the treatment setup. The majority of patients with cancer of the head and neck will have a CT scan with contrast in the treatment position with a plastic mesh mask made for immobilization of the head and neck. These thermoplastic (i.e., the plastic becomes soft and pliable when warmed and hardens as it cools to room temperature) masks can extend over the shoulders to provide immobilization of the entire head and neck region (Fig. 30.1). Optimal positioning of the patient requires oversight of the treating radiation oncologist to account for tumor location, normal structure anatomy, and individual patient variation. Following simulation, or at the time of the first treatment, patients may receive a permanent skin marking (“tattoo”) midline near the sternal notch that is used as a reference mark during daily treatment to align the patient in the correct position for treatment. Daily image-guided radiation therapy techniques are gradually reducing the need for skin markings. CT images are obtained of the area to be treated and this dataset is exported to the treatment-planning system. In most cases, the actual radiation start date will occur 7 to 14 days after this simulation to allow time for the subsequent steps to be completed. Occasionally, a CT simulation is not necessary (e.g., a superficial skin cancer), and instead, a clinical simulation is performed on the radiation treatment machine.



A
B

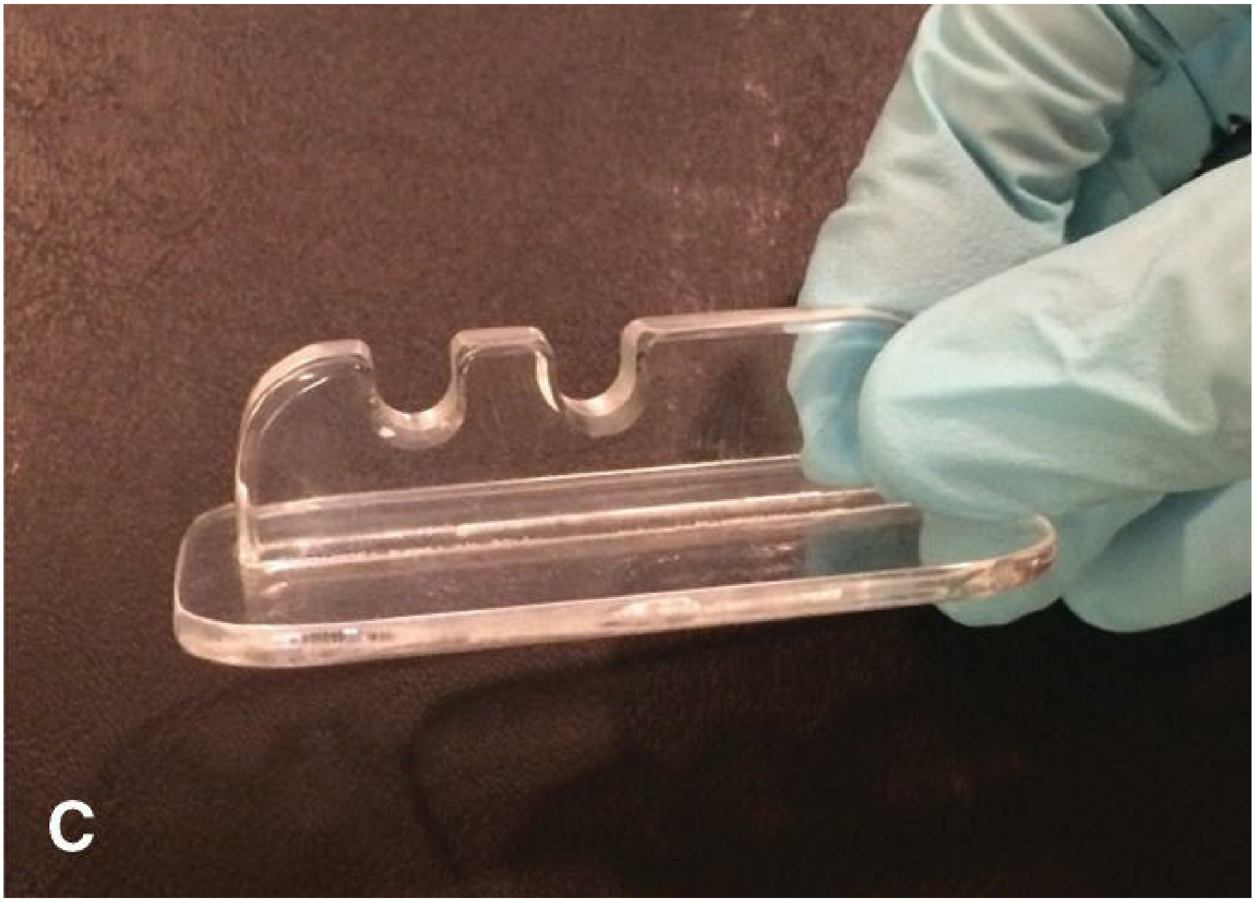


Figure 30.1. Patient setup. Patient immobilization and setup at the time of simulation is a critical step in the radiation treatment-planning process. **A:** Thermoplastic masks immobilize the patient with high reproducibility to minimize day-to-day variation in patient setup. **B:** Additional modifications that can be taken to position the patient include the use of different degrees of neck flexion. **C:** The use of bite blocks can provide spatial separation between critical structures and tumor.

Treatment Planning

Designing a radiation treatment plan is a multistep, iterative process. Representative contours and dose distributions are shown in Figure 30.2. Following the simulation, the radiation oncologist uses treatment-planning software to delineate target regions and avoidance structures (i.e., normal tissues). Modern intensity-modulated radiation therapy (IMRT) treatment planning begins with the radiation oncologist using the imaging studies [e.g., CT, positron emission tomography (PET)/CT, or magnetic resonance imaging (MRI)], the physical examination (including fiberoptic

nasopharyngoscopy), and the pathologic information to identify the tumor and involved lymph nodes (gross tumor volume or GTV) and areas of subclinical tumor extension believed to be at risk for harboring disease (clinical target volume or CTV). The CTV may be further subdivided into high-risk and low-risk regions and differential radiation doses prescribed to each of these regions. The GTV and CTV are then uniformly expanded to account for setup variations and day-to-day differences in patient position to form a planning target volume (PTV). In the past, many centers used weekly patient position verification checks, and thus, PTV expansions of 1 cm were not uncommon. With the use of daily image guidance, PTV margins have been safely reduced to the 3- to 5-mm range, significantly decreasing the volume of normal tissue treated. Critical normal structures (e.g., parotid glands, submandibular glands, brainstem, cochlear apparatus, globe, lens, oral cavity, larynx, esophagus, mandible, pharyngeal constrictors, and spinal cord) are also contoured for dose reduction. The radiation oncologist then enters a treatment-planning order. This written directive defines the desired dose to be delivered to target structures (e.g., GTV + 3 mm = 70 Gy, $CTV_{intermediate}$ = 60 Gy, $CTV_{lowrisk}$ = 50 Gy) and the dose constraints to critical normal structures (e.g., mandible <70 Gy, spinal cord <45 Gy).[57–64] The planning process is then transferred to a dosimetrist who will arrange beams and refine the delivery of radiation to meet prescribed goals with physicist oversight. Physician review of the dose distribution is then carried out on cross-sectional imaging viewed in the axial, coronal, and sagittal planes with evaluation of dose volume histograms (DVHs) that graphically depict each target or avoidance structure and the dose received by percentage of the total volume (Fig. 30.3). If any metrics are unsatisfactory, an iterative process is used to further refine the treatment plan until an acceptable one is identified. Approval of the final plan precedes the next step of quality assurance checks to ensure that the machine is capable of delivering the designed plan and that the dose delivered meets the prescription dose. Only after each of these steps is completed is the plan ready to be delivered to the patient.

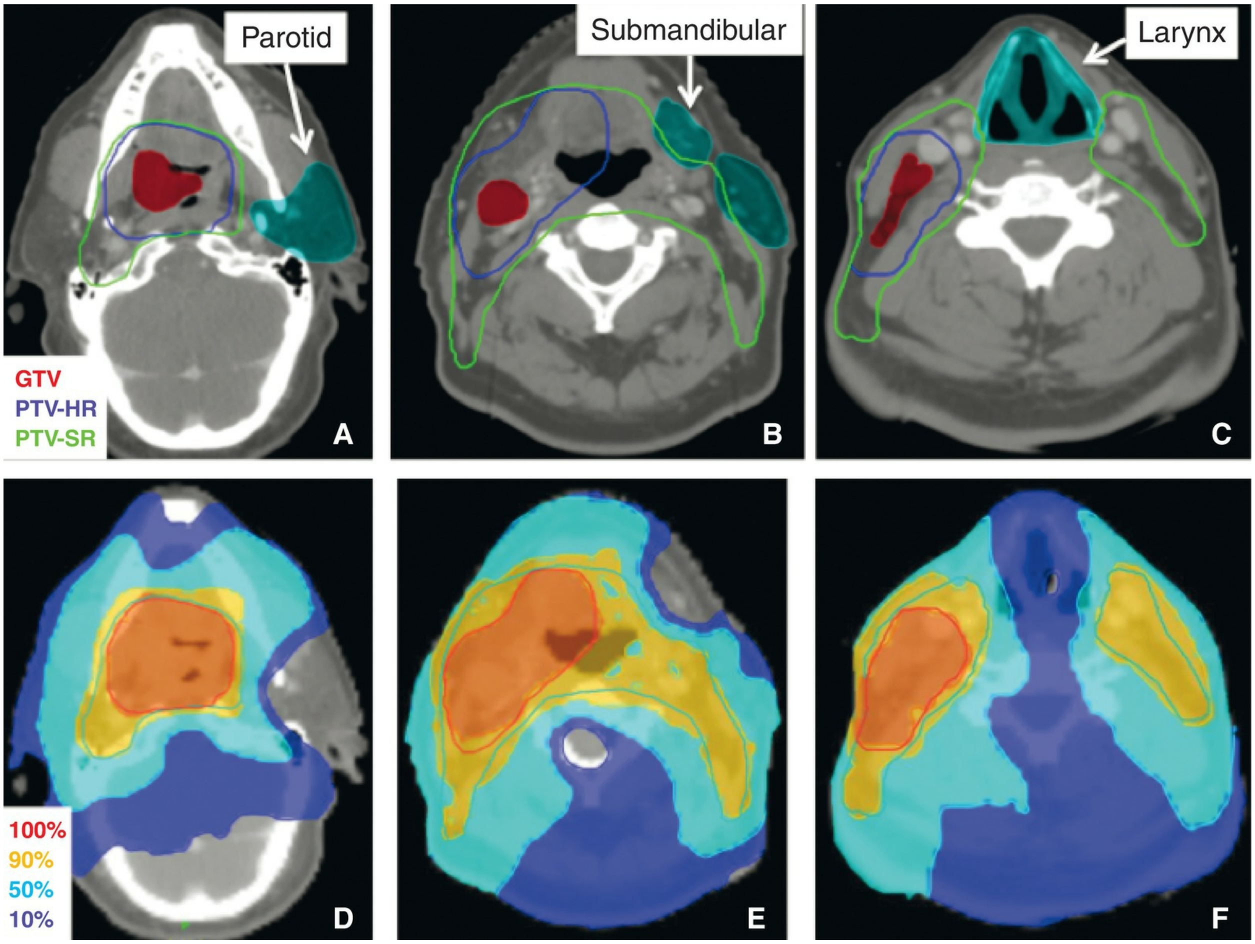

Figure 30.2. Representative IMRT plan for a patient with a T2 N2b M0 squamous cell carcinoma of the tonsil. Panels **A** to **C** show the delineated normal tissues and target volumes. Panels **D** to **F** show the isodose distribution from the IMRT plan. Note that the parotid, submandibular, and larynx are spared. (GTV, gross target volume; PTV-HR, planning target volume-high risk; PTV-SR, planning target volume-standard risk.)

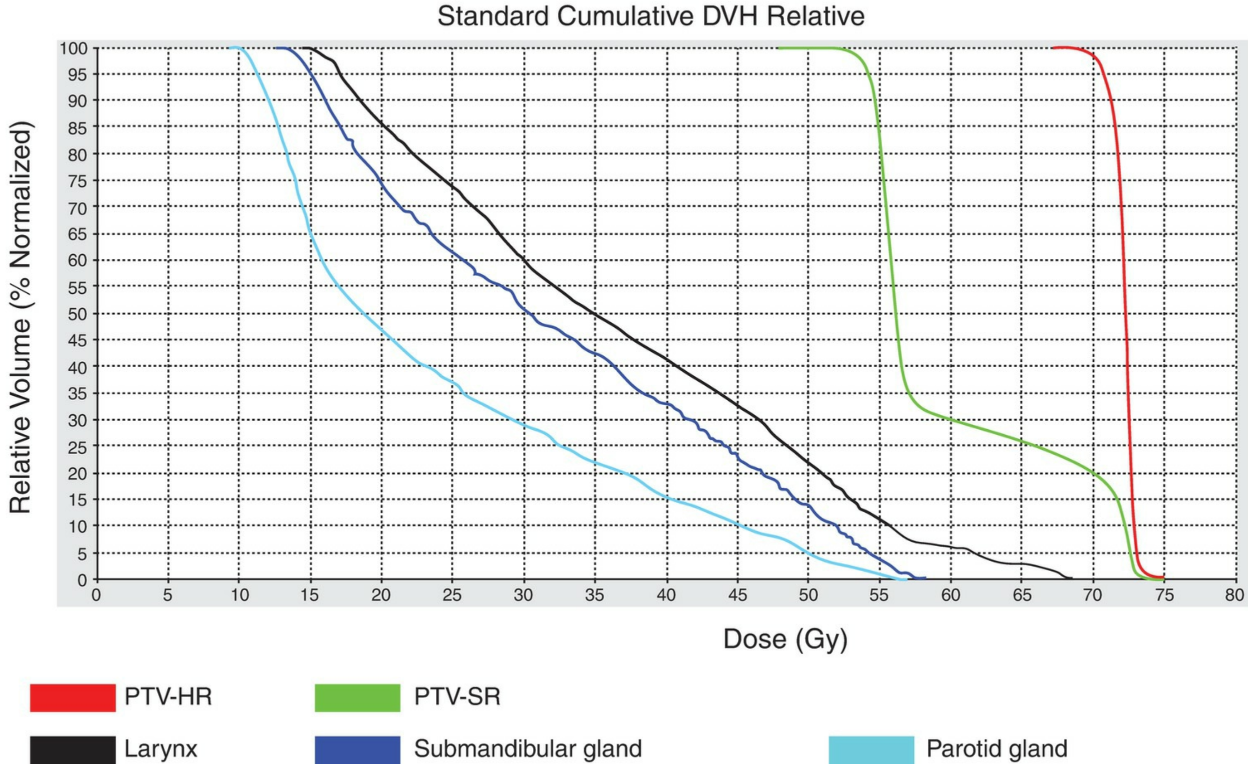

Figure 30.3. DVHs relate radiation dose to tissue volume. Graphical representation of dose to volume is provided by a DVH but do not provide spatial context as to the location of the dose within a given tissue. For most PTVs, more than 95% of the volume should receive at least 95% of the dose. Depending upon the normal structure, the median or maximal dose has greater relevance to potential toxicities.

It is important to note that when requesting outside radiation records for review, one should ask for the DVH's and isodose distribution on cross-sectional imaging. The treatment summary should also be reviewed, but this typically does not include the graphical information required to understand the complex three-dimensional dose distributions delivered using current techniques. Historically, portal radiographs (a.k.a. port films) would also be requested. These provide a view of the treated field from the machines point of view but are of limited relevance in an IMRT plan.

Quality Assurance/Control

The sophistication and complexity of clinical treatment planning and delivery has increased significantly over the last 20 years. This complexity is managed, in part, through overarching quality assurance/control programs

that are typically managed by medical physicists working directly with the radiation oncologist. The role of the medical physicist in quality assurance begins before the patient ever enters the radiation oncology workflow and continues until the treatment is completed (Table 30.2). Encompassing multiple steps in the process, quality assurance is performed to regulate and validate each step in the process with the ultimate goal of ensuring the accurate and precise delivery of radiation treatments.

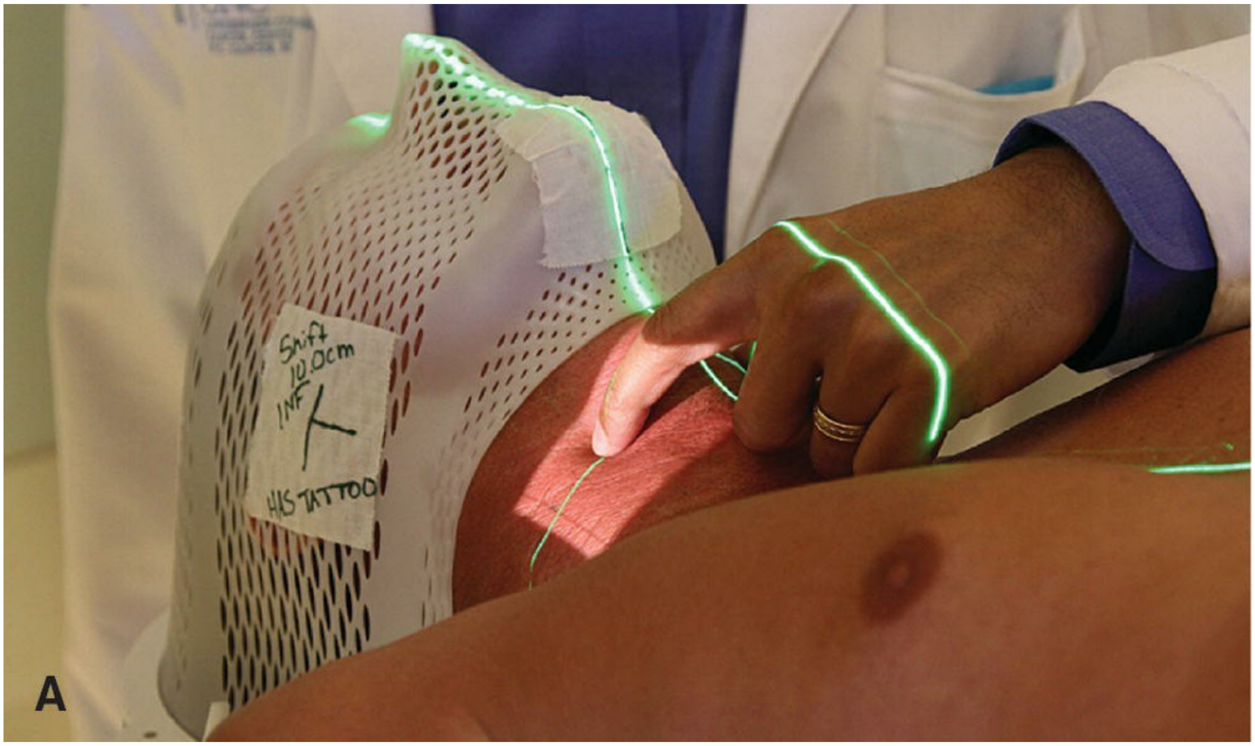
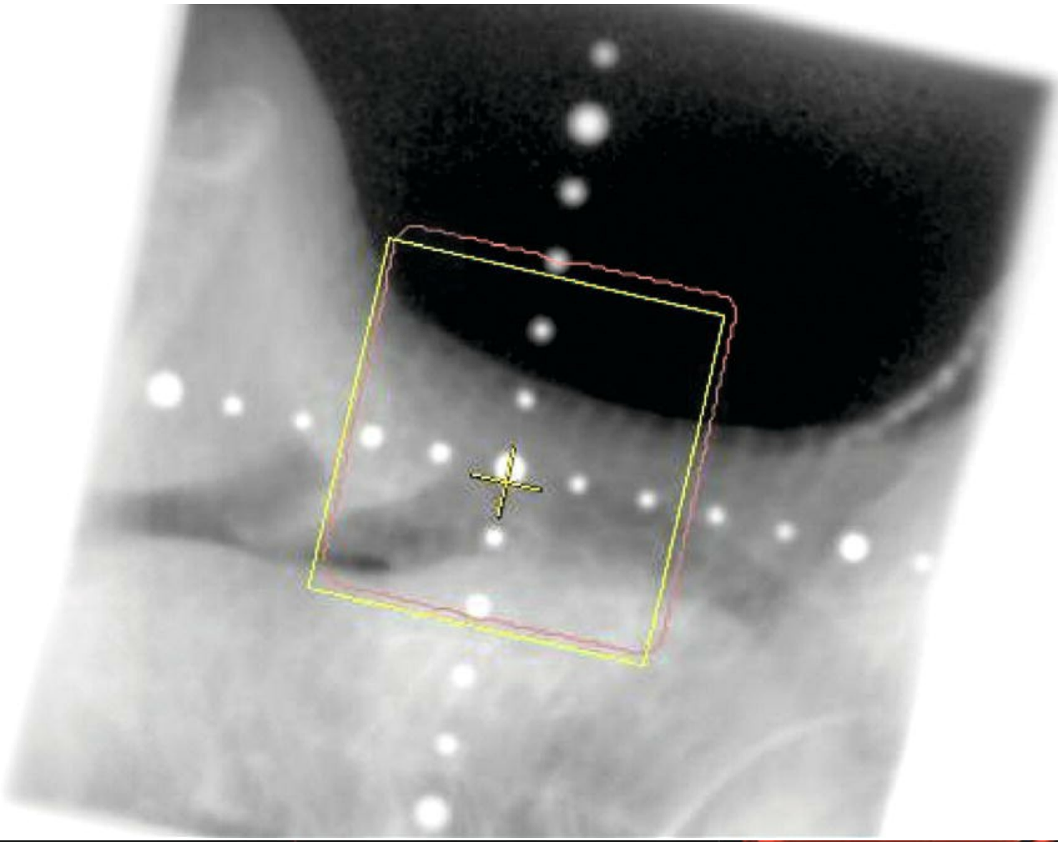
Daily Imaging

During treatment, a patient's setup is verified with onboard imaging technology that is part of modern linear accelerators (LINACs; Fig. 30.4). Although the images that are obtained on the LINAC are not the same quality as diagnostic images, they are adequate to verify the accuracy of patient setup. Verification imaging is typically performed weekly, biweekly, or daily. Historically, with two-dimensional and three-dimensional radiation plans, "PORT" films, which are plain radiographic films of the actual treatment fields transposed on the patient's skeletal anatomy, were performed (Fig. 30.4C). In the modern IMRT era, daily imaging with onboard CT technology is commonly used. The onboard CT images are registered, or fused, with the

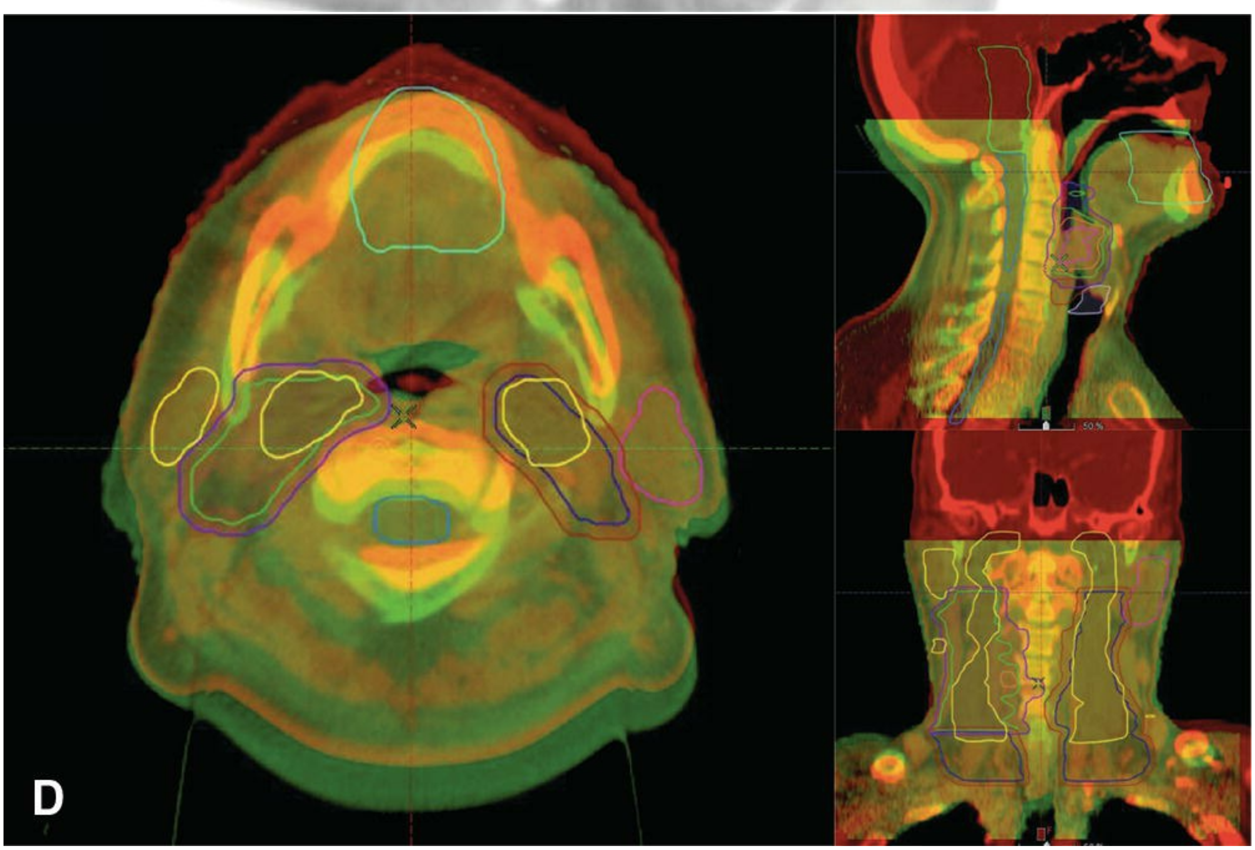
CT simulation images at the treatment console at the time of treatment and offsets are made to correctly align the patient (Fig. 30.4D).



B



C



D

Figure 30.4. Setup and verification of patient positioning. **A:** Initial patient

setup can be verified by physical exam and a set of precision positioning lasers. **B:**The treatment-planning software creates a virtual x-ray or digitally reconstructed radiograph (DRR) projecting the treatment field onto the patient as shown for this patient with a T1N0 vocal cord cancer. **C:** The DRR is then matched to a portal imaging films to ensure that the patient is properly aligned prior to treatment. **D:** Daily imaging is most commonly performed using cone-beam imaging, which involves production of a CT image (*yellow shades*) and matching patient position to the original planning CT scan (*red shades*).

Weekly Management

Each week during treatment, the patient is seen by the radiation oncologist to review the progress of treatment, manage acute toxicities, and preemptively address expected toxicities. The weekly check or on-treatment visit (OTV) is an important part of the radiation oncologist's management of the patient and involves not only a directed history and physical exam but also review of labs and assessment of any needed changes in the overall treatment plan. For patients with cancer of the head and neck, this visit often includes a visit with a nurse or nutritionist to maximize nursing and nutritional support. Of course, as needs arise on other days, toxicity management and patient counseling can occur throughout the course of radiation.

Posttreatment Follow-up

Most patients are seen for a brief posttreatment follow-up visit within the first month after completing radiation. The purpose of this visit is to assess response to treatment, continue management of acute toxicities, and plan further follow-up visits. Most acute toxicities of treatment (e.g., skin erythema and desquamation, mucositis, fatigue, odynophagia, dysphagia) nadir 10 to 14 days following completion of radiation and are improving gradually by 4 weeks posttreatment. Some toxicities (e.g., xerostomia, dysgeusia) take significantly longer to resolve. For most patients with cancer of the head and neck, a posttreatment imaging assessment occurs 8 to 16 weeks following the end of treatment to allow for resolution of acute toxicities and inflammation induced by radiation. Follow-up visits then occur every 2 to 3 months in the first year, every 3 to 4 months in the 2nd year, every 3 to 6 months through year 5, and yearly thereafter. Due to radiation

effects on the thyroid, thyroid-stimulating hormone (TSH) levels should be checked regularly and replacement levothyroxine prescribed, as necessary. Multidisciplinary follow-up, alternating between the head and neck surgeon, medical oncologist, and the radiation oncologist, is an important component of long-term survivorship and multidisciplinary care.

Basic Radiation Treatment Delivery Approaches

2-D/3-D

Clinical and plain radiograph–based two-dimensional radiotherapy use findings from the physical or endoscopic examination to delineate regions at risk to target radiotherapy delivery. With the advent of CT-based imaging, conformal three-dimensional approaches can be used to shape the radiation field to the individual patient and their tumor. These plans often used parallel opposed fields to deliver a homogeneous radiation dose. The use of multiple angles from which the radiation dose is delivered results in improved conformality of the dose to the true target. With the advent of IMRT techniques, these “conventional” techniques are less commonly used at most centers today.

Intensity-Modulated Radiation Therapy

Advances in the ability to modulate beam intensity and delineate the tumor with greater accuracy make it possible to deliver radiation doses to three-dimensional volumes that conform to the shape of the target tissue and limit dose to critical normal structures. IMRT is now the preferred radiation treatment technique for the majority of cancers of the head and neck. IMRT uses multiple radiation beams from various directions and creates steep dose gradients and highly conformal dose distributions resulting in strong coverage of tumor and high-risk targets while maximizing the ability to limit total dose to normal tissues.

For IMRT treatment planning, the radiation oncologist delineates (i.e., contours or identifies on cross-sectional imaging) the GTV(s), CTV(s) (GTV

+ a margin accounting for subclinical disease), and PTVs (CTV + a margin for setup error on the radiation machine). In addition to these target regions, the radiation oncologist also delineates normal organs at risk. These structures are included in the radiation planning software with constraints to limit the dose delivered to them with the goal of improving functional outcomes or limiting morbidity (e.g., spinal cord, larynx, brainstem, salivary glands). Figure 30.2 shows a representative IMRT plan with contoured targets and isodose distributions.

Brachytherapy

Brachytherapy is the delivery of radiation by radioactive sources placed within the tumor. Brachytherapy is often combined with external beam therapy to selectively boost the primary tumor to higher dose while minimizing exposure of surrounding normal tissues. Brachytherapy used in patients with cancer of the head and neck can take several forms.[65] Interstitial implantation for cancer of the tongue, floor of the mouth, or lip involves the temporary placement of multiple hollow catheters into the tumor bed.[66,67] Radioactive sources are then placed within these catheters to deliver the prescribed dose. Mold brachytherapy can be used for lesions of the hard palate or skin whereby a customized surface applicator with built-in channels for radioactive catheters is placed overlying the lesion.[68–70] Mold brachytherapy can provide superficial doses, and thus, its use is primarily valuable for superficial lesions where deep dose penetration is not required. Intracavitary applicators have been used to deliver radiation to regions such as the nasopharynx and are most commonly used for recurrent nasopharyngeal carcinoma.[71,72] Improvements in conformal external beam radiation techniques including IMRT and proton therapy have gradually reduced the use of brachytherapy for many patients with cancer of the head and neck.

Intraoperative Radiation Therapy

Intraoperative radiotherapy (IORT) provides a steep dose falloff to spare normal tissues and is typically delivered to the tumor bed following a gross total or near total resection (reviewed in[73]). Delivery of IORT is typically done through the use of electrons or a high–dose rate, low-energy photon source such as Ir-192. Electrons are delivered via a LINAC or, more recently,

using mobile electronic sources. Retrospective reviews of IORT for treating patients with cancer of the head and neck have shown low rates of surgical wound complications.[74–78] Delivery of IORT requires coordinated multidisciplinary care with the surgeon and radiation oncologist working together to identify critical structures and sites of microscopic residual cancer in order to provide the optimal treatment. The common clinical use of IORT is for patients with isolated, resectable, regionally recurrent disease who have previously received external beam radiation therapy.

Basic Radiation Physics

A complete description of the physics of radiation therapy is beyond the scope of this chapter. A good reference for those interested is *The Physics of Radiation Therapy* by Khan.[79] In this section, we provide a brief overview of x-rays, electrons, protons, and several other types of radiation.

Electromagnetic Radiation

The most commonly used type of radiation involves high-energy x-rays or gamma (γ) rays, commonly referred to as photons. Both x-rays and γ-rays have similar physical and biologic properties and differ primarily in how they are produced. X-rays are generated by LINACs, which use electricity to accelerate electrons toward a metal target (typically tungsten). As high-speed electrons pass close to the nuclei of the tungsten target, negatively charged electrons are attracted to the nucleus, lose energy, and are deflected or accelerated. The energy loss is radiated as a high-energy photon. γ-rays are emitted by fission of radioactive isotopes such as cobalt or iodine. Today, most modern radiotherapy is delivered using high-energy x-rays produced by LINACs. One relevant exception to this that is important to the head and neck oncologist is the use of radioactive iodine for the treatment of cancer of the thyroid.[80,81]

The unit of absorbed dose in tissue is the centigray (cGy) with 100 cGy equal to 1 gray (Gr). Doses of protons and neutrons are typically reported as gray equivalents. For a more complete review of absorbed dose and the details of radiation physics, the reader is referred to *The Physics of Radiation*

Therapy.[79]

Electrons

Electrons are small, negatively charged particles that can be accelerated to high energy by a LINAC. Electrons exhibit favorable depth dose characteristics with a finite range, relatively rapid dose deposition and falloff, and higher surface dose (Fig. 30.5A). Electron beams are widely used for the treatment of superficial lesions such as cancer of the skin or in an intraoperative setting for exposed tumor beds. Electrons are also produced by LINACs by removing the tungsten target out of the path of the original high-speed electrons produced in the head of the LINAC.

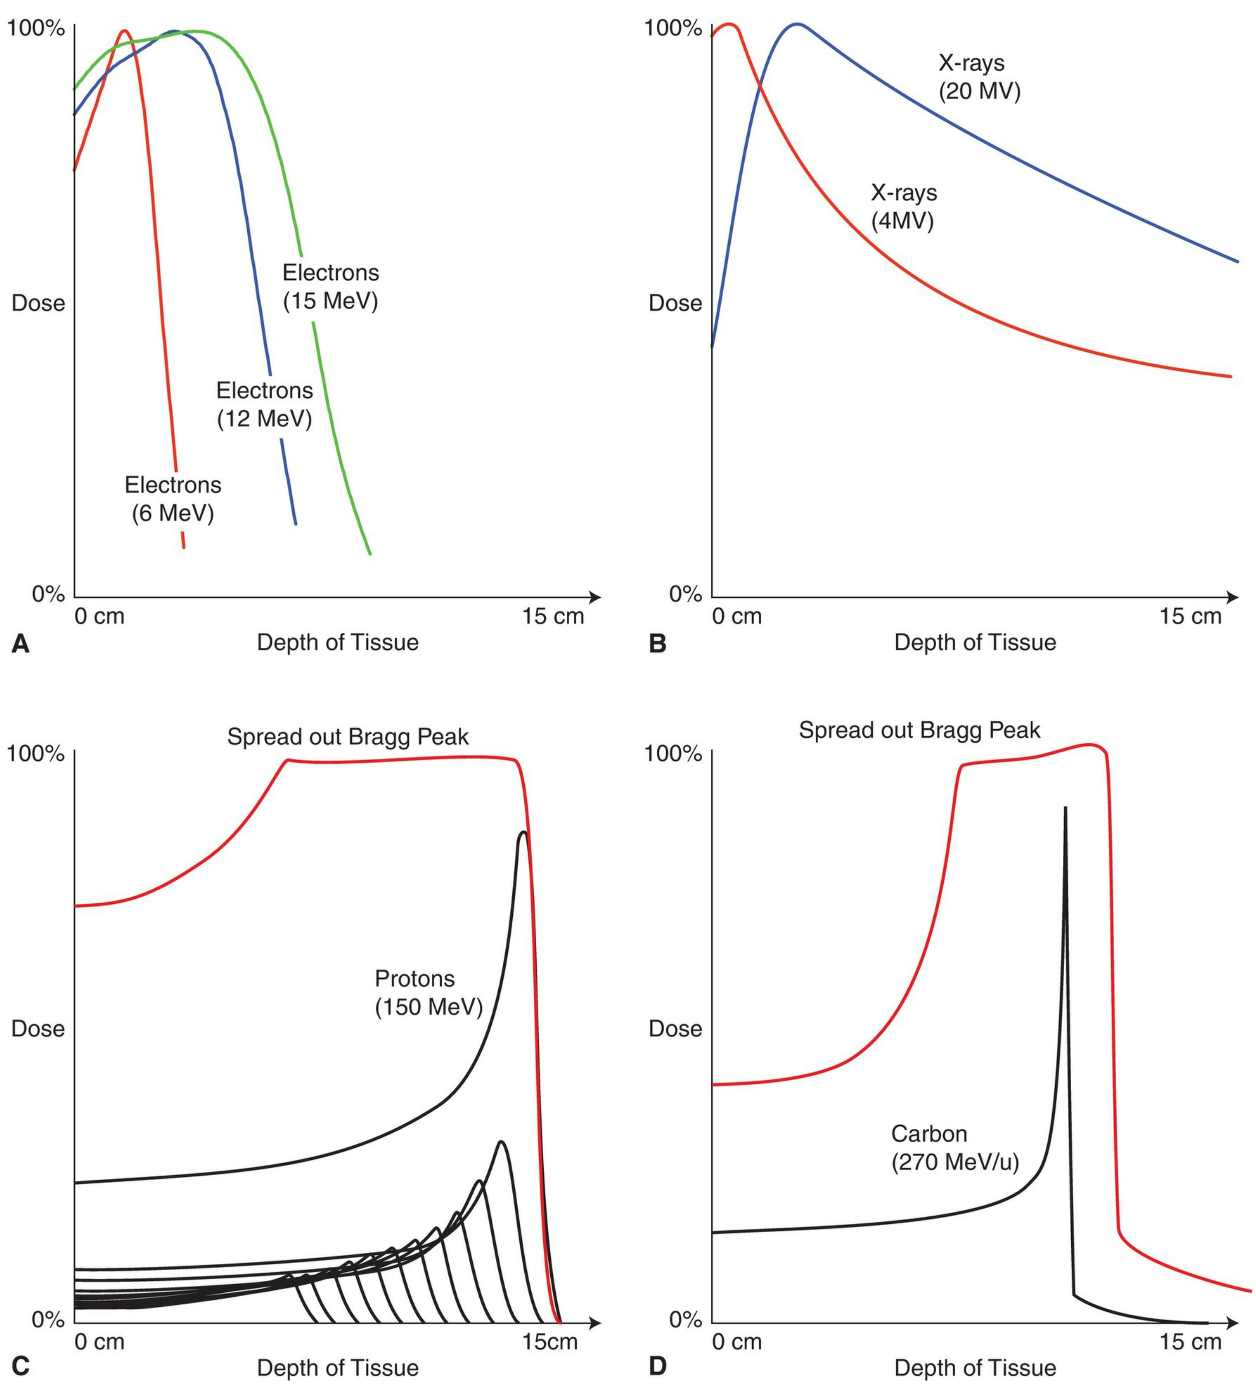


Figure 30.5. Depth dose characteristics of radiation modalities. **A:** Electron beams exhibit high entrance dose and rapid dose falloff with depth. Higher-energy electrons deliver both higher surface dose and deeper penetrating ability. **B:** Photons whether derived from LINACs (x-rays) or from radioactive sources (γ-rays) are more penetrating than electrons. Increasing photon energy results in more surface sparing, deeper maximal dose, and greater penetration. **C:** Protons exhibit a Bragg peak resulting in significant

dose deposition at depth. The spread out Bragg peak increases entrance dose in order to treat a significant volume. Little exit dose results from proton radiation, but there is a degree of uncertainty regarding the true stopping point of protons. **D:** Heavy ions such as carbon or helium exhibit greater stopping certainty, lower entrance doses, and greater biologic effectiveness compared to protons. Similar to protons, a spread out Bragg peak increases entrance dose.

Photons

The majority of radiation treatments to the head and neck consist of high-energy x-rays generated by a LINAC. Therapeutic and diagnostic photons differ in their energy with therapeutic photons being in the megavoltage (MV) range whereas diagnostic photons are in the kilovoltage (KV) range. The higher the energy, the deeper the penetration of the radiation dose (Fig. 30.5B). The most commonly used energy x-ray beam is 6 MV, the energy that is used in most IMRT plans. Photons deposit energy and thus radiation dose by liberating electrons from the outer shells of atoms. These energized electrons interact with other particles, resulting in energy transfer and the generation of free radicals leading to cell death (see section on Radiation Biology).

Particle Radiation

Particle therapy (i.e., protons, neutrons, or heavy ions) is used less often than photons and electrons for the treatment of cancer of the head and neck. Due to the higher mass of particles, either a cyclotron or a synchrotron is required to accelerate particles to relevant speeds. Due to this expense associated with installation of these centers, particle therapy installations are limited in number.

Protons

Protons are positively charged particles that deposit relatively constant dose until they reach the end of their range where the majority of dose is deposited in a Bragg peak (Fig. 30.5C) with rapid subsequent falloff. The ability to modulate the depth of proton dose deposition results in advantages in the treatment of tumors located close to critical organs including skull base

tumors, choroidal melanomas, and a number of pediatric malignancies. Proton therapy centers have proliferated over the last several years in the United States and are now used in the treatment of a variety of malignancies. The ultimate clinical benefit of improved physical dose distribution from proton therapy remains to be determined and several clinical trials addressing this issue are currently ongoing.

Neutrons

Neutron irradiation, which exhibits different biologic effects than electrons, photons, or protons (discussed below), has been used in the past to treat a number of different cancer types. The use of neutrons has been limited due to the small number of centers with the necessary technology and to the fact that efficacy has only been documented in tumors of the salivary gland.

Heavy Ions

Other types of particle radiation (e.g., α-particles, negative π mesons, and heavy charged ions such as carbon or helium) exhibit depth dose distributions that may prove even more favorable than protons (Fig. 30.5D) and continue to be studied at a small number of specialized centers around the world.

Basic Radiation Biology

For the interested reader, a thorough examination of radiation biology is available in *Radiobiology for the Radiologist* by Hall and Giaccia.[82] Radiation induces pleiotropic effects on affected tissues including both normal tissues and tumors. In general, the mechanisms of cell death due to radiation vary based upon the type and dose of radiation. All types of radiation cause breaks in chemical bonds. These breaks can occur either as a direct consequence of the radiation or indirectly via the generation of free radicals (Fig. 30.6A). Radiation delivered via neutrons, α-particles, or heavy ions exerts the majority of their effects via direct damage. The more commonly utilized electrons or photons exert approximately two-thirds of their effects via indirect mechanisms.

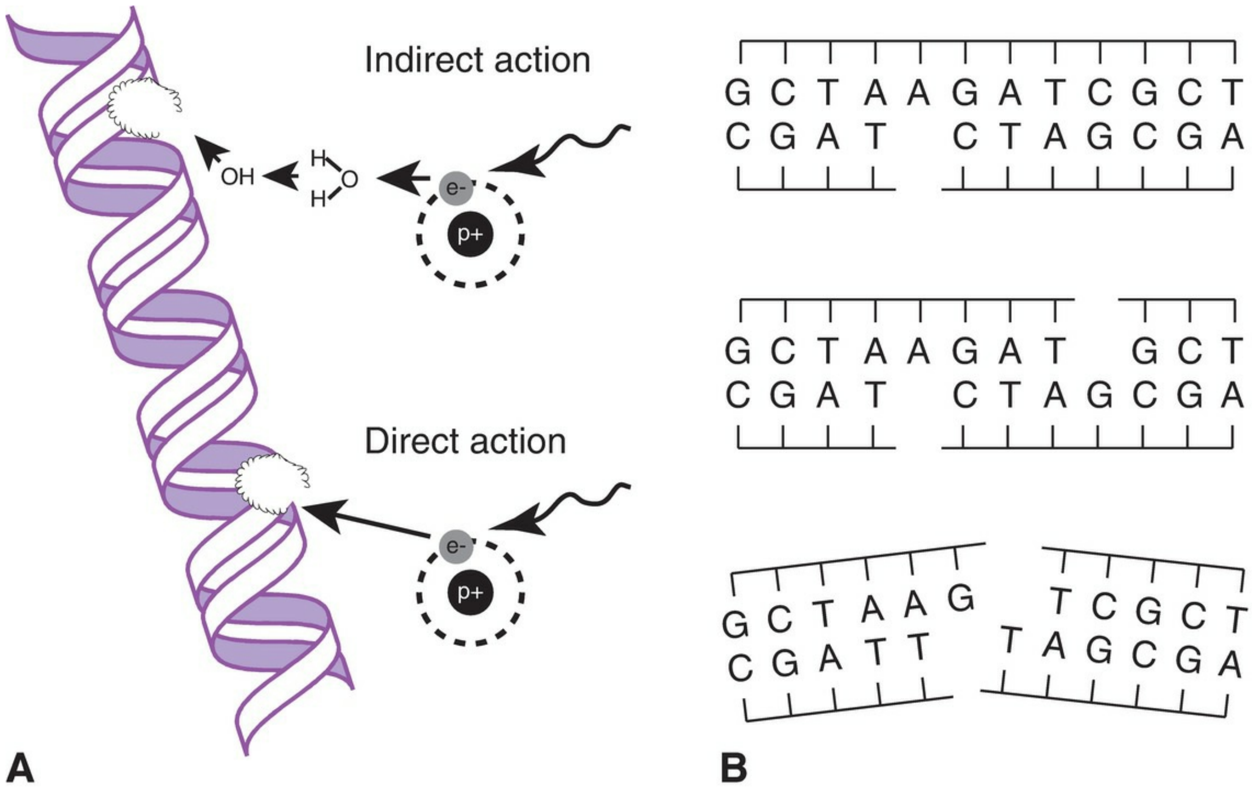

Figure 30.6. Schematic of DNA demonstrating direct and indirect effects of radiation. **A:** Schematic demonstrating the direct and indirect actions of radiation with DNA. An incident photon is absorbed by an atom of DNA producing a secondary electron and directly damaging the DNA (**top**). Indirect action involves photonic effect upon a secondary molecule (often water) to produce a free radical such as hydroxyl (OH•), which then produces damage to the DNA (**bottom**). **B:** Generation of single-strand breaks (**top**) are easily repaired using the opposite strand as a template for repair. Breaks in both strands that are separated by enough distance are repaired independently (**middle**). When two breaks occur opposite each other, or separated by only a few base pairs, double-strand breaks occur (**bottom**). Double-strand breaks can result in duplications, abnormal chromosome structure, lost chromosome segments, or error-prone repair and often have significant consequences.

Radiation-Induced Cell Killing

Radiation-induced cell death is classically modeled by the linear-quadratic equation. This model calculates the survival probability of a given cell as a function of the overall radiation dose, the dose per fraction, and the overall

treatment time.[83] The dose response of both tumors and normal tissues can be described according to the α/β ratio, which is an indication of the sensitivity of a particular cell type to different radiation fraction sizes. The α/β for most tumors and for "early-responding" normal tissues such as skin and mucosa is high (≥10), whereas for "late-responding" normal tissues such as spinal cord and brain, it is low (≤5).[84] One important implication for this difference between tumor and critical normal tissues is that different fractionation schemes can be used to modulate the therapeutic ratio to improve outcome. Cells injured by radiation can die in several distinct ways: mitotic death, senescence apoptosis, or via immunogenic cell death. Each of these is discussed briefly below.

Mitotic Cell Death

Mitotic death occurs when cells with damaged DNA attempt to divide. Depending upon the radiation dose, cells may die either at the first postradiation cell division or after several apparently normal cell divisions. Thus, irradiated cancer cells may continue to die days to weeks after the final radiation dose is delivered. This simple feature underlies the rationale for waiting 8 to 10 weeks after completing therapy prior to assessing response with cross-sectional imaging or biopsies. Mitotic cell death occurs due to aberrations in DNA induced by radiation (Fig. 30.6B). Single-strand breaks in DNA are the most common type of damage but are easily repaired. Double-strand breaks can result in chromosomal aberrations (e.g., ring chromosomes, dicentric chromosomes, acentric fragments, etc.) and are considered the main molecular events preceding mitotic cell death. Mitotic cell death has been thought to be the primary mechanism of radiation-induced cell death for many years, although more recent data suggest that apoptosis and immune-mediated cell death also play important roles.

Apoptosis

Radiation-induced apoptosis occurs in all types of cancer but is most commonly seen in lymphomas and other rapidly dividing tumors. Unlike mitotic cell death, apoptosis usually occurs within hours of radiation and can be seen after relatively low doses of radiation. Apoptosis, a form of programmed cell death, is an orderly process by which cells undergo a defined set of biochemical steps including endonuclease activation,

chromatin condensation, cellular shrinkage, and cellular fragmentation. These cellular fragments are phagocytosed by adjacent cells or macrophages eventually leaving no cellular debris. In addition to contributing to tumor cell death, apoptosis has also been described in both salivary and lacrimal gland tissues[85]–[87] and can thus contribute to xerostomia and xerophthalmia early during the course of radiation.

Immunogenic Cell Death

Enhanced tumor-specific immunity induced by radiation is a concept that has gained attention in recent years as accumulating evidence supports its relevance in the clinical setting and novel agents capable of enhancing this effect have been identified.[88,89] The interaction of radiation with the immune system is complex and remains the subject of ongoing study. Locally and systemically, radiation induces a cascade of pro immunogenic effects (e.g., release of tumor antigens, upregulation of cytokines, etc.), which have been observed to result in immunogenic cell death (i.e., antitumor immunity). Radiation-mediated cell death may trigger uptake of antigenic compounds by dendritic cells thus stimulating antigen-specific cytotoxic T lymphocytes (CTLs) and production of tumor-specific antibodies. These CTLs can then target tumor tissue both within the irradiated mass and potentially at sites of distant disease. The response of tumor distant from the irradiated field is termed the abscopal effect and was first described over 50 years ago.[90] The use of immune-modulating therapies may augment this effect.[91,92]

Radiation Effects on Cells and Tissues

Radiation can impart effects on patients at the cellular, tissue, and organ level. Cellular responses to radiation play a major role in the acute effects of cancers and normal tissues. The organization of organs into parallel or serial systems is an important determinant as to whether dose to a single point (maximal dose) or dose to the entire organ (mean dose) plays a more important role in the organ response to radiation.

Cell Kinetics

Radiation results in numerous cellular responses that impact upon the cell cycle by affecting the expression of proteins that regulate cell cycle

progression. In general, these responses result in cell cycle arrest or mitotic delay, providing the irradiated cell time to repair damage to DNA and cellular organelles. The duration of this mitotic delay depends on the radiation dose, dose rate, cell type, and the preradiation cell cycle phase.

Radiation is also known to affect the proliferation rate of both normal and cancer tissues. Removal of cells by chemotherapy, radiation, or surgical resection can trigger a regenerative response through a process known as **accelerated repopulation**. This process results in an increase in cell division that varies greatly among tissues and tumors. In general, tissues with rapid cell turnover (e.g., mucosal epithelial cells and tumor cells) exhibit early onset of repopulation. This response in normal tissues helps to speed the recovery of injury. Unfortunately, within tumors, accelerated repopulation can reduce the likelihood of cure through progressive tumor growth and is exemplified by the importance of overall treatment time on local tumor control. It is also thought to underlie the potentially beneficial effects of accelerated or twice daily radiation although the magnitude of this effect may be partially overcome by the concomitant delivery of chemotherapy.[93]

Tissue Effects

Most normal tissues are able to tolerate moderate radiation doses without losing structural integrity or function. Tissue injury occurs when sufficient numbers of cells are killed such that mature cells can no longer be replenished. The timing of damage depends upon both the organizational structure of the affected tissue and its cellular kinetics. Discussions of tissue damage often divide effects into acute, subacute, or late/chronic responses.

Tissues with a small number of slowly proliferating stem cells that produce rapidly proliferating progenitor cells exhibit toxicity within days or weeks after the initiation of radiation. Examples include the epithelial cells of the mucosa and skin. Radiation-induced injury of these cells occurs within a predictable time frame that is approximated by the life span of the mature cells. These tissues can recover essentially all of their functions when sufficient stem cells survive to reconstitute the depleted cellular compartments.

Subacute effects occur weeks to months after radiation in tissues with long cellular turnover times and are generally reversible. Examples include

Lhermitte syndrome, pneumonitis, and somnolence following radiation of the spinal cord, lung, and brain.

Late responses occur in tissues with very low cellular turnover including the bone, soft tissue, nervous system, and endocrine tissues with resulting complications including osteonecrosis, fibrosis, trismus, myelopathy, and endocrine dysfunction. These responses can occur years after radiation and are highly dependent upon radiation dose. Radiation regimens have been designed to minimize these serious complications to the extent possible.

Radiation Sensitivity

The radiation sensitivity of cells, tissues, organs, individuals, and tumors has important implications for their treatment and the side effects and toxicities that can be expected. Measurement of radiation sensitivity in vitro does not necessarily correlate with sensitivity in vivo due to built-in redundancies in tissues and organs and to the importance of the cellular microenvironment for individual cell responses.

Measurements of Radiation Sensitivity

The ability of a single cell to grow into a colony that can be easily seen is strong evidence that the cell has retained reproductive integrity. This type of assay (i.e., a colony formation assay) has for many years been considered the gold standard for in vitro radiation sensitivity studies (Fig. 30.7A). Typically, a colony consists of at least 50 cells or more than 5 cell divisions from a single-plated cell (25 = 32 cells). Colony formation assays are plotted on semilogarithmic axes with radiation dose plotted on the linear *x*-axis and surviving fraction on the logarithmic *y*-axis. Use of semilogarithmic axes results in a straight line for an exponential process whereby a doubling of radiation dose results in a reduction in the surviving fraction by 50%. A number of different mathematical models have been used to describe the characteristic shape of the cell survival curve. Overall, the most commonly used model across a range of radiation doses is currently the linear-quadratic model.[94]

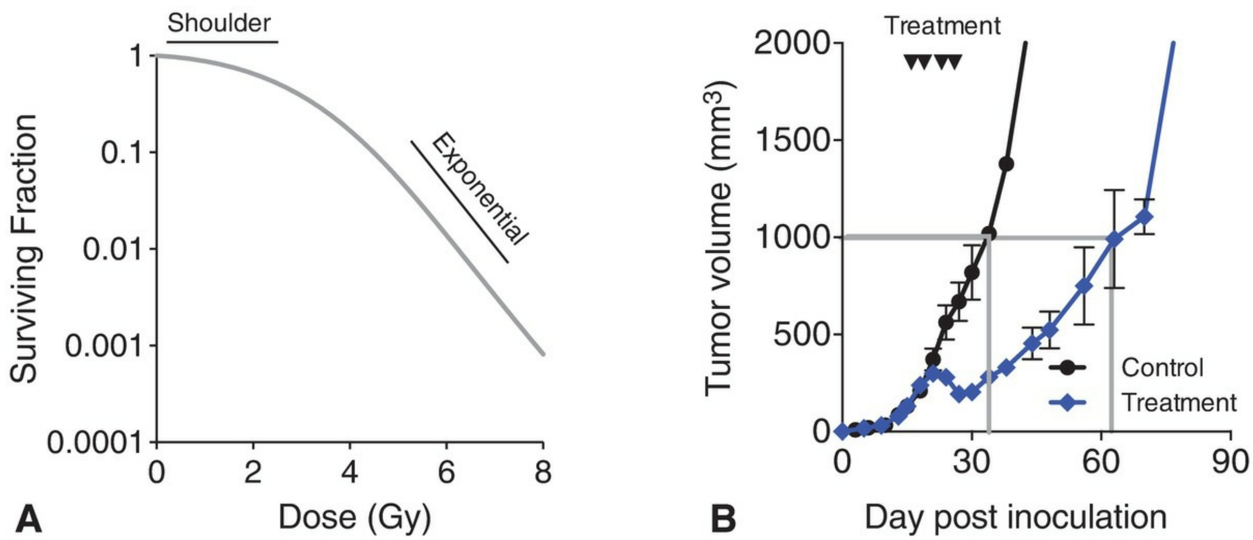

Figure 30.7. Radiation survival assays. **A:** Colony formation assays are graphed on a semilog plot and commonly demonstrate a shoulder region, an exponential decline, and can be modeled using a linear-quadratic model. **B:** Tumor growth delay can be reported using in vivo models and is calculated by determining the excess time required for a treated tumor to reach a predetermined size relative to the control tumor.

In vivo radiation sensitivity can be evaluated using a variety of different assays. The most common of these is the tumor growth delay assay in which in vivo growing tumors are irradiated and the difference in time to reach a predetermined tumor size is calculated (Fig. 30.7B).[95] Tumor control assays utilize large numbers of mice treated with a range of relatively high radiation doses to determine the proportion of tumors that are locally controlled to determine the dose required to "cure" 50% of tumors (TCD_{50}).[96] Several other techniques of assessing radiation sensitivity in vivo have been used including lung or spleen colony formation,[97] in vivo radiation/in vitro colony formation, and dilution assay but are not further discussed here.[98]

Factors Affecting Radiation Sensitivity

Significant work is ongoing to understand biologic, epigenetic, and physical factors affecting radiation sensitivity. However, several factors including tumor oxygen levels, germline patient variations, tumor etiology, and the type of radiation bear mention here due to their importance in head and neck oncology.

Powerful in its effect and extraordinarily simple in its action, oxygen represents the most potent modulator of radiosensitivity. Over 100 years ago, the effect of limiting oxygen was first described from simple models of skin erythema. Oxygen exerts its effect by altering how cells process radiation-induced free radicals and, importantly, must be present within milliseconds of the radiation exposure. As radiation travels through tissue, ion pairs are produced. These ion pairs have very short life spans and produce free radicals (i.e., molecules with an unpaired electron). These free radicals break chemical bonds that can either be repaired through reaction with a sulfhydryl group or made permanent (i.e., fixed) by the formation of anorganic peroxide (RO_2), a reaction that requires oxygen. The oxygen effect increases with oxygen concentration in the range of 0 to 20 mm Hg, but beyond this level, further increases have little additional effect. Adequate oxygenation results in a two- to threefold increase in the effect of radiation compared to hypoxic conditions.

Consistent with the importance of oxygen, the presence of hypoxia in cancers of the head and neck is associated with poorer outcomes.[99–101] Several prospective trials have investigated the effect of hypoxic modification in head and neck cancer. The use of a hypoxic modifier (nimorazole or tirapazamine) results in improved local–regional control.[102,103] Other groups have attempted to improve tumor oxygenation by treating anemia; however, this approach has not proven successful. In one randomized study, patients treated with erythropoietin had improved hemoglobin levels but worse cancer outcomes.[104]

Factors intrinsic to the patient and the tumor also affect radiation sensitivity. For example, patients with ataxia–telangiectasia demonstrate abnormal sensitivity to ionizing radiation that can result in greater than expected toxicity due to radiation therapy.[105] From a tumor standpoint, we and others have recently provided preclinical data suggesting that patients with cancer of the head and neck caused by HPV have increased sensitivity to radiation,[106,107] a result that may partially underlie the improved outcomes seen in this group of patients.[29,34,36,40,103,108–112]

Finally, different types of radiation can deposit differing amounts of energy. Linear energy transfer (LET) is a measure of the energy deposition per track length (i.e., distance). X-rays/γ-rays, electrons, and protons are all

considered low-LET radiation and induce similar amounts of damage per gray. Neutrons and heavy nuclei (e.g., carbon or helium) produce a stronger biologic effect per dose and are referred to as high-LET radiation. High-LET radiation not only induces greater damage in tumors but also causes greater damage in normal tissues. Currently, high-LET radiation is only delivered at a handful of centers around the world (discussed in Reference 113), and although neutron therapy has shown a benefit over photon radiotherapy for the treatment of salivary tumors in a randomized trial,[114] the modality is not commonly used due to the dearth of neutron centers worldwide.

Biology and Physics in the Clinic

Over the last century, fractionation (delivery of multiple small doses of radiation) has become the most common way to deliver therapeutic radiation. Although exceptions such as stereotactic radiosurgery (SRS), stereotactic body radiotherapy (SBRT), and stereotactic ablative body radiotherapy (SABR) are being used more frequently in a variety of disease sites, fractionated therapy remains the mainstay of radiotherapy for head and neck cancer. Four well-known biologic processes underlie the use of fractionated therapy. Often referred to as the four R's of radiotherapy, they include *repair* of sublethal damage, *redistribution*, *reoxygenation*, and *repopulation*.[115] Some articles refer to the intrinsic radiosensitivity of a tumor as the fifth "R,"[116] but because at this time radiation oncologists are unable to control this aspect of tumor biology, we will restrict the discussion to that provided above.

Biologic Basis of Dose Fractionation

Cells are able to recover from radiation doses that do not directly cause cell death. As seen in Figure 30.7A, the shoulder region of the radiation survival curve lies at low end of the dose spectrum. The **repair** capacity of cells varies greatly but is consistently greater in normal tissue than in tumor tissues. The clinical implication of delivering dose within the shoulder region of the dose survival curve is that critical normal structures are preferentially spared due, in part, to their ability to repair sublethal damage.

As cells move through the cell cycle, they vary considerably in their radiosensitivity. The first dose of radiation is delivered to an asynchronous cell population and preferentially kills cells in the sensitive phases. Cells that survive the radiation dose are often briefly paused in their cell cycling and ultimately **redistribute** to a new asynchronous population prior to the next radiation dose. Because the redistribution phenomenon primarily affects rapidly proliferating cells, it is negligible in many critical normal tissues and is greater in tumor cells. Thus, redistribution results in a net gain in therapeutic ratio with increasing number of radiation fractions.

Radiation has been shown by a number of groups to result in improved oxygenation of previously hypoxic tumor regions. Because hypoxic cells are more resistant to radiation, **reoxygenation** aids in tumor cell kill. The mechanism of reoxygenation during fractionated radiotherapy remains the focus of significant experimental efforts but appears to involve increased oxygen availability due to removal of tumor cells, lowering of interstitial pressure resulting in improved tumor microcirculation, and normalization of tumor vasculature resulting in improved delivery of oxygenated blood.

Removal of cells by radiation, subtotal surgical resection, or cytotoxic agents in both normal and cancer tissues results in a regenerative response. The time of onset and kinetics of this **repopulation** vary among tissues; in general, rapidly proliferating cells experience early onset of repopulation. Although this response helps reduce normal tissue injury, repopulation of tumors reduces the likelihood of cure. Accelerated repopulation can be overcome by shortening the course of radiotherapy and, as described above, underlies approaches that used 6 fractions per week and twice daily fractionation both of which shorten the overall treatment time. Accelerated repopulation is also thought to underlie the finding that patients with extended treatment times experience worse tumor control rates.

Radiobiology Principles in Clinical Practice

Understanding the “R’s” of radiobiology led to the development of new classes of fractionation schedules. Hyperfractionation delivers two or more small doses of radiation per day while keeping the overall treatment time the same as, or slightly faster than, standard daily fractionation. The use of small fractions increases the tolerance of late-reacting tissues enabling the total dose to be increased by 10% to 15% without worsening late complications.

Accelerated fractionation attempts to deliver similar doses over a shorter treatment time by delivering more than 10 Gy per week. Accelerated fractionation can also be achieved by delivering more than 2 Gy per fraction to the tumor while simultaneously delivering lower doses to at-risk nodal regions. For example, we commonly deliver 70 Gy in 33 fractions of 2.12 Gy to cancers of the head and neck with at-risk nodal regions receiving 60 Gy or 54 Gy in 33 fractions of 1.82 Gy or 1.64 Gy, respectively.

Over the last 25 years, these radiobiologic concepts have been tested in multiple randomized trials of hyperfractionation and accelerated fractionation.[12,117,118] These trials show a consistent 10% to 15% improvement in local control with altered fractionated schedules and little increase in late toxicity. Not surprisingly, they also suggest that acute toxicity (i.e., that related to rapidly proliferating tissues such as the mucosal lining of the oral cavity or skin) is increased by hyper- or accelerated fractionation.

Combination of Radiation with Cytotoxic Agents

Over the years, radiation has been combined with cytotoxic chemotherapeutic agents (e.g., cisplatin, carboplatin, paclitaxel, 5-fluorouracil, mitomycin C, hydroxyurea) to improve organ preservation, local control, and overall survival in head and neck, anal, lung, gynecologic, and brain tumors.[14,119–122] Chemotherapy can be given before (i.e., induction or neoadjuvant therapy), after (i.e., adjuvant therapy), or concurrent with radiation. Over the last few decades, a large number of phase I and II trials have been conducted to test these combinations. To date, only a small fraction of tested regimens have undergone evaluation in randomized clinical trials.[123–126] These studies have been performed based on the premise that compounds that improve the tumor response to radiation more than they do that of normal tissues may increase the therapeutic window (Fig. 30.8), resulting in better patient outcomes (reviewed in Reference 127).

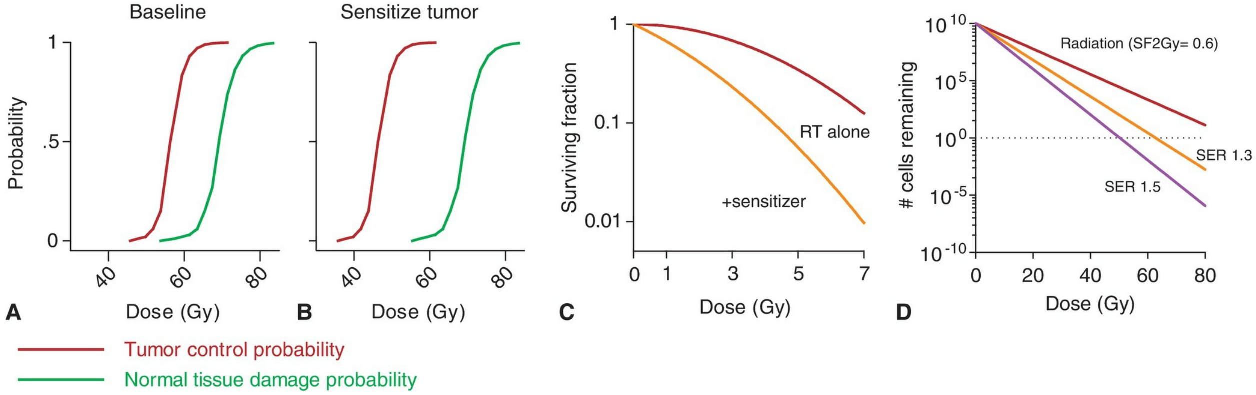

Figure 30.8. Modeling tumor control probability. **A:** The probability of radiation resulting in tumor control (*red*) and normal tissue damage (*green*) can be modeled as sigmoidal dose–response curves. Treatments that sensitize both normal tissue and tumor may shift both curves to the left (not shown). **B:** Treatments that preferentially sensitize the tumor to radiation shift the tumor control curve to the left. **C:** Treatments that sensitize tumor to radiation shift the survival curve left and down (*orange*) compared to radiation alone (*red*). **D:** A palpable tumor may comprise around 10^{10} cells. To cure the tumor, all cells must be removed (<10^{0} cells remaining, *dashed line*). The compounding effect of increased cell kill with the use of a sensitizing agent over 30 or more days of radiation is quite large. In this simplified graphic, a theoretical tumor with 10^{10} cells is treated with multiple 2 Gy daily doses (assume a surviving fraction of 60% per dose) of radiation (*red line*). A treatment that results in 30% greater cell kill each day (SER = 1.3, *orange*) results in theoretical "cure" at around 64 Gy, whereas a 50% increase (SER = 1.5, *purple*) results in "cure" around 52 Gy.

Overall, multiple randomized trials have confirmed a small but defined benefit of concurrent chemoradiotherapy over radiation alone in advanced-stage cancer of the head and neck. Whereas the specifics of these trials are discussed in more detail throughout this book, the sum of these studies favors concurrent therapy for patients with locally advanced cancers in the nasopharynx, larynx, hypopharynx, and oropharynx and for postoperative patients with specific high-risk pathologic features.[18,19]

"Targeted" Combined-Modality Therapy

Although the results of radiation and concurrent cisplatin are encouraging,

there remains substantial room for improvement for most patients with advanced head and neck cancers. Paralleling advances in molecular biology, identification of tumor-specific alterations in normal biologic processes has led to an explosion in targeted therapies. Although a comprehensive review of this rapidly growing field is beyond the scope of this chapter, we will discuss the two best-studied approaches of targeting tumor biology in combination with radiation in head and neck cancer. However, additional studies are underway investigating compounds that target the mitogen-activated protein kinase kinase (MAP2K/MEK/ERK), protein kinase B (PKB; a.k.a., Akt), phosphatidylinositol 3-kinase (PI3K), mammalian target of rapamycin (MTOR), and poly-ADP ribose polymerase (PARP) pathways,[128–132] among others.

In 2006, Bonner and colleagues reported the first trial demonstrating the ability of an antibody-based therapeutic (i.e., cetuximab) to improve outcomes in combination with radiation in locally advanced cancer of the head and neck.[26,27] Cetuximab is a monoclonal antibody that targets the EGFR, a protein that is overexpressed in a large percentage squamous cell carcinomas of the head and neck.[133,134] Upon receptor activation, EGFR initiates a coordinated signaling cascade that regulates cell division, proliferation, differentiation, and cell death. EGFR expression is correlated with poor outcome in patients with head and neck cancer.[34,108,110] In addition, numerous in vitro studies have demonstrated that inhibition of EGFR signaling results in improved tumor control.[135,136] Of particular importance to head and neck cancer, treatment with cetuximab resulted in significantly improved tumor control when given in combination with radiation.[24,137]

Hypoxic Cell Sensitizers

For over 60 years, it has been known that hypoxic tumors are less sensitive to radiation than are well-oxygenated tumors.[138] Worse outcomes in patients with hypoxic tumors appears to be due to both decreased sensitivity to radiation[139,140] and transcriptional changes induced by hypoxia leading to more aggressive tumors.[141–143] As a result of these findings, several studies have investigated the effect of hypoxic modification on outcomes in patients with head and neck cancer.[102,103,144–147] With few exceptions (DAHANCA

study of radiotherapy+/− nimorazole), most of these studies have failed to identify a clinical benefit to hypoxic modification although recent analyses have suggested that the use of a hypoxic modifier results in improved local–regional control in HPV-negative tumors.[102,103] Unfortunately, the lack of direct hypoxia measurements in these studies leaves the absolute benefit of hypoxic modification somewhat ill-defined in the clinical setting.

Intensity-Modulated Radiotherapy

Since its development in the late 1990s, studies have shown that IMRT can effectively limit dose to the salivary glands, mandible, larynx, and pharyngeal constrictors resulting in reduced long-term toxicities and improved patient quality of life as compared to 3-D radiotherapy techniques.[148–150] However, with the exception of cancer of the nasopharynx, cure rates with IMRT appear to be similar to those with older techniques. In the case of cancer of the nasopharynx, as the tumor is often concave in shape and close to many critical normal tissues (e.g., brainstem and optic apparatus), IMRT allows the radiation oncologist to deliver improved dose coverage of the tumor and therefore achieve increased tumor control rates compared to traditional 3-D approaches.[151,152]

Multidisciplinary Care

Cancer care has become increasingly multidisciplinary over the years. Whereas single-modality treatment was historically quite common for many malignancies, this is seldom true today where the majority of cancer patients interface with multiple cancer specialists and treatment modalities to effect a modern treatment package. The multidisciplinary nature of cancer care requires high-quality communication among specialists on behalf of each patient and timely follow-through to ensure that all elements of treatment are efficiently coordinated. The complexity of head and neck cancer care renders this a challenge and the incorporation of tumor boards, case managers, navigators, and routine case reviews can serve a valuable purpose to enhance coordination of care. Once established, the culture of multidisciplinary care becomes second nature and provides great benefit and satisfaction to patients and practitioners alike. No one can master every aspect of care for such a

complex group of cancer patients. Establishing and continually refining (based on evidenced-based review) the multidisciplinary team approach for head and neck cancer patients provides the best opportunity to contend successfully with this challenging disease.

31 Chemotherapy in the Treatment of Squamous Cell Carcinoma of the Head and Neck

Nabil F. Saba Fadlo R. Khuri

INTRODUCTION

Cancers of the upper aerodigestive tract comprise a variety of malignancies with different sites of origin extending from the lips to the cervical esophagus, with squamous cell carcinoma (SCC) representing the most prevalent histology. Squamous cell carcinoma of the head and neck (SCCHN) is an aggressive malignancy affecting close to 52,000 patients yearly in the United States and leading to more than 300,000 yearly deaths worldwide.[1] Tobacco smoking and alcohol use are known to be synergistic risk factors in the development of these cancers, which combined, accounted for approximately three-fourths of all SCCHN in the United States in the 1980s.[2] The incidence and prevalence of human papillomavirus (HPV)-associated oropharyngeal cancers have increased in recent years.[3–6] Multiple retrospective series have shown that patients with HPV(+) oropharyngeal squamous cell carcinoma (OPSCC) have a better prognosis than do patients with HPV(−) tumors.[7,8] Recent data suggest that smoking has an adverse effect on prognosis for HPV-positive as well as HPV-negative disease, with the risk of death significantly increasing with each additional pack-year of tobacco smoking.[9] HPV-positive disease also seems to have an unusual metastatic pattern.[10]

Although cancer of the head and neck represents only 5% of all newly diagnosed malignancies in the United States, it remains one of the most challenging to treat. Surgery and radiation therapy are two key components of the initial treatment of locally advanced SCCHN. Based on meta-analysis

data, chemotherapy improves survival in patients treated for cure for nonmetastatic SCCHN with a higher benefit when used concomitantly along with radiotherapy.[11] These trials included patients with cancer of the oral cavity, oropharynx, hypopharynx, and larynx. The role of induction chemotherapy prior to concurrent chemoradiotherapy remains controversial, even though the addition of a taxane to a platinum-based induction regimen has augmented the effectiveness of induction therapy.[12,13] Although this finding has been confirmed by a recent meta-analysis,[14] randomized trials have yet to prove the superiority of adding induction chemotherapy to the standard concurrent therapy approach.[15,16]

Cytotoxic chemotherapy was initially used primarily for palliation in the treatment of cancer of the head and neck. However, its use has gained increased acceptance as a primary and/or adjuvant modality over the past two decades and is now an integral part of the multidisciplinary management of SCCHN. As the objectives of chemotherapy in this field have changed dramatically, systemic therapy has such wide-ranging applications as radiation sensitization and chemoprevention. This chapter reviews the historical usage and current role for chemotherapy in the management of SCCHN.

TREATMENT OF NEWLY DIAGNOSED CANCER—GENERAL APPROACHES

Treatment of SCCHN is complicated by the diversity of cancer sites and origins, the vital anatomic structures within the treated area, and the need for preservation of organ function. The ideal approach to therapy involves a multidisciplinary team of surgeons, radiation and medical oncologists, dieticians, speech pathologists, and dentists. Approximately 30% to 40% of patients with SCCHN present with early-stage cancer manageable with either primary surgery or definitive radiation therapy. In these patients, despite the curative nature of these treatment modalities, the risk of a second primary malignancy is significantly increased compared with the age-matched general population.[17,18] Smoking cessation is of primary importance in reducing the incidence of second primary cancers, and chemoprevention to reduce recurrence rates of index cancers and to prevent the occurrence of second

primary cancers in the aerodigestive tract has been a topic of interest and substantial research effort.[19] Unfortunately, none of the chemopreventive agents studied to date in patients who completed definitive therapy for early-stage disease has shown a clear benefit in prospective randomized clinical trials (please refer to the section of Chemoprevention in this chapter for a more detailed account of this topic).

Even though local therapeutic interventions remain a key component for the treatment of locally advanced SCCHN, chemotherapy has earned a significant role and is now an essential component of managing locally advanced cancer.[20] Treatment planning, including decisions about the use of chemotherapy, should be made within the setting of a multidisciplinary approach. Although functional organ preservation for patients with cancers of the oropharynx, larynx, and hypopharynx has been widely adopted, using nonsurgical approaches in many instances, this still does not apply to oral cavity malignancies where management still relies heavily on surgical resection. Some studies have suggested an added benefit for less extensive surgery when chemotherapy is used for oral cavity cancers, yet this has not been proven in large randomized clinical trials.[21,22]

CONCOMITANT CHEMORADIOTHERAPY

Concurrent chemoradiotherapy significantly decreases the risk of death compared with definitive radiotherapy alone based on the meta-analysis of chemotherapy in cancer of the head and neck (MACH-NC) study, which revealed a 6.5% total decrease in 5-year mortality with the addition of chemotherapy.[11] Although the meta-analysis confirmed a greater benefit with platinum-based chemotherapy, the optimal regimen in the concurrent setting is still a point of debate. High-dose, single-agent cisplatin administered at 100 mg/m^2 on days 1, 22, and 43 in concurrence with conventional single daily fractionated radiation therapy has been considered the standard systemic regimen.[23] However, the improved survival noted with this regimen was also associated with increased toxicities, both acute and chronic.[23,24] It is unclear whether a third cycle of cisplatin would have made a significant difference in outcome. The Radiation Therapy Oncology Group (RTOG) 0129 study

randomized patients to once-daily radiation fractionation with three cycles of cisplatin in comparison to accelerated boost administered over a total of 6 weeks with two cycles only. No significant difference in survival was observed between the two arms. More recent cooperative group trials have restricted cisplatin to two cycles if administered with a concomitant boost approach.

For patients who are not candidates for high-dose cisplatin, a weekly cisplatin regimen has been used with cisplatin doses ranging from 30 to 50 mg/m^2. Although considered to be reasonable options by many, these approaches have not been tested in a randomized prospective fashion in comparison with the every 3 weeks platinum regimen.

Alternative regimens in the case of contraindications to cisplatin include combinations of carboplatin and 5-fluorouracil (5-FU).[25] Taxane-based regimens with the most commonly used weekly paclitaxel and carboplatin have also been considered as acceptable alternatives.[26] Limitations of these approaches have been the lack of agreement on the best taxane schedule and dose and the lack of randomized clinical trials comparing these regimens to cisplatin. A recent meta-analysis comparing the two approaches revealed no clear advantage of cisplatin over the taxane-based regimens that include carboplatin.[27]

Concomitant chemoradiotherapy has been investigated over the past four decades as a primary treatment approach in locally advanced cancer of the head and neck. It is administered with the intent of curing locoregional cancer and controlling the occurrence of distant metastases. Theoretically, systemic control may be feasible if the dose of chemotherapy administered is equivalent to standard systemic doses when given in combination with radiotherapy. Chemotherapy should also act as a radiation sensitizer (by improving the tumoricidal activity of radiation) or as an enhancer (with direct cytotoxic properties against the primary tumor). Therefore, combined chemoradiotherapy provides potentially increased antitumor activity, although often at the risk of substantial local toxicity.

Generally, radiation therapy is administered in two basic schedules: concomitant (simultaneous) or in an interrupted fashion (alternating or split-course schedule). The schedule of radiation delivery may have an impact on both treatment outcome and the incidence of acute and chronic toxicities. A

phase III trial (RTOG 9003) enrolled more than 1,000 patients with locally advanced SCCHN[28] to four arms, including[1] standard radiotherapy,[2] hyperfractionated twice-daily radiotherapy,[3] accelerated fractionated twice-daily therapy, and[4] accelerated fractionated therapy with concomitant boost. After a median follow-up of 23 months, it was determined that hyperfractionated or accelerated radiation therapy with boost provided increased locoregional control and a trend toward improved disease-free survival (DFS) in comparison with conventional radiation therapy. However, no improvement was noted in overall survival (OS). Patients given accelerated split-course fractionation had outcomes similar to those who had received conventional radiotherapy. Clinical investigators continue to incorporate accelerated, fractionated, hyperfractionated, and intensity-modulated radiotherapy (IMRT) approaches in an attempt to maximize tumoricidal activity while minimizing associated toxicities.

Earlier studies examined single-agent chemotherapy with concomitant daily radiotherapy. Cytotoxic agents used in the palliative setting for recurrent or advanced disease have demonstrated single-agent activity when combined with radiation therapy. Frequently administered single agents included cisplatin, methotrexate, 5-FU, bleomycin, ifosfamide, and the taxanes. Several randomized studies have been completed, demonstrating the benefits of combined therapy in comparison with radiation therapy alone. An early randomized trial of radiotherapy alone versus radiotherapy with bolus 5-FU[29] clearly demonstrated superior local control and survival with the addition of 5-FU to radiotherapy in patients with cancer of the oral cavity and oropharynx. Other studies demonstrated the enhanced radiosensitization properties of 5-FU when administered continuously for at least 48 hours following radiation therapy.[30] The continued exposure to 5-FU (via continuous infusion rather than bolus) following radiation therapy seemed to provide superior radiosensitization.[30] On the basis of this principle, a phase I/II pilot study was conducted to study the effects of dose-escalating continuous infusion 5-FU (20 to 30 mg/kg in 5-mg/kg increments) over a 5-day period with four sequential daily fractions of radiotherapy (2.5 Gy) on days 1 to 4, repeated every 14 days.[31] A complete response (CR) rate of 75% was attained in stage IV patients.

In addition, based on preclinical animal models and promising results from earlier studies, hydroxyurea was approved by the FDA for use in

patients with SCCHN when administered concomitantly with radiotherapy.[32] Hydroxyurea has not gained widespread use in concurrence with radiation therapy despite its common use in a few centers such as the University of Chicago. Earlier studies of bleomycin examined its potential synergistic activity in combination with radiotherapy. Two previous randomized studies involving more than 200 patients suggested improved locoregional control in the combined chemoradiation arm.[33] However, the European Organisation for Research and Treatment of Cancer (EORTC) could not confirm benefit of response after completing a randomized study of conventional radiotherapy with or without single-agent bleomycin.[34] Only 64% of patients in the chemoradiation arm received the recommended dose, which may have contributed to the suboptimal response rate and survival time in the combined chemoradiation arm.

The platinum analogues, carboplatin and cisplatin, have a well-defined role in combination with radiation therapy. A large phase III European study evaluated the benefits of concomitant cisplatin (100 mg/m^2, days 1, 22, and 43) with radiation therapy.[35] The study randomly assigned 334 patients to daily radiation therapy or chemoradiotherapy after surgical resection. After a median follow-up of 60 months, the rate of progression-free survival (PFS) was significantly higher in the combined therapy group than in the group given radiotherapy alone (p = 0.04). The OS rate was also significantly higher in the combined therapy group than in the radiotherapy group (p = 0.02), confirming that postoperative concurrent administration of high-dose cisplatin with radiotherapy is more efficacious than is radiotherapy alone in patients with locally advanced cancer of the head and neck and does not cause an undue number of late complications.

Several similar studies have confirmed the advantage of platinum-based concurrent therapy over radiation therapy alone as a definitive therapy for locally advanced SCCHN.[11,36–38] The platinum agent of choice remains cisplatin despite the equivalent results observed in small international trials. Other potential chemosensitizing agents that remain largely investigational include carboplatin and docetaxel.[39,40] The toxicity profile of other agents such as gemcitabine has precluded development in this setting.[41]

Several studies have explored the use of multiagent chemotherapy in concurrence with radiation. Early studies investigated the platinum 5-FU

regimen and revealed encouraging results.[38,42–45] In all, more than 70 randomized trials have compared radiation alone with chemoradiotherapy. Several of these studies involved small cohorts of patients.[11] An example of a study using concurrent cisplatin and 5-FU is the Cleveland Clinic study that enrolled 222 patients with locally advanced SCCHN and administered 96-hour continuous infusion of cisplatin (20 mg/m^2/day) and fluorouracil (1,000 mg/m^2/day) with standard or fractionated radiation.[38] With a median follow-up of 73 months, a 5-year OS rate of 65.7% and a local control rate of 86.7% were observed. The toxicity profile was similar to that of bolus-dose cisplatin with radiation therapy: 78.4% of patients required nutritional support via PEG tube, and one died from a pulmonary embolism.

The MACH-NC meta-analysis, which evaluated a total of 87 trials and 16,485 patients, showed an absolute benefit for chemotherapy of 4.5% at 5 years and a significant interaction ($p < 0.0001$) between chemotherapy timing (adjuvant, induction, or concomitant) and treatment. Both direct (six trials) and indirect comparisons showed a more pronounced benefit of the concomitant chemotherapy as compared to induction chemotherapy.[11]

More recently, investigators and cooperative groups have placed increasing focus on the exploration of less intensive regimens with lower end-organ toxicities. This has been accelerated by the finding that HPV status is a strong and independent prognostic factor for survival among patients with cancer of the oropharynx[9] and by the increased incidence of HPV-related oropharyngeal SCC predominantly in Caucasian males.[3,46]

The use of noncisplatin taxane-based regimens in the concurrent setting remains an attractive secondary option for patients who are not candidates for cisplatin therapy, despite the lack of randomized clinical trials in this area. A regimen of weekly carboplatin (100 mg/m^2) and paclitaxel (45 mg/m^2) and concurrent radiotherapy of 70.2 Gy resulted in a CR rate of 75% with a median OS of 33 months that was higher in complete responders with OS rates of 79% and 61% at 2 and 3 years follow-up, respectively.[47] Even though significant acute toxicities were reported, with 70% of patients experiencing grade 3 mucositis, 30% leukopenia, and 25% skin desquamation. However, the ototoxicity and nephrotoxicity typically seen with cisplatin use were not observed. In a second phase II trial, weekly carboplatin with an area under the curve (AUC) of 1 with paclitaxel at 45

mg/m^2 was given with 69.6 Gy of daily radiotherapy to the primary cancer. The primary toxicities included grade 3 or 4 stomatitis, dysphagia, and mucositis in 55% of patients; however, the regimen was effective with an overall response rate (ORR) of 84%, CR rate of 67%, and an OS rate of 60% at a median follow-up of 36 months.[48] Taxane-based regimens remain a very rational approach for patients with contraindications to cisplatin-based therapy. However, no clear randomized trials have established a therapeutically equivalent regimen to the standard cisplatin-based therapy. A recent meta-analysis comparing the two approaches was recently reported[27] and revealed at least equivalent results with the use of taxane-based regimens. The optimal dose and schedule of paclitaxel and carboplatin remain, however, poorly defined.

SEQUENTIAL THERAPY

Induction chemotherapy is administered in a sequential fashion before the provision of definitive surgery and/or radiation therapy. The goal of induction therapy is to assist in both local and distant cancer control. Theoretically, this is done by reducing overall tumor burden before the definitive therapy, which ultimately allows organ preservation and function and possibly improved quality of life. Distantly, the systemic effects of induction chemotherapy may prevent the dissemination of microscopic disease eventually promoting OS. In addition, an improvement in the chance of organ preservation such as preservation of the larynx and hypopharynx is possible, which would have a profound positive impact on quality of life. With the increasing toxicity noted with concurrent therapy schedules, and with the improvement in locoregional control observed with the use of concurrent therapy, interest in curtailing distant metastases as a significant cause of mortality has gained increased importance;[49] hence the concept of sequential therapy, which combines both induction and concurrent therapy approaches. In the MACH meta-analysis, induction chemotherapy offered a meager advantage of 5% improvement in survival over radiation alone; however, this was observed with platinum-based regimens that did not include taxanes.[50,51] Since then, randomized clinical trials comparing induction chemotherapy with cisplatin and 5-FU and a taxane (docetaxel or paclitaxel) showed a clear advantage to adding a taxane in the induction setting and led to the approval of Docetaxel, Cisplatin, 5FU (TPF) as the induction regimen of choice for locally advanced

SCCHN[12,13] (**Table 31.1**).

Table 31.1 Major Randomized Phase III Trials of Induction Chemotherapy in Treating SCCHN

Trial	*N*	Regimens	LRC (2 Years)	OS (2 Years)	PFS (2 Years)
CONCERT (phase II)[99]	150	Panitumumab vs. cisplatin with XRT	51% vs. 61% (NS)	In favor of CRT ($p = 0.03$)	In favor of CRT ($p = 0.10$)
RTOG 0522[100]	895	Cisplatin vs. cisplatin and cetuximab with 70–72 Gy XRT	NA	83% vs. 80% at 2 ($p = 0.17$)	63% vs. 64% ($p = 0.66$)
Bonner trial[101]	213	Cetuximab vs. 70–72 Gy XRT different fractions only	In favor of Cet 41% vs. 50% ($p = 0.005$)	In favor of Cet 45% vs. 55% ($p = 0.03$)	In favor of Cet 37% vs. 46% ($p = 0.006$)
RTOG 1016	742	Cetuximab vs. cisplatin with 70 Gy IMRT (HPV positive only)	Analysis in progress	Analysis in progress	Analysis in progress

In achieving the desired goals of induction chemotherapy, combination treatment with platinum-based 5-FU has been the traditional approach based on its earlier success in recurrent and advanced cancer. Review of the literature suggests that all studies incorporating induction chemotherapy have failed to provide improved locoregional control or a benefit in OS.

Three landmark phase III trials have established the benefits of induction chemotherapy in laryngeal preservation. The Veterans Affairs Laryngeal Study randomly assigned 332 patients with stage III or IV laryngeal carcinoma to receive three cycles of cisplatin/5-FU (PF) followed by conventional radiotherapy or laryngectomy followed by conventional radiotherapy.[52] Response was assessed after the completion of two cycles of chemotherapy. Patients with a partial response (PR) received a third cycle of chemotherapy followed by radiotherapy. In contrast, nonresponders immediately underwent a laryngectomy followed by radiation therapy. An integral component of this study was salvage surgery, which was offered to all patients with residual disease at the completion of radiotherapy. After two cycles of induction, the ORR was 85% (31% CR, 54% PR). Histologic specimens were obtained in 103 patients at the completion of chemotherapy, validating a complete response in 88% of patients with a clinical CR; 45% of those presumed to have a clinical PR were confirmed histologically. Overall, 64% of patients had a histologically confirmed CR. After a median follow-up of 33 months, the estimated 2-year survival was 68% in both treatment groups, and there was no difference in OS ($p = 0.9846$). However, preservation of the larynx was maintained in 64% of patients. Patterns of recurrence differed between the two groups, with increased locoregional

disease failure (p = 0.0005) but decreased metastases (p = 0.016) in the induction chemotherapy group. Although there was no significant difference in OS, this study demonstrates that induction chemotherapy is feasible in the setting of cancer of the larynx, allowing organ preservation without compromising OS. It should be noted that of the 166 patients on the chemotherapy arm, 120 patients (72%) had N0 or N1 disease.

In the RTOG 9111 study, a total of 547 patients with stage III/IV laryngeal carcinoma[53] were randomized to three cycles of induction chemotherapy of cisplatin/5-FU followed by daily radiation therapy, concurrent cisplatin (100 mg/m^2, days 1, 22, and 43) and radiation therapy, or daily radiation therapy only (70 Gy). The primary endpoint was laryngeal preservation rather than OS. A preliminary analysis of laryngectomy-free survival at 2 years showed improvement in both the chemotherapy-containing arms, but notably so in the concurrent chemotherapy arm (58% vs. 66%). Although DFS appeared to be favorable in both chemotherapy arms in comparison with radiation therapy only, no clear difference in OS was noted among the three arms of the study. Time to laryngectomy was superior in the concurrent chemotherapy arm in comparison with the induction arm (p = 0.0094). These recently updated 10-year results continue to show that induction PF followed by RT and concomitant cisplatin/RT shows similar efficacy for the composite endpoint of laryngectomy-free survival. Locoregional control and larynx preservation were significantly improved with concomitant cisplatin/RT compared with the induction arm or RT alone.[53] Hence, it can be concluded that despite variation in methods of treatment, neither has provided an advantage in OS despite the trends favoring induction chemotherapy. Nonetheless, the results from this trial suggest a prolonged DFS and laryngectomy-free interval with the addition of chemotherapy to radiation therapy.

The EORTC verified the benefits of organ preservation in a randomized phase III clinical trial in patients with stage III/IV cancer of the pyriform sinus or aryepiglottic folds.[54] One hundred ninety-four eligible patients were randomly assigned to immediate surgery followed by radiotherapy (94 patients) or induction chemotherapy (100 patients) with cisplatin (100 mg/m^2, day 1) and continuous-infusion 5-FU (1,000 mg/m^2/day, days 1 to 5). An endoscopic examination was completed after each cycle. Patients with a CR or a PR following cycle 2 were offered a third cycle of chemotherapy. Unlike

the Veterans Affairs Laryngeal Cancer Study, patients were required to achieve a CR before undergoing radiation therapy; patients with stable disease were offered salvage surgery followed by radiotherapy. Induction chemotherapy resulted in a CR in 54% of patients at the primary site, and 51% of patients achieved a locoregional CR. Overall, induction chemotherapy provided fewer distant metastases ($p = 0.041$) and an improved median survival (44 months) versus the surgical arm (25 months). Unfortunately, neither arm demonstrated superiority in the prevention of locoregional recurrence. Treatment with induction chemotherapy managed to preserve the larynx in 42% and 35% of patients evaluated for 3- and 5-year estimates of survival. This European study suggests that induction chemotherapy is a feasible alternative if organ preservation is desired without compromising OS. However, it should be noted that only 31% of patients had N2/N3 disease, of which only 6% were N3. Furthermore, patients with N3 disease were eventually excluded from this trial because the first six patients failed to achieve a CR following induction.[54] The updated 10-year results of the EORTC trial 24891 continue to show that more than half of the survivors retain their larynx without compromising survival.[55]

Despite the reduction in distant metastases observed in a number of trials using the induction or sequential approach, the superiority of these approaches over the standard concurrent regimen has yet to be proved in a randomized phase III trial.

Sequential and concurrent therapy were compared head to head in a phase II randomized clinical trial in 101 patients with stage III to IV SCCHN. Patients randomized to concurrent therapy received two cycles of cisplatin plus 5-FU in combination with radiation therapy. Patients assigned to the sequential therapy arm first received three cycles of docetaxel, cisplatin, and 5-FU, followed by the same chemoradiation therapy. The complete radiologic response rate was clearly superior in the sequential arm with an accompanying increase in OS and PFS, providing substantial support to the proponents of induction therapy.[56]

Unfortunately, these results could not be reproduced in two US-based randomized phase III studies comparing the sequential to the concurrent approach (Table 31.1). In the PARADIGM trial, 145 patients were randomized to sequential versus concurrent therapy. The schema of the sequential arm was, however, complicated and was dependent on the

response to induction TPF. Docetaxel was chosen as the concurrent agent of choice with a concomitant boost radiotherapy given to patients with less than good response to induction therapy, whereas standard radiation with concurrent carboplatin was used for the good responders. The trial fell short of completing accrual and accrued <50% of its intended goal. No sign of any benefit from sequential therapy on overall outcome was observed.[15]

The DECIDE trial randomized patients to induction with two cycles of docetaxel, cisplatin, and 5-FU followed by chemoradiotherapy with docetaxel, 5-FU, and hydroxyurea in concurrence with radiation therapy. There was no noted difference in PFS or OS.[16] Febrile neutropenia was also more frequent on the induction arm. Of note is that both of these phase III studies suffered from lack of reaching their accrual targets and an overly pessimistic prediction of outcome for the control arm in the era of HPV-positive OPSCC.

CANCER OF THE NASOPHARYNX

Nasopharyngeal cancer (NPC) is staged according to the International Union Against Cancer (UICC) and the American Joint Committee on Cancer (AJCC) criteria[57,58] and classified into three subtypes based on the World Health Organization (WHO) criteria: type I or keratinizing, type II or differentiated nonkeratinizing, and type III or undifferentiated, which is usually associated with the EBV virus.[59,60]

It is unclear if systemic therapy in the adjuvant setting or primary therapeutic setting has any value in patients with early-stage NPC given the paucity of clinical trials examining this question. For stage II or intermediate-stage cancer, concurrent therapy is considered a valid approach given the results of a randomized trial favoring the concurrent approach to single-modality radiation therapy. A total of 1,992 patients with stage II NPC were randomized to weekly cisplatin and radiotherapy versus radiation alone. Better OS and PFS were observed on the concurrent therapy arm. In addition, the rate of metastases was more favorable in the concurrent arm.[61]

Concurrent chemoradiotherapy remains the mainstay for the treatment of locally advanced NPC. An early RTOG study opened the door for exploring concurrent modality therapy as the treatment of choice for locally advanced

NPC. In a phase II study comparing concurrent radiotherapy plus cisplatin (100 mg/m^2, days 1, 22, and 42) to standard radiotherapy alone in 124 patients with locally advanced SCCHN,[62] patients with NPC receiving concurrent treatment had an impressive CR of 89% in a subset analysis. Comparison with historically matched controls revealed that DFS and OS were greater in the concomitant arm, thereby revolutionizing the standard treatment of NPC. Subsequently, the large phase III intergroup study 00 to 99 of daily radiotherapy and cisplatin (100 mg/m^2, days 1, 22, and 43) followed by three cycles of adjuvant cisplatin (80 mg/m^2, day 1) and continuous-infusion 5-FU (1,000 mg/m^2, days 1 to 4) every 28 days revealed a clear advantage of the concomitant arm with a 3-year DFS of 69% versus 24% ($p < 0.001$) and a 3-year OS of 78% versus 47% ($p = 0.005$).[63]

Even though the results of the phase III intergroup 00 to 99 study were confirmed in subsequent trials,[64] the acute and late toxicities associated with this regimen have led to the exploration of other effective and less toxic chemotherapeutic combinations. Carboplatin, which is deemed to be less toxic, was compared head to head with cisplatin in this setting with similar efficacy and reportedly lower toxicity. Still, more studies are needed to confirm these preliminary findings.[65]

Given the difficulty in completing the therapeutic regimen on the intergroup 00 to 99 study, an increased interest has developed in sequential therapy for NPC. Patients with stages III and IV disease were randomized to sequential versus concurrent therapy. Although the results were encouraging, the sequential group had a different fractionation schedule for radiation and a higher incidence of toxicities,[66] begging for more studies to investigate this question.

A meta-analysis of six randomized trials evaluating chemoradiation therapy (induction, concomitant, and adjuvant) versus radiation therapy alone verified that the addition of chemotherapy to radiation therapy increased DFS by 37% at 2 years, 40% at 3 years, and 34% at 5 years. The addition of chemotherapy to standard radical radiation therapy for locoregionally advanced cancer of the nasopharynx increases both disease-free/progression-free and OS by 19% to 40% at 2 to 4 years after treatment.[67] In contrast, in a large single-institution study in Hong Kong, 240 patients were randomly assigned to radiation therapy or to two or three cycles of induction

chemotherapy (cisplatin 60 mg/m^2 and epirubicin 110 mg/m^2) followed by radiation therapy.[68] After a median follow-up of 71 months, the investigators determined no statistical benefit with induction chemotherapy in nodal relapse-free survival (p = 0.13), prevention of distant metastases (p = 0.56), or survival (p = 0.55). Despite these results, the addition of chemotherapy is the overwhelmingly accepted standard of care for treating locoregionally advanced NPC.

Systemic therapy is considered the mainstay of care for patients with advanced or recurrent NPC who are not candidates for local therapeutic interventions. In this setting, combination therapies seem to produce superior results when compared to single-agent therapies.[69] Several regimens appear to have equivalent results; however, there is a clear paucity of randomized clinical trials comparing different agents in this setting.[70] EBV DNA levels measured in plasma are reported to predict overall outcome of patients with recurrent metastatic NPC and may be used as a method to assess response and predict outcome.[71] Recently, markers of cisplatin sensitivity such as polymorphism of ERCC1 C8092A were found to be predictors of outcome in cisplatin-treated patients.[72]

Second-line agents for the treatment of refractory disease may include gemcitabine, 5-FU derivatives, the taxanes, topoisomerase I inhibitors, methotrexate, and the vinca alkaloids.[73–76]

POSTOPERATIVE THERAPY

In addition to concurrent or sequential chemoradiotherapy, surgical resection followed by postoperative therapy guided by pathologic findings is considered a standard definitive therapeutic approach in SCCHN. Local and distant recurrences remain frequent after surgery for locally advanced cancer, which presses the need for improved postsurgical adjuvant approaches.[77,78] Radiotherapy in the postoperative setting has been delivered to patients with resected stages III, IVa, and IVb disease with specific indications including surgical margin involvement, perineural and lymphovascular involvement, bone or cartilage invasion, extracapsular lymph node extension, advanced T3 or T4 primary tumors, and N2 or N3 lymph node metastases. This approach has resulted in a 5-year survival rate of close to 30% to 40%.[35,79,80] The

addition of systemic chemotherapy has been shown to improve locoregional as well as overall and disease-free survival in patients with high-risk features.[79,81]

Cisplatin at 100 mg/m^2 added to 60 to 66 Gy of postoperative radiotherapy was tested in trials by both EORTC and RTOG.[35,79] The studies had notable differences in their inclusion criteria as well as their primary objectives, which were locoregional control in the RTOG study and PFS in the EORTC study. Adjuvant concurrent therapy was associated with an improved 5-year PFS (47% vs. 36%, $p = 0.04$) and OS (53% vs. 40%, $p = 0.02$) as well as a lower rate of locoregional recurrence (18% vs. 31%, $p = 0.007$) and a longer time to progression (55 vs. 23 months) on the EORTC trial. This came at a higher toxicity price on the concurrent arm with a significant difference in acute mucositis (41% vs. 21%). On the RTOG study, despite the improved locoregional control and DFS observed in the initial 3-year analysis, the updated 5-year results revealed a loss of significant difference in DFS (37.4% vs. 29.1%, $p = 0.098$) and locoregional control (79.5% vs. 71.3%, $p = 0.086$). It is of note that in both studies, cisplatin did not influence the rate of distant metastases, which were 21% versus 25% in the EORTC study ($p = 0.61$) and 23% versus 21% in the RTOG trial ($p = 0.46$), for the radiation alone arm and concurrent arm, respectively.

To better determine the pathologic characteristics that exerted most of the influence on clinical outcome in these two trials, a more recent pooled analysis of both trials confirmed the importance of microscopically involved surgical margins as well as extracapsular spread of cancer as the most important predictors for the derived benefit in DFS, OS, and locoregional control (23%, 48%, and 30% risk reduction, respectively) when cisplatin was added to radiation.[81]

Cisplatin at the schedule used in both the RTOG and EORTC trials remains the most widely accepted standard of care for patients with high-risk postoperative features. Other smaller trials have scheduled cisplatin on a weekly basis resulting in improvements of 15% in locoregional control ($p = 0.05$), 23% in OS ($p < 0.01$), and 22% in DFS ($p < 0.02$) compared to the nonchemotherapy arm.[82] The role of concurrent adjuvant therapy in patients without high-risk features but with intermediate-risk features including T4 disease, perineural or lymphovascular invasion, N2a or N2b nodal disease, or a surgical margin within 5 mm remains a controversial issue and is currently

being examined by study RTOG 0920. This trial is randomizing intermediate-risk patients to radiation therapy at 60 to 66 Gy only versus the same radiation schedule in concurrence with cetuximab administered at an initial loading dose of 400 mg/m^2 1 week before the start of radiation followed by 250 mg/m^2 weekly during radiation.

Despite the fact that no randomized data exist on the use of taxanes in the postoperative setting, encouraging results from small phase II trials have opened the door for exploring postoperative taxane use in patients with high-risk features. A phase II randomized trial of postoperative radiation with cetuximab combined with either cisplatin or docetaxel (RTOG 0234) revealed a favorable improvement in DFS and OS in the docetaxel arm.[83] This has opened the door for the recently activated RTOG 1216 trial randomizing patients with high-risk features to postoperative radiation delivered with concurrent cisplatin versus docetaxel versus docetaxel and cetuximab.

TARGETING THE EPIDERMAL GROWTH FACTOR INHIBITOR

Overexpression of the epidermal growth factor receptor (EGFR) is recognized in more than 80% of SCCHN.[84] Ligand binding of the extracellular domain results in homodimerization or heterodimerization, causing phosphorylation of the tyrosine kinase domain, leading to cell proliferation and activation. An inverse correlation may also exist between EGFR expression and radioresistance.[85,86] Administration of the chimeric monoclonal antibody against the EGFR cetuximab has been shown to increase radiosensitization, decrease tumor cell line growth, and increase apoptosis (programmed cell death).[87] In vitro and xenograft studies have shown that inhibiting EGFR with cetuximab decreases tumor cell proliferation through the indirect inhibition of its tyrosine kinase activity.[88–91]

Preclinical studies explored the interaction between cetuximab and radiation in human SCCHN cell lines.[92] Cells were treated with cetuximab alone, radiation alone, or cetuximab and radiation. The degree of cell proliferation was markedly inhibited with the combined treatment, regardless

of the degree of EGFR overexpression. When the cell lines were assessed after 48 hours, the extent of apoptosis was greatest in the cetuximab/radiation-treated cell line.

Extensive preclinical and clinical research has led to the approval of cetuximab for the treatment of recurrent metastatic SCCHN. Despite the fact that the ORR with cetuximab in patients with recurrent or metastatic SCCHN does not exceed 13%, a disease control rate of 40% to 46% has been noted.[93,94] Cetuximab was approved as monotherapy for treatment of chemotherapy refractory disease and as a single agent in combination with radiotherapy for treatment of locally advanced SCCHN.

Studies with tyrosine kinase inhibitors of EGFR (EGFR TKIs) resulted in lower responses that did not exceed 10% in small phase II studies.[95,96] EGFR TKIs have also been used in combination with platinum-based systemic therapies with a noted response rate of 21% and a median OS of 7.8 months.[97]

Earlier combinations of cetuximab with radiation led to encouraging results,[98] which set the stage for several larger randomized studies investigating monoclonal antibodies to EGFR in combination with radiation for primary therapy of locally advanced SCCHN (**Table 31.2**). A phase III trial by Bonner et al. in patients with locally advanced SCCHN compared radiation alone to radiotherapy and cetuximab. A total of 213 patients with locally advanced disease received radiation alone and 211 patients received radiation and cetuximab at 400 mg/m^2 loading dose and 250 mg/m^2 subsequent weekly doses. PFS and OS as well as duration of locoregional control were significantly improved with cetuximab despite an equivalent rate of distant metastases on both arms. Patients on the cetuximab versus control arm had a PFS of 17.1 versus 12.4 months (p = 0.006), loco regional control (LRC) of 24.4 versus 14.9 months (p = 0.005), and median OS of 49 versus 29.3 months (p = 0.03), respectively.[101] Updated data continue to show a significant improvement in OS with the addition of cetuximab (45.6% vs. 36.4% at 5 years). Of note however is the lack of information regarding the influence of HPV on response and survival in this study of relatively younger patients with predominantly primary cancers of the oropharynx.[102] A comparison of the toxicity profile revealed no significant differences between the two arms with the exception of the incidence of a rash and infusion

reactions related to cetuximab.

Table 31.2 Major Randomized Phase II/III Trials Using Monoclonal Antibodies to EGFR in Combination with Radiation for Primary Therapy of Locally Advanced SCCHN

Trial	*N*	Regimens	RR	Median OS (Months)	Median PFS (Months)
E5397[106]	117	Cisplatin vs. cisplatin/ cetuximab	10% vs. 26% ($p = 0.03$)	8 vs. 9.2 ($p = 0.21$)	2.7 vs. 4.2 ($p = 0.09$)
EXTREME[107]	442	Platinum based vs. platinum + cetuximab	20% vs. 36% ($p < 0.01$)	7.4 vs. 10.1 ($p = 0.04$)	3.3 vs. 5.6 ($p < 0.001$)
SPECTRUM[108]	657	Cis/5-FU vs. Cis/5-FU + panitumumab	25% vs. 36%	9 vs. 11.1 ($p = 0.14$)	4.6 vs. 5.8 ($p = 0.004$)
ZALUTE[109]	286	Zalutumumab vs. support or methotrexate	6.3% vs. 1.1%	6.7 vs. 5.2 ($p = 0.065$)	9.9 vs. 8.4 ($p = 0.001$)

One of the major criticisms of this study is the choice of radiation alone as the comparator arm, because this is considered a substandard approach at the present. The lack of direct comparison between cisplatin and cetuximab in a randomized phase III trial, in addition to results from retrospective single-institution studies favoring cisplatin, has hindered the adoption of cetuximab and radiation therapy as the standard approach of choice in patients with locally advanced SCCHN. The results of a recently completed phase III study comparing cisplatin with cetuximab (RTOG 1016) are eagerly awaited and may help to resolve this question at least in patients with HPV-positive disease. RTOG 1016 is comparing 5-year OS between cisplatin at 100 mg/m^2 administered every 21 days for 2 doses to cetuximab at 400 mg/m^2 loading dose followed by 250 mg/m^2 weekly in concurrence with 70 Gy IMRT. Local and distant failure rate as well as toxicity and correlative biomarkers will be examined as secondary endpoints.

Given the improvement in outcome observed with the addition of cetuximab to radiotherapy in treating locally advanced cancer, study RTOG 0522 attempted to answer the question of whether the addition of cetuximab to the standard platinum radiation combination would improve PFS for patients with locally advanced disease. The study enrolled a total of 895 evaluable patients, 447 on the cetuximab/cisplatin arm and 448 on the cisplatin only arm. No significant difference in OS was reported in a preliminary analysis presented at American Society of Clinical Oncology (ASCO) in 2011.[100] Additional follow-up is needed to reach the study

endpoints. In the interim analysis, no clear difference in outcome was observed in the subset of HPV-positive patients. In a phase II, randomized trial (CONCERT-2) of the same design using the humanized EGFR monoclonal antibody panitumumab plus radiotherapy compared with chemoradiotherapy in patients with unresected, locally advanced SCCHN, there was a favorable trend for the nonpanitumumab arm for the primary endpoint (locoregional recurrence at 2 years), as well as other measures of efficacy, mostly observed in the HPV-negative population. The relatively small number of patients enrolled compared to RTOG 0522 and the subset analysis limits the conclusions, especially for the HPV-positive group.[99]

At present, no clear standard of care exists in the HPV-positive cancer of the oropharynx (OPCA) patient population. It is clear, however, that HPV-positive OPCA is a distinct clinicopathologic entity with different clinical behavior and improved overall prognosis compared to HPV-negative SCCHN. In an analysis of study RTOG 0129, which examined accelerated-versus standard-fractionation radiation therapy in concurrence with cisplatin, 63.8% of patients with OPCA had HPV-positive status. A significantly improved 3-year OS was observed compared to that in HPV-negative patients (82.4% vs. 57.1%, $p < 0.001$ in HPV-positive vs. HPV-negative OPCA, respectively). Of note is the negative effect of smoking, a higher lymph node metastases, and cancer stage on overall outcome.[9] These findings have opened the door to a newer generation of studies including RTOG 1016, ECOG 1308, and others focusing on HPV-positive OPCA. The standard of care for early, locally advanced as well as metastatic cancer has yet to be defined for HPV-positive disease.

EGFR INHIBITION IN RECURRENT AND METASTATIC SCCHN

Numerous phase II trials have evaluated the activity of cetuximab in the treatment of recurrent or metastatic cancer. Earlier studies enrolled a small number of patients. In one phase II trial, 53 patients with recurrent or metastatic cancer received cetuximab in combination with platinum-based chemotherapy. A response rate of 36% was reported with the most common grade 3/4 toxicities being leukopenia (38%), asthenia (25%), and thrombocytopenia (15%), consistent with the known adverse events noted

with chemotherapy.[103] In a multicenter phase II trial reported by Vermorken et al.,[93] 103 patients with disease progression after platinum-based therapy were treated with cetuximab monotherapy. The response rate did not exceed 13% unfortunately, with a median progression time of 70 days.[93] Hitt et al.[104] reported another phase II study in which cetuximab was combined with weekly paclitaxel at 80 mg/m^2. The ORR in the 42 evaluable patients was 60% with a median PFS of 5.6 months.[104] The regimen was fairly well tolerated. A phase II study reported by Baselga et al.[105] enrolled 96 patients with recurrent metastatic SCCHN who received cetuximab in combination with platinum-based chemotherapy. A response rate of 10% was reported with a disease control rate of 53%. The median PFS time was 85 days with a median OS of 183 days.[105]

Several larger phase III studies have investigated several EGFR monoclonal antibodies in the recurrent metastatic setting (**Table 31.3**). The phase III randomized ECOG 5397 trial enrolled 117 patients who were administered cisplatin with weekly cetuximab or placebo. The median PFS was 2.7 months for the chemotherapy-only arm versus 4.2 months for the cetuximab arm. Despite the lack of difference in OS ($p = 0.21$), the objective response rate favored the cetuximab arm (26% compared to 10%, $p = 0.03$). Skin toxicity manifesting as rash was correlated with improved survival ($p = 0.1$).[106]

Table 31.3 Major Randomized Phase III Trials Using Monoclonal Antibodies to EGFR in Recurrent Metastatic SCCHN

Trial	*N*	Regimens	RR	Median OS (Months)	Median PFS (Months)
E5397[106]	117	Cisplatin vs. cisplatin/cetuximab	10% vs. 26% ($p = 0.03$)	8 vs. 9.2 ($p = 0.21$)	2.7 vs. 4.2 ($p = 0.09$)
EXTREME[107]	442	Platinum based vs. platinum + cetuximab	20% vs. 36% ($p < 0.01$)	7.4 vs. 10.1 ($p = 0.04$)	3.3 vs. 5.6 ($p < 0.001$)
SPECTRUM[108]	657	Cis/5-FU vs. Cis/5-FU + panitumumab	25% vs. 36%	9 vs. 11.1 ($p = 0.14$)	4.6 vs. 5.8 ($p = 0.004$)
ZALUTE[109]	286	Zalutumumab vs. support or methotrexate	6.3% vs. 1.1%	6.7 vs. 5.2 ($p = 0.065$)	9.9 vs. 8.4 ($p = 0.001$)

The phase III EXTREME trial randomized 442 patients with recurrent or metastatic SCCHN to cisplatin or carboplatin plus 5-FU every 3 weeks with or without cetuximab. Close to 39% of patients had received prior systemic therapy prior to randomization as part of first-line therapy. A total of six

cycles of chemotherapy were allowed with cetuximab maintenance continuing until disease progression for patients randomized to the cetuximab arm. Patients on the cetuximab arm had a significantly longer OS compared with those receiving chemotherapy alone (median 10.1 vs. 7.4 months, 95% CI: 0.64 to 0.99). An improvement in PFS (5.6 vs. 3.3 months) as well as response rate (36% vs. 20%) was also noted for the cetuximab arm. EGFR expression did not correlate with skin toxicity from cetuximab.[107] Patients on the cetuximab arm appeared also to have improvements in quality of life measures including symptomatic pain, speech and swallowing, and eating compared to the noncetuximab arm.[110] Unlike HER2 expression in breast cancer, EGFR expression level does not seem to correlate with the chance of responding to cetuximab. In addition, no association between EGFR copy number measured by FISH and overall clinical outcome was noted on this trial.[111]

Other monoclonal antibodies to EGFR have been evaluated in the recurrent metastatic setting. In the SPECTRUM 657 study, patients were randomized to cisplatin plus 5-FU, with or without panitumumab, which is a fully humanized monoclonal IgG2 antibody to EGFR. A nonsignificant trend of improvement in OS was observed on the experimental arm (11.1 vs. 9.0 months, CI: 0.73 to 1.05).[108] Of importance is that patients on the control arm had the option to receive cetuximab off protocol upon disease progression given that cetuximab was approved by that time. This was not the case in the EXTREME trial where patients were not allowed to cross over. Some believe these facts may have contributed to the lack of OS benefit on the SPECTRUM and other trials of similar designs using other EGFR monoclonal antibodies.

In the ZALUTE trial, patients with recurrent and metastatic SCCHN who had failed platinum-based chemotherapy were randomized to receive the EGFR monoclonal antibody zalutumumab versus best supportive care. A total of 286 patients were enrolled. Even though there was a trend favoring OS improvement in the zalutumumab arm, the difference did not reach statistical significance (6.7 vs. 5.2 months, hazard ratio 0.77, 95% CI: 0.57 to 1.05). The disease control rate and PFS rate favored the zalutumumab arm.[109]

THE ROLE OF ANGIOGENESIS AND

VEGF INHIBITION

Angiogenesis is the process by which a cancer develops its own blood supply to promote cell growth and facilitate metastases. Vascular endothelial growth factor (VEGF) is known to increase vascular permeability and promote angiogenesis. Our understanding of the mechanism of angiogenesis has significantly increased over the past two decades resulting in the introduction of antiangiogenic agents as antitumor agents.[77] Elevated VEGF levels have been implicated as a poor prognostic indicator of increased risk of recurrent disease in addition to radioresistance.[112,113] A large number of molecules that are capable of inducing angiogenesis are reportedly released from SCCHN cells. These include, in addition to VEGF, platelet-derived growth factor (PDGF), transforming growth factor alpha and transforming growth factor beta, fibroblast growth factor, and interleukin-8.[114–117] Although most antiangiogenic compounds target VEGF, others target VEGF receptor-2 (VEGFR2) via monoclonal antibodies or small molecule inhibitors or enzymes that degrade the extracellular matrix (matrix metalloproteinases MMPs).[118] TIMP-1 is a natural inhibitor of MMP that also seems to be expressed in SCCHN and may have prognostic value in patients with SCCHN.[119,120] Tumor expression of MMPs may be an important determinant of tumor growth, spread, and clinical outcome.

The recombinant humanized monoclonal antibody against VEGF, bevacizumab, has been one of the most widely investigated antivascular agents in cancer therapy.[117] Multiple phase II and III studies have determined its activity in colon cancer, non–small cell cancer of the lung, and breast cancer.[121,122] Life-threatening pulmonary hemorrhage has been attributed to bevacizumab in patients with cancer of this histology leading to increased caution when using it in patients with this tumors of this histology, including SCCHN.[123] Risk factors that have been identified in patients with cancer of the lung include squamous cell histology and centrally located lesions lying adjacent to major blood vessels.

Conceptually, inhibiting both the extracellular and the intracellular domains of tyrosine kinase may promote further tumoricidal activity. Eventual resistance to EGFR inhibitors has been well established but occurs largely due to an unknown mechanism. Previous in vitro studies have demonstrated up-regulation of VEGF expression through activation of

EGFR.[124] A correlation between resistance to anti-EGFR inhibitors and increased levels of VEGF mRNA in cell lines has been established through in vitro studies.[125] Although VEGF levels were eventually down-regulated in vitro by as much as 50% following administration of an EGFR inhibitor, resistant cell lines continued to demonstrate two- and fourfold increased VEGF levels in comparison with the parent cell line. Hence, combined inhibition of both EGF and VEGF receptors should theoretically result in increased apoptosis, decreased cell proliferation, decreased vascular permeability, and improved cytostatic activity in comparison with the respective single-agent activities.

A phase II randomized clinical trial was recently completed comparing the activity of the combination of cetuximab with sorafenib, which is a multityrosine kinase as well as VEGF inhibitor, with cetuximab alone in patients with recurrent and metastatic disease. The results of this study are still being analyzed. ECOG 1305 is another phase III randomized clinical trial addressing the value of adding bevacizumab to chemotherapy in patients with recurrent metastatic SCCHN. The trial is expected to complete accrual in the summer of 2014.

In summary, even though preclinical data do exist to support the role of angiogenesis and its inhibitors in SCCHN, the use of antiangiogenic agents in SCCHN should also be considered within the context of a clinical trial.

CHEMOPREVENTION

The well-described multistep carcinogenesis process in upper aerodigestive tract malignancies and the predilection for developing cancers throughout the mucosa of the upper aerodigestive tract (field cancerization) in patients with known SCCHN provide the rationale for pharmacologic intervention in patients with known premalignant lesions or patients at risk for developing second primary cancers.[19,126–128] One of the goals of chemoprevention is to decrease the chance of developing other primary cancers, which requires large randomized clinical trials.

Early trials of chemoprevention have focused on vitamin A derivatives. One of the early trials utilized vitamin A (300,000 IU) and beta carotene (360 mg) once a week versus placebo for a duration of 12 months. The rate of complete remission of oral precancerous lesions was improved with either

agent over the placebo arm (52%, 33%, and 10%) for the vitamin A, beta carotene, and placebo arms, respectively.[129] Other trials focusing on primary prevention using vitamin E (alpha-tocopherol) and beta carotene as single agents or in combination have failed to show a benefit over placebo.[130,131] The same agents have been tested in a large double-blind, placebo-controlled, randomized chemoprevention trial enrolling 540 patients with stage I or II cancer of the head and neck with the aim of reducing the risk of second primary cancers. Surprisingly, compared with patients receiving placebo, patients receiving alpha-tocopherol supplements had a higher rate of second primary cancers during the supplementation period (HR = 2.88, 95% CI: 1.56 to 5.31) that declined after discontinuation of the supplement (HR = 0.41, 95% CI: 0.16 to 1.03).[132]

The utility of synthetic retinoids, isotretinoin (13-cis-retinoic acid), all-trans-retinoic acid, and etretinate was extensively studied in chemoprevention studies. In a large randomized European trial, a 2-year supplementation of retinyl palmitate and/or *N*-acetylcysteine resulted in no benefit in terms of survival, event-free survival, or second primary cancers for patients with cancer of the head and neck or with cancer of the lung, most of whom were previous or current smokers.[133,134] In a pivotal randomized placebo-controlled clinical trial, 44 patients with documented oral leukoplakia were randomized to 13-cis-retinoic versus placebo for 3 months and followed for 6 months. There were major decreases in the size of the lesions in the intervention group versus placebo (p = 0.0002), and dysplasia was significantly reversed (p = 0.01). However, over 50% of responders relapsed within 3 months of treatment cessation, and the observed toxicity precluded the development of this approach in larger trials.[135] A subsequent study with low-dose isotretinoin showed more activity against leukoplakia than with beta carotene and that it was better tolerated.[136] In a subsequent large randomized phase III trial of low-dose isotretinoin for prevention of second primary cancers in patients with stage I and II cancer of the head and neck, low-dose isotretinoin was not effective in reducing the rate of second primary cancers or death or smoking-related disease. Smoking statistically significantly increased the rate of second primary cancers and death.[137] Other approaches have focused on biochemopreventive therapy using high-dose isotretinoin, alpha-tocopherol, and interferon alpha and have produced encouraging results; however, these could not be tested in a large cooperative

group trial in light of poor accrual.[138,139] Overcoming resistance to retinoids and minimizing toxicity have been the focus of the newer generation of receptor-selective, synthetic retinoids.[140]

The high rate of EGFR expression in SCCHN has raised interest in targeting this receptor in a newer generation of SCCHN chemoprevention studies.[141–143] Given their route and relative ease of administration, the EGFR TKIs were preferred over monoclonal antibodies to target premalignant lesions.[144,145]

A large spectrum of preclinical and clinical studies has suggested that inhibition of cyclooxygenase-2 (COX-2) enzyme may provide a therapeutic and possibly preventive value for different malignancies including SCCHN.[146–153] The gradual increase in the different grades of dysplasia up to invasive SCCHN supports the use of these agents in subjects with premalignant lesions of the head and neck.[154,155] Consequently, a number of clinical trials have been launched using COX-2 inhibitors as chemopreventive agents for SCCHN.[156] Studies using COX-2I as a single agent in oral premalignant lesions revealed evidence of improvement in the degree of dysplasia.[157]

As evidence also exists of an interaction between EGFR and COX-2 pathways, targeting these two pathways simultaneously has been evaluated in preclinical and clinical studies.[154,158,159] Clinical trials using a combination of EGFR and COX-2 inhibitors in patients with premalignant lesions have revealed a correlation between biomarker modulation and reversal of dysplasia.[160,161] The toxicities observed using these combinations have precluded the possibility of dose escalation or the use of these combinations in larger phase II or III trials in this patient population of healthy subjects.[160] There is an increased interest in exploring natural compounds as chemopreventive agents in light of their low toxicity profile and the higher likelihood to have a higher benefit-to-risk ratio in combination studies.[162]

COMMON CYTOTOXIC AGENTS USED IN TREATING SCCHN

Cisplatin

Review of the literature identifies cisplatin as the only chemotherapy agent evaluated in a randomized phase III trial in comparison with best supportive care; historically, it provided an extension in OS of ~10 weeks.[163,164] Standard regimens have evaluated cisplatin 100 mg/m^2 every 21 to 28 days.[164] However, systemic treatment with cisplatin may be difficult to tolerate, with potential adverse reactions of emesis, electrolyte disturbance, nephrotoxicity, peripheral neuropathy, and ototoxicity. There is an interest in exploring weekly regimens of cisplatin in concurrence with radiation therapy. Cisplatin remains an essential chemotherapeutic agent in the treatment of locally advanced as well as recurrent or metastatic cancer.

Carboplatin

The platinum analogue carboplatin is associated with reduced nephrotoxicity and emetogenicity but is infrequently used as a palliative single agent.[165] Carboplatin has been extensively examined in combination regimens. It is rarely used as a single agent in combination with radiation therapy or in recurrent or metastatic disease and is usually combined with a taxane in the concurrent setting.[166]

Methotrexate

Methotrexate is an antifolate that was initially considered the standard for palliative treatment owing to its ease of administration and moderate associated toxicities. Methotrexate provided variable response rates ranging from 10% to 40% with a short median duration of response as a single agent.[163,167–169] Several characteristics of methotrexate qualify it as an ideal palliative agent. It is currently used mostly in refractory recurrent metastatic cancer as a form of palliation. Methotrexate is not recommended in the concurrent setting.

Ifosfamide

The efficacy of ifosfamide has been investigated in the palliative care setting. Ifosfamide is a synthetic analogue of cyclophosphamide. Diversified schedules have been attempted when ifosfamide is used, with variable

response rates.[168,170–172] Ifosfamide is rarely used in the recurrent or metastatic setting or in the induction setting.

5-Fluorouracil

5-FU is given primarily by continuous infusion for 4 to 5 days every 3 weeks.[164,173] A single-institution retrospective analysis observed a response rate of 31% with bolus infusion of 5-FU.[174] Primary toxicities that have been encountered with 5-FU on both continuous infusion and bolus schedules are palmar–plantar erythrodysesthesia (hand–foot syndrome), mucositis, myelosuppression, and diarrhea. It is a component of the standard induction regimen (TPF) and also a component of the combination of carboplatin/5-FU used in the recurrent metastatic setting in combination with cetuximab in patients who cannot tolerate cisplatin.[12,13,15]

Paclitaxel and Docetaxel

Members of the taxoid class, paclitaxel (Taxol) and docetaxel (Taxotere), have a distinct mechanism. Paclitaxel functions to promote the assembly of microtubules from tubulin dimers and to stabilize microtubules by preventing depolymerization, resulting in mitotic arrest at the G2/M phase and subsequent apoptosis (programmed cell death).[175] This cytotoxic agent was originally discovered in 1971 and is derived from the Pacific yew tree, *Taxus baccata*. Paclitaxel is formulated in Cremophor (polyoxyethylated castor oil), resulting in severe hypersensitivity reactions in 2% to 4% of patients. Additional adverse events that have been reported include urticaria, angioedema, dyspnea, hypotension, and anaphylaxis. All patients require premedication with corticosteroids, diphenhydramine, and H_2-antagonists to prevent adverse reactions.

A variety of infusion schedules have been evaluated to determine the optimal method of administering paclitaxel without compromising efficacy.[176–178] Paclitaxel continues to be evaluated in both single-agent and combination chemotherapy treatment regimens. Response rates have varied from 20% to 40% in the recurrent or metastatic disease setting. Peripheral neuropathy and myelosuppression are the primary treatment-limiting toxicities. Paclitaxel is often used in combination with platinum in the recurrent or metastatic setting as well as in concurrence with radiation

therapy for locally advanced cancers. Markers of taxane sensitivity such as acetylated tubulin or beta-tubulin have been suggested as possible predictors of response to these agents in SCCHN.[179,180]

The semisynthetic taxane, docetaxel, has a mechanism of action similar to that of paclitaxel in promoting microtubule stabilization. Unlike paclitaxel, however, docetaxel does not alter the number of protofilaments in the bound microtubules, and it prevents formation of the centrosome rather than affecting the mitotic spindle. Docetaxel is now an integral part of the approved induction regimen of TPF and is often used in the recurrent metastatic setting as well.[12,14,15]

Traditional schedules of docetaxel in the treatment of cancer of the head and neck have been administered at 100 mg/m^2 every 21 days with response rates of 20% to 40%. Docetaxel was determined to be active and safe, with an ORR in one study of 42%.[181] A similar French study provided an ORR of 20.8%.[182] These two studies differ in their patient populations, with the majority of patients in the French study (73.9%) having metastatic disease. Principal toxicities of docetaxel include leukopenia, asthenia, peripheral edema, peripheral neuropathy, and hypersensitivity reactions. Docetaxel continues to be evaluated in palliative, induction, and concurrent radiation treatment settings.[12,13,15]

Hydroxyurea

Hydroxyurea is an oral agent that inhibits ribonucleotide diphosphate reductase, which interferes with DNA synthesis, specifically disrupting the S-phase of the cell cycle.[183] In preclinical animal models, hydroxyurea may prevent cells from moving from the G1-radiosensitive phase to the radioresistant phase.[184] It has been FDA approved for use in combination with radiation therapy in SCCHN based on results from earlier studies[32] and has been more recently used in concurrence with radiation in a large randomized trial of induction with two cycles of docetaxel, cisplatin, and 5-FU followed by chemoradiotherapy with docetaxel, 5-FU, and hydroxyurea—the DECIDE trial.[16] The use of hydroxyurea in SCCHN remains however limited to few centers and has not gained widespread use.

32 Cancer of the Head and Neck: Targeted Molecular Therapy of Head and Neck Cancer

Katharine A. Price Rafael Santana-Davila Laura Q. M. Chow Cesar A. Perez Garrett Green Loren K. Mell, Ezra E. W. Cohen

INTRODUCTION

Significant progress has been made in understanding the molecular biology of squamous cell carcinoma of the head and neck (SCCHN) including large-scale comprehensive sequencing, mutational analysis, and transcriptome arrays. From these analyses, it has become clear that several actionable alterations occur in SCCHN and that distinct biologic subtypes exist that depend on different biologic processes. The two broadest subtypes of SCCHN can be divided generally by etiology into tobacco related and human papillomavirus (HPV) related. It is clear that these subtypes not only represent entities that behave differently clinically but are quite disparate in their molecular phenotype and presumably in their sensitivity to specific targeted agents. This chapter will review the development of the most commonly tested targeted agents in SCCHN with an emphasis on drugs that have at least reached clinical trials. The only approved molecularly targeted agent in SCCHN currently is cetuximab, but as the number of agents grows and our ability to use predictive biomarkers improves, it is likely that many more will become part of standards of care in the near future.

Epidermal Growth Factor Receptor

The epidermal growth factor receptor (EGFR) is a transmembrane cell

surface receptor that is a member of the ErbB family of receptor tyrosine kinases. The EGFR is activated by ligand binding that results in receptor homodimerization and stimulation of intracellular protein tyrosine kinase activity and activation of downstream signaling pathways including PI3K/AKT and RAS/MAPK/ERK. Dysregulation of the EGFR by increased expression or mutations can lead to altered growth signals and tumorigenesis.

The discovery that the EGFR is highly expressed in SCCHN marked the beginning of the era of targeted therapy for the treatment of SCCHN. The EGFR is expressed in the majority of patients with SCCHN and is associated with poor prognosis.[1–7] In a landmark paper by Grandis et al.,[2] it was demonstrated that mRNA from both the ligand TGF-α and the EGFR were significantly elevated in both tumor specimens and histologically normal mucosa specimens from patients with SCCHN compared with tissue from normal control patients. Ang and colleagues retrospectively tested tissue from 155 patients with SCCHN enrolled in a phase III trial for EGFR overexpression and correlated the results with multiple variables including T and N stage and survival endpoints. There was no association between high EGFR expression and T or N stage or the rate of distant metastases. However, both overall survival and disease-free survival rates of patients with high EGFR-expressing SCCHN were significantly lower (p = 0.0006 and p = 0.0016, respectively), and the local–regional relapse rate was significantly higher (p = 0.0031) compared with those of patients with low EGFR-expressing SCCHN.[4]

The strong preclinical evidence for the role of EGFR signaling in the genesis and progression of SCCHN led to the development of drugs targeting the EGFR that have met with mixed success in the clinical arena. Both monoclonal antibodies and small molecule tyrosine kinase inhibitors (TKIs) have been studied in clinical trials, but to date, only the EGFR monoclonal antibodies have achieved routine use in clinical practice.

EGFR Monoclonal Antibody: Cetuximab

Cetuximab (Erbitux, Bristol-Meyers Squibb, Princeton, NJ) is a chimeric monoclonal antibody that was first approved by the FDA in 2006 for use in patients with locally advanced cancer of the head and neck in combination with radiation therapy, thus making it the first approved targeted therapy for SCCHN. The standard dosing for cetuximab is an initial loading dose of 400

mg/m^2 followed by weekly doses of 250 mg/m^2. The long half-life of cetuximab does allow for every other week dosing with similar efficacy.[8] The classic side effect of cetuximab is an acneiform rash, present in 76% to 88% of patients, with 1% to 17% having a severe rash.[9] Other skin toxicities are commonly seen including skin dryness and fissuring, paronychia, and secondary bacterial skin infections. Infusion reactions are also common with cetuximab and can be serious (even fatal) in ~3% of patients overall. However, the rate of infusion reactions can vary by geographic region, with consistently higher rates (up to 25%) reported in the southeastern United States.[10–13] Cardiopulmonary arrest and sudden death have been reported in 2% of patients receiving cetuximab concurrent with radiation therapy and 3% of patients receiving cetuximab in combination with cytotoxic chemotherapy. Close monitoring of serum electrolytes, including magnesium, is strongly recommended.[9]

Cetuximab has been approved for use in SCCHN as part of definitive treatment in combination with radiation therapy, for R/M-SCCHN in combination with platinum-based cytotoxic chemotherapy, and as a single-agent for R/M-SCCHN after progression on platinum-based therapy. The subsequent pages will describe the key clinical trials that led to these approved indications.

Cetuximab with Radiation therapy for Locally Advanced SCCHN

In 2006, Bonner et al.[14] published a landmark trial in the New England Journal of Medicine that showed the benefit of cetuximab when added to definitive radiation therapy for the treatment of locally advanced SCCHN (LA-SCCHN). In this phase III, multinational, randomized study, 213 patients with LA-SCCHN were treated with radiation therapy and 211 patients were treated with radiation therapy plus weekly cetuximab (initial dose 400 mg/m^2 followed by 250 mg/m^2 weekly for the duration of radiation therapy). Baseline patient characteristics were well balanced. The majority of patients in both arms had cancer of the oropharynx followed by cancer of the larynx and hypopharynx; patients with cancer of the oral cavity were not included. Approximately 30% of the primary cancers in each arm were T4. Treatment toxicities were similar in both arms with the exception of

increased grade 3 or 4 rash and infusion reactions in the patients receiving cetuximab. With a median follow-up of 54 months, the addition of cetuximab to definitive radiation therapy significantly improved survival outcomes. In patients treated with cetuximab and radiation therapy, the median duration of locoregional control was 24.4 months compared with 14.9 months in patients treated with radiation therapy alone (HR for locoregional progression or death, 0.68, p = 0.005). The median 3-year overall survival for patients treated with cetuximab plus radiation therapy was 49.0 months compared with 29.3 months in patients treated with radiation therapy alone (HR for death, 0.74, p = 0.03). The addition of cetuximab to radiation therapy significantly prolonged 3-year progression-free survival from 12.4 to 17.1 months (HR 0.70, p = 0.006). Long-term follow-up results of this landmark trial reported persistent survival benefit at 5 years in patients who received cetuximab and suggested a benefit in those patients who developed a rash greater than or equal to grade 2.[15] The Bonner trial established concurrent cetuximab and radiation therapy as a curative treatment option for LA-SCCHN, although the standard of care for most patients remains concurrent radiation therapy and cisplatin. The fact that the control arm in the Bonner trial was radiation therapy alone, which is no longer considered standard of care for patients with LA-SCCHN with a good performance status, makes it difficult to interpret the results in light of other, more established treatment options. The TREMPLIN study for larynx preservation randomized 116 patients who responded to induction chemotherapy to either chemoradiation with high-dose cisplatin or radiation therapy with cetuximab, but could not prove one regimen to be superior to the other.[16] To date, there are no completed phase III trials that definitively show that cetuximab with radiation therapy is superior to chemoradiation therapy for LA-SCCHN.

Based on the premises that cetuximab added to chemotherapy enhances the response rate and improves survival in patients with R/M-SCCHN and that cetuximab is a radiation sensitizer, the randomized, phase III trial by the Radiation Therapy Oncology Group (RTOG) 0522 was conducted to assess the incremental benefit of adding cetuximab in the curative treatment setting to a backbone of accelerated radiation therapy (72 Gy in 42 fractions over 6 weeks) and two cycles of high-dose cisplatin (100 mg/m^2).[17] From November 2005 through May 2009, 941 patients with stage III or IV SCCHN were enrolled and 891 analyzed. Most of the patients were men (88%) with cancer

of the oropharynx (70%; 73% p16 positive). Although the results were much anticipated, the addition of cetuximab failed to improve any outcome measures but did increase overall treatment toxicity. Patients with p16-positive cancer of the oropharynx had improved overall survival compared with p16-negative patients (85.6% vs. 60.1%, $p < 0.001$), as expected. EGFR expression did not determine survival outcomes. The combination of concurrent radiation therapy, cisplatin, and cetuximab as curative-intent therapy should not be routinely used unless specific subsets of patients who may benefit can be identified.[17]

Cetuximab for Recurrent/Metastatic SCCHN

Multiple studies have investigated the use of cetuximab for recurrent/metastatic squamous cell carcinoma of the head and neck (R/M-SCCHN) both as a single agent and in conjunction with cytotoxic chemotherapy. In 2005, two phase II trials that examined the role of cetuximab in patients with platinum-refractory R/M-SCCHN were published in the *Journal of Clinical Oncology*.[18,19] One trial by Herbst and colleagues treated 132 patients with squamous cell carcinoma of the oral cavity, pharynx, and larynx with a platinum doublet (cisplatin/paclitaxel or cisplatin/5-fluorouracil) to assess for responsiveness to platinum therapy. The 30 patients who responded to the initial chemotherapy were continued on the same regimen. The remaining patients with either stable disease ($n = 51$) or disease progression ($n = 25$) were subsequently treated with cisplatin (75 to 100 mg/m^2 once every 3 weeks) plus cetuximab at standard doses. A protocol amendment was performed after trial initiation to allow treatment of patients with progressive disease within 90 days of initial response to the platinum regimen with cisplatin and cetuximab ($n = 54$). Cetuximab did have activity in patients with proven platinum-refractory disease. In the group of patients with immediate progression or stable disease on platinum therapy, 20% and 18%, respectively, of patients subsequently responded to platinum and cetuximab. In contrast, only 6% of the patients who initially responded to platinum therapy but progressed within 90 days achieved a response upon treatment with cisplatin and cetuximab. Median durations of response for patients with immediate progression on platinum therapy, with progression within 90 days of platinum therapy, and with stable disease were 4.2, 4.1, and 7.4 months, respectively, with corresponding median overall survivals of 6.1,

4.3, and 11.7 months in patients who received cisplatin with cetuximab.[18] Although the response rate to cisplatin/cetuximab in patients with initial progressive disease and those with stable disease were similar, the median response rate and overall survival were much better in the patients with stable disease, likely speaking to a more favorable underlying biology in this group of patients. Nonetheless, this trial was proof of principle that platinum resistance could be overcome with the addition of cetuximab in a subset of patients with R/M-SCCHN, albeit short-lived. The second trial by Baselga et al.[19] enrolled patients with R/M-SCCHN with documented disease progression on a regimen of cisplatin or carboplatin. Ninety-six patients who met eligibility criteria were treated with platinum therapy at the same doses on which they progressed along with cetuximab at standard doses. The response rate was 10%, and the disease control rate (all responses plus stable disease) was 53%. Median time to progression was 85 days, and median overall survival was 183 days.

The single-agent response to cetuximab in patients with R/M-SCCHN after failure of platinum-based chemotherapy was shown to be 13% in an open-label, multicenter phase II trial by Vermorken et al.[20] The study design allowed patients who progressed on cetuximab alone to subsequently receive salvage therapy with platinum and cetuximab. In the initial phase, 103 patients with platinum-refractory disease were treated with cetuximab at standard doses with a response rate of 13%, disease control rate of 46%, and median time to progression 70 days. Of the 53 patients who progressed on cetuximab and went on to receive salvage therapy, there were no responders. This trial highlights the very modest benefit of single-agent cetuximab and underscores the need for a reliable biomarker for patients who will respond to cetuximab, so as to avoid unnecessary toxicity and treatment cost in those patients unlikely to derive a benefit from this therapeutic approach. Given the similar response rates of the trials by Baselga and Vermorken in platinum-refractory disease (10% and 13%, respectively), there does not appear to be any benefit of retreating patients with platinum-refractory R/M-SCCHN with a platinum agent, as a similar response could likely be achieved with cetuximab alone with less toxicity.

In 2006, Burtness and colleagues reported in the Journal of Clinical Oncology that the addition of cetuximab to cisplatin in patients with R/M-SCCHN improved overall response rate but not progression-free or overall

survival. In this phase III, randomized, placebo-controlled trial, 117 patients with R/M-SCCHN were randomized to receive cisplatin 100 mg/m^2 IV once every 4 weeks with cetuximab (Arm A) or placebo (Arm B). The study was negative for its primary endpoint of progression-free survival (4.2 months with cetuximab, 2.7 months with placebo; p = 0.09). Median overall survival was 9.2 months with cetuximab and 8.0 months with placebo (p = 0.21). The objective response rate was significantly improved with the addition of cetuximab from 10% with placebo to 26% (p = 0.03).[21]

The EXTREME trial by Vermorken et al.[22] in 2008 that added cetuximab to a regimen of platinum and 5-fluorouracil was the first trial to demonstrate an improvement in overall survival in patients with recurrent/metastatic cancer since the introduction of cisplatin in the 1980s.[23] The study was a first-line therapy trial for patients with R/M-SCCHN and randomized 220 of 442 eligible patients to platinum (cisplatin 100 mg/m^2 IV or carboplatin [AUC 5] on day 1) and 5-fluorouracil (1,000 mg/m^2/day days 1 to 4) with or without cetuximab at standard doses for a maximum of six cycles. In patients with a response of stable disease or better, cetuximab was continued until disease progression or unacceptable toxicities. The addition of cetuximab to cytotoxic chemotherapy improved the median overall survival from 7.4 to 10.1 months (HR 0.80, p = 0.04). Both progression-free survival and response rate were also significantly improved in the cetuximab arm. Sepsis was significantly more common in the patients who received cetuximab (p = 0.02), but no cetuximab-associated deaths were reported. A separate quality of life (QOL) analysis reported that the addition of cetuximab to chemotherapy did not adversely affect patient QOL.[24] Although the EXTREME trial to date represents the regimen with the longest median overall survival in patients with recurrent/metastatic cancer, it is not known whether first-line platinum-based chemotherapy followed by second-line cetuximab could achieve the same survival benefit. Given the overall survival benefit and lack of measurable effect on QOL, it is a very appropriate regimen to consider for patients with R/M-SCCHN who have a good performance status for whom aggressive therapy is appropriate.

Although most of the studies of cetuximab in combination with chemotherapy in patients with R/M-SCCHN have included platinum-containing regimens, one promising phase II trial studied the combination of weekly cetuximab at standard doses with paclitaxel (80 mg/m^2 weekly) as

first-line treatment for patients with R/M-SCCHN.[25] Treatment was well tolerated, and the overall response rate was 54% (95% confidence interval [CI] 39% to 69%), with 10 (22%) complete responses and a disease control rate of 80%. Median progression-free and overall survival times were 4.2 (95% CI 2.9 to 5.5 months) and 8.1 months (95% CI 6.6 to 9.6 months), respectively.[25] This regimen represents a good therapeutic option, particularly for patients who develop recurrent/metastatic disease shortly after completing definitive chemoradiation therapy with a platinum agent, or for those patients whose performance status precludes the use of platinum chemotherapy.

Lack of Predictive Biomarkers for Benefit of EGFR Monoclonal Antibodies

Despite the fact that the majority of SCCHN overexpress EGFR, only a fraction of patients will have a major response to treatment with EGFR inhibitors.[20] To date, there is no reliable biomarker that can predict response or primary resistance to EGFR inhibition in SCCHN. Multiple secondary analyses of the EXTREME trial have been conducted to try to identify a predictive biomarker for response to cetuximab, including analyses of EGFR copy number, tumor EGFR expression, and p16/HPV status. Licitra et al.[26,27] performed sequential analyses of the tissue of patients treated on the EXTREME trial to explore whether EGFR copy number or EGFR expression were candidate predictive biomarkers for efficacy of cetuximab in the first-line recurrent/metastatic setting in combination with platinum-based chemotherapy. In 2011, the investigators used dual-color fluorescent in situ hybridization (FISH) techniques to determine the absolute and relative EGFR copy number in 312 of 442 (71%) patient samples. Only 11% of tumors were found to have a high level of amplification of the EGFR gene; most tumor samples were modestly amplified. There was no association of EGFR copy number with overall survival, progression-free survival, or best overall response. The authors concluded that EGFR copy number was not a candidate predictive biomarker for response to cetuximab in combination with first-line platinum/5-fluorouracil chemotherapy in patients with R/M-SCCHN.[26] In 2013, the same investigators published a similar analysis exploring whether tumor EGFR expression level was predictive of cetuximab benefit. Tissue was available from 93% of patients treated on the EXTREME

study, and tumor EGFR expression level was scored (scale 1 to 300). The benefit of adding cetuximab to chemotherapy was seen across all score ranges, indicating that tumor EGFR expression was not a valid predictive biomarker.[27]

In 2014, a retrospective analysis of the EXTREME trial was conducted to see if there was a differential response to cetuximab and first-line platinum chemotherapy by p16 and HPV status.[28] Paired tissue samples were used to assess p16INK4A expression and HPV status in extracted DNA samples using oligonucleotide hybridization assays. A total of 416 (of 442) patients had available tissue. Only 10% of tissue was positive for p16 and 5% for HPV; these patients had improved survival compared with patients who were p16 or HPV negative. HPV or p16 status did not appear to influence response to therapy; cetuximab combined with chemotherapy improved outcomes in both groups.[28] In contrast, p16 subset analysis of the SPECTRUM trial (chemotherapy with or without panitumumab in patients with R/M-SCCHN, see section “Other EGFR Monoclonal Antibodies”) suggested a possible increased benefit of EGFR inhibition in patients with p16-negative tumors. In 443 (67%) patients, p16 status was assessed and 99 samples (22%) were p16 positive. Median overall survival in patients with p16-negative tumors was longer in the panitumumab group than in the control group (11.7 months [95% CI 9.7 to 13.7] vs. 8.6 months [6.9 to 11.1]; HR 0.73 [95% CI 0.58 to 0.93]; p = 0.0115), but this difference was not shown for p16-positive patients (11.0 months [7.3 to 12.9] vs. 12.6 months [7.7 to 17.4]; 1.00 [0.62 to 1.61]; p = 0.998).[29] Further studies are needed to validate or refute these findings.

Cetuximab as a Component of Induction or Adjuvant Therapy

Induction chemotherapy followed by definitive chemoradiation is an acceptable treatment paradigm for LA-SCCHN. The accepted standard induction therapy regimen is cisplatin (75 to 100 mg/m^2 day 1), docetaxel (75 mg/m^2 day 1), and 5-fluorouracil (1,000 mg/m^2 days 1 to 4) once every 21 days for three cycles followed by definitive chemoradiation.[30,31] Cetuximab as part of induction chemotherapy was initially studied in a phase I trial and found to be safe and tolerable.[32] Two phase II studies added cetuximab to

carboplatin and paclitaxel in both the induction and definitive chemoradiation component of treatment. The regimen was felt to be safe and effective.[33,34] However, the Brown study compared their results to prior studies that had been conducted at their institution using the same regimens without cetuximab, and the survival results appeared the same.[35,36] The future of induction therapy with or without cetuximab remains to be determined.[37]

The role of cetuximab as part of adjuvant therapy for resected SCCHN is still under investigation. The randomized phase II trial conducted by the RTOG 0234 randomized patients with resected stage III or IV SCCHN with one or more risk factors including extracapsular extension, positive surgical margins, or two or more involved lymph nodes to radiation therapy with either weekly cetuximab and cisplatin (30 mg/m^2) or weekly cetuximab and docetaxel (15 mg/m^2). Cetuximab was safely incorporated into both treatment regimens. The cetuximab/docetaxel arm was better tolerated and had improved disease-free and overall survival compared with cetuximab/cisplatin and historical controls. The regimen of cetuximab/docetaxel is currently undergoing further study as part of an adjuvant phase II/III RTOG trial for resected stage III or IV SCCHN with high-risk features (RTOG 1216). Cetuximab alone in combination with radiation therapy is currently being investigated in patients with intermediate risk, resected SCCHN (RTOG 0920); future results may provide an additional indication for the use of cetuximab.

Other EGFR Monoclonal Antibodies

Several other monoclonal antibodies directed against the EGFR have been developed and tested in patients with SCCHN, although none to the same extent as cetuximab, and the advantage of these EGFR monoclonal antibodies over cetuximab remains to be defined. Panitumumab (Vectibix, Amgen Inc., Thousand Oaks, CA) is a human IgG2 monoclonal antibody targeting EGFR domain III that was shown to be safe in combination with intensity-modulated radiation therapy (IMRT) and chemotherapy in a phase I trial of stage III and IV SCCHN,[38] but met with limited success in patients with R/M-SCCHN. The SPECTRUM trial was an open-label, phase III, multicenter, international trial that randomized 657 patients with R/M-SCCHN to up to six 3-week cycles of cisplatin (100 mg/m^2 on day 1) and 5-

fluorouracil (1,000 mg/m^2 on days 1 to 4) with or without panitumumab (9 mg/kg on day 1). Patients in the panitumumab arm were given the option of continuing panitumumab as maintenance therapy. The study failed to meet its primary endpoint of overall survival, but the addition of panitumumab did improve progression-free survival to 5.8 months (95% CI 5.6 to 6.6) in the panitumumab group from 4.6 months (4.1 to 5.4) in the control group (HR 0.780, 95% CI 0.659 to 0.922; p = 0.0036). Grade 3 or 4 toxicities were higher in the panitumumab arm, notably skin and eye toxicity, diarrhea, hypomagnesaemia, hypokalemia, and dehydration. Fourteen patients (4%) on the panitumumab arm died during treatment, five of which (2%) were attributed to the drug; eight patients (2%) died in the control arm. Planned subset analysis suggested a possible preferential benefit of panitumumab for patients with p16-negative SCCHN (see section on “Lack of Predictive Biomarkers for Benefit of EGFR Monoclonal Antibodies”). The role that panitumumab may play in the clinical management of patients with R/M-SCCHN remains to be further defined.

Zalutumumab (formerly HuMax-EGFr; Genmab, Princeton, NJ), a human IgG1 monoclonal antibody targeting the EGFR domain III, has shown single-agent activity in patients with R/M-SCCHN[39,40] and prolonged progression-free survival compared with best supportive care.[39] The largest trial of zalutumumab was published in 2011 by Machiels and colleagues and randomized 191 patients with R/M-SCCHN and progressive disease on platinum therapy in a 2:1 fashion to zalutumumab or best supportive care with the option to receive methotrexate (maximum dose 50 mg/m^2 weekly). In order to exploit the observation that the characteristic rash associated with EGFR inhibitors can be an indication of treatment response, the dose of zalutumumab was individually titrated (after standard loading doses of 8 mg/kg followed by two weekly doses of 4 mg/kg) to a maximum dose of 16 mg/kg every 2 weeks to try and achieve a grade 2 rash. Based on survival analysis of 82 patients with a grade 2 to 3 rash and 78 patients with a grade 0 to 1 rash, maximum rash grade was not predictive of overall survival (8.0 months for grade 2 to 3, 95% CI 6.7 to 9.8, vs. 6.8 months for grade 0 to 1, 95% CI 6.1 to 1.7; HR for death 0.72, 95% CI 0.51 to 1.02; p = 0.068). Single-agent activity of zalutumumab was 6.3% compared with 1.1% in the best supportive care/methotrexate arm. As with panitumumab, progression-free survival but not overall survival was improved by zalutumumab. Median

overall survival was 6.7 months (95% CI 5.8 to 7.0) in the zalutumumab group and 5.2 months (4.1 to 6.4) in the control group (hazard ratio [HR] for death, stratified by WHO performance status, was 0.77, 97.06% CI 0.57 to 1.05; $p = 0.0648$). Progression-free survival was longer in the zalutumumab group (9.9 weeks) than in the control group (8.4 weeks; HR for progression or death, stratified by WHO performance status, was 0.63, 95% CI 0.47 to 0.84; $p = 0.0012$). A second, smaller, open-label, phase II study investigated the efficacy and safety of zalutumumab in patients with platinum-refractory R/M-SCCHN.[40] Ninety patients were enrolled; notably 23% of patients had an Eastern Cooperative Oncology Group (ECOG) performance status of 2. Objective response rate for zalutumumab was 5.7%, and disease control rate (objective responses + stable disease) was 39.8%. Median overall survival was 5.3 months (95% CI [4.1, 7.1]), and median progression-free survival was 2.1 months (95% CI [2.0, 2.6]). Performance status, as would be expected, impacted survival outcomes: patients with an ECOG performance status of 0 to 1 survived a median of 6.3 months compared with 2.5 months for those patients with a performance status of 2.[40] Side effects of zalutumumab in both studies were consistent with those reported for other EGFR monoclonal antibodies.[39,40] Zalutumumab appears to have single-agent activity comparable to cetuximab. Although it statistically prolonged progression-free survival compared with best supportive care/methotrexate, the magnitude of the benefit is small and the clinical relevance of this benefit is questionable. Perhaps the clinical utility for zalutumumab will lie in the treatment of patients with a poor performance status who are not candidates for more aggressive treatment regimens.

Nimotuzumab (formerly h-R3; Oncoscience AG, Germany, and YM Biosciences Inc., ON, Canada) is a humanized anti-EGFR IgG1 monoclonal antibody that is approved for treating SCCHN in multiple countries in Asia, Africa, and South America.[41] Most of the trials of nimotuzumab have used it along with radiation therapy or chemoradiation therapy for LA-SCCHN.[42–44] A phase I trial using nimotuzumab in combination with radiation therapy in patients with SCCHN unsuitable for standard chemoradiation therapy confirmed activity of nimotuzumab by demonstrating decreased phosphorylation of the EGFR and was tolerated in this patient population.[42] An open-label, phase II study in India demonstrated improvement in long-term survival in patients who received nimotuzumab in combination with

radiation therapy or chemoradiation therapy. The trial randomized 92 treatment-naive patients (1:1) with advanced SCCHN into chemoradiation (CRT +/− nimotuzumab) or radiation (RT +/− nimotuzumab) group by investigator's discretion. Overall response was 100% with CRT + nimotuzumab, 70% with CRT, 76% with RT + nimotuzumab, and 37% with RT alone. Five-year overall survival was 57% with CRT + nimotuzumab, 26% with CRT ($p = 0.03$), 39% with RT + nimotuzumab, and 26% with RT alone ($p > 0.05$). Studies from Cuba also suggested a survival benefit for nimotuzumab when given along with radiation or chemoradiation therapy[44,45] with associated improvement in disease-related symptoms and QOL.[44] Notably, nimotuzumab does not cause significant skin toxicity, making it an attractive option compared with other EGFR monoclonal antibodies.

EGFR Tyrosine Kinase Inhibitors

Specific EGFR Tyrosine Kinase Inhibitors: Gefitinib and Erlotinib

Gefitinib (Iressa; AstraZeneca, Wilmington, DE) and Erlotinib (Tarceva; Genentech, Inc., South San Francisco, CA) are highly specific, reversible EGFR TKIs that have been studied in patients with SCCHN as part of definitive treatment and in patients with R/M-SCCHN, but neither drug has become part of standard practice.

Gefitinib (Iressa; AstraZeneca, Wilmington, DE) is a highly selective oral EGFR TKI with a single-agent response rate of 7% to 11% in phase II trials of R/M-SCCHN[46]–[49]; escalating the dose of gefitinib to achieve a rash greater than or equal to grade 2 did not alter the response rate.[49] A single phase II trial of gefitinib for the treatment of platinum-refractory nasopharynx cancer showed no activity.[50] A single phase I trial showed promising results with the combination of gefitinib and celecoxib, but this combination was not pursued in subsequent clinical trials. Two phase III trials have investigated the activity of gefitinib in patients with R/M-SCCHN.[51,52] The first trial published in 2009 randomized 486 patients to gefitinib (250 mg/day), gefitinib (500 mg/day), or methotrexate (40 mg/m^2 IV weekly). There were no significant differences in response rate or overall survival across all arms, and the gefitinib arms had increased rates of tumor bleeding events compared

with methotrexate (8.9%, gefitinib 250 mg/day; 11.4%, gefitinib 500 mg/day; 1.9%, methotrexate).[51] Given promising preclinical and phase I data of the combination of docetaxel and EGFR TKIs,[53,54] a phase III trial through the ECOG was conducted investigating the efficacy of docetaxel and gefitinib in patients with previously treated R/M-SCCHN. A total of 270 patients were randomized to receive weekly docetaxel plus either placebo (arm A) or gefitinib 250 mg/day (arm B) until disease progression. Patients in the placebo arm were allowed to receive gefitinib at the time of disease progression. The study was closed early due to lack of benefit. Median overall survival was 6.0 months in arm A versus 7.3 months in arm B (HR, 0.93; 95% CI, 0.72 to 1.21; $p = 0.60$).[52]

Multiple phase I and II trials demonstrated the feasibility of adding gefitinib to definitive radiation therapy[55] or chemoradiation therapy[56–59] for patients with stage III and IV SCCHN without clear benefit and with potential increased toxicity.[57,60] Three phase II trials utilized gefitinib concurrent with definitive chemoradiation therapy for LA-SCCHN followed by maintenance gefitinib with mixed responses.[61–63] No benefit was seen when gefitinib was used in combination with hyperfractionated radiation, cisplatin, or 5-fluorouracil, followed by gefitinib maintenance,[61] or when gefitinib was combined with standard cisplatin and radiation followed by maintenance gefitinib.[62] A possible benefit, compared with historical controls, was seen when gefitinib was added to a regimen of split-course concurrent chemoradiation therapy with fluorouracil, hydroxyurea, and twice daily radiation therapy followed by maintenance gefitinib for 2 years.[63] Given the overall lack of benefit of gefitinib in patients with LA-SCCHN receiving radiation therapy or chemoradiation therapy and in patients R/M-SCCHN, treatment with this agent is not considered an acceptable standard practice.

Erlotinib has been studied in R/M-SCCHN as a single agent, in combination with cytotoxic chemotherapy, and in combination with other targeted agents. Although an early study of erlotinib as neoadjuvant therapy in an untreated patient population showed encouraging results with a single-agent response rate of 29%,[64] the activity of erlotinib in patients with R/M-SCCHN is modest and consistent with that seen with gefitinib. The best evidence for single-agent activity of erlotinib comes from a multicenter phase II study published in 2004 in the *Journal of Clinical Oncology* of 115 patients

with R/M-SCCHN treated with erlotinib that showed an overall response rate of 4.3% (95% CI, 1.4% to 9.9%) and disease stabilization in 38.3% of patients for a median duration of 16.1 weeks.[65] Erlotinib in combination with chemotherapy for patients with R/M-SCCHN did not appear to have any additional benefit over other regimens. The combination of erlotinib and docetaxel was not tolerated,[66] and a phase I/II trial reported a 21% response rate for the combination of erlotinib and cisplatin, consistent with established regimens in this patient population.[67] Erlotinib maintenance therapy after treatment with platinum and gemcitabine for recurrent nasopharynx cancer was not effective.[68] The combination of erlotinib and temsirolimus was poorly tolerated and led to early closure of the study. Erlotinib and bevacizumab were investigated in a phase I/II trial and showed a 14% response rate in the phase II portion, including four patients with a complete response. Median time of overall survival and progression-free survival were 7.1 months (95% CI 5.7 to 9.0) and 4.1 months (2.8 to 4.4), respectively.[69] Unfortunately, there were three patients with significant bleeding events, which likely limit the routine use of this combination.

Multiple phase I and II trials demonstrated the feasibility of erlotinib in combination with chemoradiation therapy for LA-SCCHN as definitive treatment[70]–[72] and in the adjuvant setting.[73] The largest study by Martens and colleagues randomized 204 patients with LA-SCCHN to standard radiation therapy with concurrent high-dose cisplatin with or without erlotinib 150 mg daily. Although erlotinib did not significantly increase the treatment toxicity, it failed to improve efficacy endpoints of complete response rate or progression-free survival.[70] Two studies used both erlotinib and bevacizumab in combination with chemoradiation therapy,[74,75] with one study reporting an increased risk of osteoradionecrosis.[74] Two phase I studies also showed the feasibility of using erlotinib in combination with reirradiation for recurrent SCCHN, one in combination with celecoxib.[76,77] Two phase III trials using erlotinib were attempted but closed early due to poor accrual—one in combination with first-line chemotherapy for R/M-SCCHN and a second as maintenance monotherapy for resected disease (NCT00448240 and NCT00412217). As with gefitinib, the overall modest activity of erlotinib did not lead to approval of its use in treating patients with cancer of the head and neck.

Dual and Pan-ErbB Tyrosine Kinase Inhibitors

Single-agent TKIs that target multiple ErbB family receptors are known as dual or pan-ErbB TKIs. Several of these agents—lapatinib, afatinib, and dacomitinib—are being studied in patients with SCCHN in both the locally advanced and metastatic settings. Lapatinib (Tykerb; GlaxoSmithKline, Research Triangle Park, NC) is a reversible TKI that targets both EGFR and HER2. A phase II study that gave 107 treatment-naive patients with SCCHN lapatinib or placebo prior to chemoradiation therapy reported a response rate of 17% with a decrease in tumor proliferation rate as measured by Ki-67 immunostaining.[78] When lapatinib was tested as monotherapy in patients with R/M-SCCHN, however, no significant antitumor activity was noted in either patients without prior EGFR exposure (arm A) or with prior EGFR exposure (arm B).[79] In an intent-to-treat analysis, no complete or partial responses were observed, and stable disease was the best response observed in 41% of arm A (median duration, 50 days, range, 34 to 159) and 17% of arm B subjects (median, 163 days, range, 135 to 195). Median progression-free survival was 52 days in both arms. Median overall survival was 288 (95% CI, 62 to 374) and 155 (95% CI, 75 to 242) days for arms A and B, respectively. Collectively, these studies suggest that any benefit for lapatinib in SCCHN may be as part of initial therapy. A phase I study established the dose of lapatinib with chemoradiation therapy for patients with SCCHN to be 1,500 mg/day.[80] A recently published placebo-controlled phase II trial of lapatinib given concurrent with chemoradiation and then as maintenance therapy showed a numerical improvement in the 6-month complete response rate—the primary endpoint of the study—from 36% with placebo to 53% with lapatinib ($p = 0.093$).[81] The secondary endpoints of progression-free and overall survival at 18 months were also improved from 41% to 55% (PFS) and 57% to 68% (OS) for placebo and lapatinib, respectively. Interestingly, p16-negative patients appeared to have a marked improvement in progression-free survival with lapatinib versus placebo (>20.4 months vs. 10.9 months).[81] The results of several phase II and III studies incorporating lapatinib into initial therapy for LA-SCCHN are pending, and will hopefully help to define the role of this agent in the future treatment strategies for patients with LA-SCCHN.

Afatinib (Giotrif; Boehringer Ingelheim, Ingelheim, Germany) and dacomitinib (PF-00299804; Pfizer Inc, New York, NY) are irreversible TKIs

that target EGFR, HER2, and HER4[82,83] and likely HER3 given the requirement for HER3 to heterodimerize with other ErbB family receptors. A randomized, crossover, phase II study compared single-agent afatinib to cetuximab. Patients treated with afatinib had increased adverse events leading to treatment discontinuations and dose reductions, but the agents were equivalent across all efficacy endpoints. In the 68 patients who crossed over to the other therapy upon disease progression, disease control rate was 33.3% for afatinib and 18.8% for cetuximab, suggesting a lack of cross-resistance in some patients with sequential treatment with different EGFR inhibitors.[84] Presently, a randomized, phase III trial (LUX Head & Neck 1) is investigating the efficacy of single-agent afatinib versus methotrexate in patients with platinum-resistant R/M-SCCHN.[85] Other phase II and III trials are under way to determine the potential benefit of afatinib as part of neoadjuvant, adjuvant, and maintenance therapy.

Dacomitinib has been studied in one open-label, multicenter, single-arm phase II trial in patients with R/M-SCCHN.[86] Sixty-nine patients were enrolled and received dacomitinib 45 mg orally daily. Partial response rate to dacomitinib was 12.7%, and 57.1% of patients had stable disease (14.3% lasting ≥24 weeks). The median progression-free survival was 12.1 weeks and the median overall survival was 34.6 weeks. The most common grade 3 or higher treatment-related adverse events were diarrhea (15.9%), acneiform dermatitis (8.7%), and fatigue (8.7%). Approximately 40% of patients required either a dose reduction or a treatment interruption secondary to drug toxicity.[86] Preclinical data support the use of dacomitinib along with radiation therapy for the treatment of SCCHN[87] and in cetuximab-resistant SCCHN,[88] but no clinical trial data are yet available.

Mechanisms of Resistance to EGFR Inhibition

Collectively, all of the evidence for EGFR inhibition, despite the overexpression of EGFR in most SCCHN, shows a relatively modest benefit in terms of treatment response and survival. The presence of primary or acquired resistance to EGFR-targeted therapy is likely a factor in mitigating the success of these agents. Recent preclinical and clinical investigations have demonstrated several possible mechanisms leading to resistance to EGFR inhibition including activation of other ErbB family receptors (e.g., HER2 and HER3) and activation of other signaling pathways such as

vascular endothelial growth factor (VEGF), the hepatocyte growth factor (HGF)/ c-MET pathway, and the Notch pathway.[89–96] Preclinical data of the role of the insulin-like growth factor receptor (IGFR) pathway have been mixed.[97–99] Activation of downstream signaling pathways has also been implicated in resistance to EGFR inhibition including the PI3K/AKT pathway, RAS/MAPK/ERK pathway, mammalian target of rapamycin (mTOR) pathway, and the signal transducer and activator or transcription 3 (STAT3) pathway.[100–102] Other mechanisms of resistance have been described as well including the potential benefit of the combination of EGFR and cyclooxygenase-2 (COX-2) inhibition, epigenetic events such as hypermethylation of death-associated protein kinase (DAPK), and nuclear EGFR expression.[103–105]

Several novel agents are now being studied in phase II and III trials to try and overcome EGFR resistance in the clinical setting. There are many new drugs that have been designed to target more than one receptor in an effort to increase clinical efficacy. Several of these agents including lapatinib, afatinib, and dacomitinib have already been discussed (see section “Dual and Pan-ErbB Tyrosine Kinase Inhibitors”). Vandetanib (Caprelsa; AstraZeneca Pharmaceuticals LP, Wilmington, DE) is an oral TKI that targets both EGFR and VEGF receptor 2. Vandetanib in combination with docetaxel in platinum-refractory patients with SCCHN was not found to be effective,[106] but it is currently being studied in combination with chemoradiation therapy for patients with LA-SCCHN (NCT00720083). The monoclonal antibody MEHD7945A (Genentech, Inc., South San Francisco, CA) targets both EGFR and HER3 and showed promising results in a phase I trial where 20% of patients with R/M-SCCHN achieved a partial response (abstract only). It is currently being compared to cetuximab in a randomized phase II trial in patients with R/M-SCCHN (NCT01577173).

Novel therapeutic combinations using an EGFR inhibitor in combination with other targeted therapies have been investigated or are under active investigation. Dual inhibition of the EGFR and vascular endothelial growth factor receptor (VEGFR) has shown responses in patients with R/M-SCCHN.[69,94] The combination has also been used along with CRT for patients with LA-SCCHN,[74] albeit with potential increased toxicity.[74,75] Multiple ongoing phase II trials are investigating the use of EGFR and VEGF inhibition in patients with R/M- and LA-SCCHN (NCT00392665,

NCT00968435, NCT00703976). Dual inhibition of the EGFR and mTOR pathways is ongoing in patients with R/M-SCCHN (NCT01256385, NCT0128334, NCT00942734), despite initial phase I/II data showing poor patient tolerability and a short progression-free survival.[107] The TKI dasatinib (Sprycel; Bristol-Myers Squibb, Princeton, NJ), despite having multiple targets including BCR-ABL, stem cell factor receptor (c-KIT), platelet-derived growth factor receptor (PDGFR), and Src family kinases, showed no responses when used as monotherapy for patients with R/M-SCCHN[108] but is being investigated concurrent with and after failure of cetuximab-based radiation therapy (NCT00882583, NCT01488318). Sorafenib (Nexavar; Bayer, Leverkusen, Germany) and sunitinib (Sutent; Pfizer Inc., New York, NY) both target multiple protein kinases but have shown poor activity and significant side effects when studied in patients with R/M-SCCHN[109–111]; tivantinib (formerly ARQ 197) is a c-MET inhibitor currently under active investigation in combination with EGFR inhibitors (see “c-MET” section below for more details). Phase I data for the use of the COX-2 inhibitor celecoxib (Celebrex; Pfizer, Inc., New York, NY) along with an EGFR inhibitor demonstrated a 22% response rate in patients with R/M-SCCHN and showed promising activity along with reirradiation for recurrent SCCHN,[77,112] but there are no current ongoing trials of this combination.

c-MET

The HGF/c-MET pathway has been shown to be involved in the pathogenesis and progression of SCCHN.[113–124] The HGF is a peptide growth factor that is secreted by mesenchymal cells and acts primarily on epithelial cells where it binds to the c-MET receptor and, through activation of multiple downstream pathways, regulates cell growth, motility, and invasion. Serum HGF and HGF concentration in tumor tissue has been shown to be significantly elevated in patients with SCCHN and is associated with tumor progression and recurrence.[113,115] Silencing Met receptor tyrosine kinase signaling through Met knockdown in established SCCHN cell lines impaired activation of downstream MAPK signaling, reduced tumor growth by increased cell apoptosis, decreased regional lymph node metastases, and increased survival of nude mice with orthotopic xenografts.[125] Increased expression of c-MET has been associated with poor response to radiation

therapy in patients with SCCHN.[126] c-MET expression in some studies has been associated with lymph node metastasis, advanced tumor stage, risk of recurrence, and decreased survival.[119,124,127] More recent studies using archival tissue of patients treated for SCCHN identified increase c-MET expression by immunohistochemistry (57% to 58%) but found no significant correlation of c-MET expression on treatment response or survival.[128,129]

Recent data suggest that the HGF/c-MET pathway may play a more critical role in HPV-negative head and neck cancers.[130] The role of HGF and c-MET expression and *c-MET* gene copy number in HPV-negative and HPV-positive tonsil cancers was recently investigated. HGF overexpression was found to be an independent prognostic factor for decreased survival in HPV-negative but not HPV-positive tumors. Neither c-MET overexpression nor *c-MET* copy number was associated with survival outcomes in either cohort.[130] Baschnagel and colleagues examined archival tissue for 107 patients with SCCHN treated with chemoradiation and correlated c-MET expression with p16 status and clinical endpoints. High c-MET expression predicted for worse disease-free survival in p16-negative but not p16-positive patients.[131]

Inhibitors of c-MET in clinical development include the small molecule tivantinib and the monoclonal antibody ficlatuzumab. Two phase I studies of single-agent tivantinib included patients with head and neck cancer (total 2 nasopharynx, 3 SCCHN) without any reported partial responses.[132,133] It was not specified in the manuscripts whether any of them had stable disease. A phase I study of the c-MET inhibitor tivantinib (formerly ARQ 197) in combination with gemcitabine in advanced solid tumors reported a 20% partial response rate and 46% rate of stable disease; one of the patients with a partial response had squamous cell of the oral tongue carcinoma.[134] A phase I study of tivantinib in combination with erlotinib included 3 head and neck patients, one of whom had a partial response and two who had disease control for 7 and 8 months, respectively.[135] Ongoing studies of c-MET inhibitors include a randomized phase II trial of cetuximab with or without tivantinib in patients with R/M-SCCHN (NCT01696955), a trial of INC280 plus cetuximab in c-MET-positive SCCHN or colorectal cancer (NCT00205398), a trial of cetuximab with or without E7050 in platinum-resistant SCCHN, and a trial of definitive therapy for LA-SCCHN using IMRT, cisplatin, and ficlatuzumab (NCT02277184).

The future of c-MET inhibition as a therapeutic option for patients with SCCHN appears promising. It remains to be determined exactly which subset of patients with SCCHN will benefit from inhibition of the c-MET pathway; perhaps more studies in the HPV-negative oropharynx cancer population are warranted in the future. Lim and colleagues demonstrated that activation of c-MET is critical for the proliferation and maintenance of cancer stem cell traits in SCCHN and suggest that c-MET inhibition should be investigated as a therapeutic strategy to target SCCHN stem cells. As with all targeted therapies in the treatment of cancer, identifying the subset of patients with a high likelihood of benefit is key.

Fibroblast Growth Factor Receptor

The fibroblast growth factor receptor (FGFR) is a family of receptor tyrosine kinases that are regulators of a variety of cellular processes that include proliferation, migration, survival, and angiogenesis.[136] The ligand for the FGFR is fibroblast growth factor (FGF), a soluble growth factor that binds to the FGFR and also plays a role in epithelial–mesenchymal transition (EMT), a process through which cells acquire the ability to invade and migrate.[137] Abnormalities in the FGR or the FGFR have been shown to be key drivers of tumorigenesis in breast cancer.[138,139] A marker of EMT is the loss of the adhesion molecule E-cadherin. Several preclinical studies provide a strong rationale for targeting the FGFR in SCCHN.[137,140–145] Nguyen et al. [137] recently investigated the expression of FGFR1 in SCCHN and the role of the FGFR1 inhibitor PD173074 in EMT and tumorigenesis. Preclinical data from six head and neck cancer cell lines identified three of the cell lines that were found to be EMT induced, characterized by loss of E-cadherin and expression of the EMT genes Snail1, Snail2, ZEB1, and ZEB2. FGFR1 was found to be strongly expressed in the EMT-induced but not the non–EMT-induced cell lines. In the EMT-induced cell lines, PD173074 inhibited the autophosphorylation of FGFR1 in a dose-dependent manner and suppressed SCCHN cell growth, invasion, and migration. Cells treated with PD173074 showed decreased activation of ERK1/2, suggesting downstream inhibition of the MAPK pathway. In 100 tumor samples from patients with SCCHN, 54% highly expressed the FGFR1, and FGFR1 expression was found to correlate with increased nuclear polymorphism, increased invasion, and high-grade histology.[137] Large-scale sequencing projects have identified FGFR as a

potentially valuable target for cancer therapies for SCCHN.[140,141] Seiwert and colleagues recently published genomic analyses of HPV-positive and HPV-negative SCCHN using pretreatment tumor samples and matched normal DNA from patients with LA-SCCHN and found that potentially targetable somatic mutations in the genes *FGFR2* and *FGFR3* were identified in 17.6% of HPV-positive tumors. In HPV-negative patients, one tumor sample showed amplification of *FGFR1*.[140] Preclinical data in an SCCHN xenograft model identified up-regulation of the FGFR as a contributor to bevacizumab resistance,[142] and the combinations of FGFR inhibition and inhibition of ERBB2 and MET showed decreased growth of SCCHN cell lines in vitro.[143] Multiple phase I studies in solid tumors are investigating the use of FGFR inhibitors. A phase II trial of ponatinib (Iclusig), an oral FGFR tyrosine kinase inhibitor, in patients with lung and SCCHN with FGFR kinase alterations was opened but is presently suspended (NCT01761747). Future trials of FGFR inhibitors alone or in combination with other pathway inhibitors such as EGFR or c-MET seem warranted.

The Phosphoinositide-3 Kinase Pathway (PI3K/AKT/mTOR)

The PI3K/AKT/mTOR signaling pathway is part of many normal physiologic processes and associated with a number of oncogenic processes. In fact, collectively, members of the pathway are among the most frequently altered pathways in cancer, including SCCHN.[146] The PI3K family of enzymes can be divided into three classes (I to III).[147] Class I PI3Ks are heterodimers comprising regulatory and catalytic subunits. The latter include isoforms, p110α (*PIK3CA* gene), p110β, p110δ, and p110γ. Class I PI3Ks are the most commonly altered in cancer and have been investigated as therapeutic targets.

Once activated, PI3K phosphorylates phosphatidylinositol 4,5-bisphosphate (PIP_2), generating phosphatidylinositol (3,4,5)-trisphosphate (PIP_3).[147] PIP_3 initiates AKT activation by its translocation to the plasma membrane, which further phosphorylates multiple proteins including those responsible for protein synthesis and cell growth through the mTOR complex (mTORC) 1. A second mTOR complex, mTORC2, also directly phosphorylates AKT on serine 473.[147]

Whole-exome sequencing data from locally advanced SCCHN revealed that the PI3K pathway is mutated in approximately one-third of tumors.[148] Altered genes include *PIK3CA*, *PIK3CD*, *PTEN*, *PDK1*, *AKT*, and *mTOR*.[148–154] In addition, *PIK3CA* amplifications and *PTEN* inactivation are also common in SCCHN. Moreover, this pathway appears to be commonly dysregulated in HPV-related SCCHN[155] with one study demonstrating *PIK3CA* mutations in 31%, *PIK3CA* amplifications in 20%, and PTEN loss in 33% of cases.[156] The Cancer Genome Analysis recently completed work on SCCHN revealing *PIK3CA* mutations in 21% of all samples with 40% to 50% of HPV-related tumors harboring an alteration in *PIK3CA*.[157]

PI3K Inhibitors

Agents that target all four class I PI3K isoforms, including buparlisib (BKM120; Novartis Pharmaceuticals Corporation, East Hanover, NJ) and PX-866 (Oncothyreon, Seattle, WA), have been investigated in SCCHN. Buparlisib has demonstrated in vitro and in vivo efficacy in SCCHN models and is currently in clinical trials.[158] PX-866 is another agent that has demonstrated antitumor efficacy in SCCHN models with *PIK3CA* alterations.[159] Two phase II trials have been completed adding PX-866 to docetaxel or cetuximab, respectively.[160,161] In neither study did the combination arm with PX-866 provide an improvement in response rate, progression-free survival, or overall survival compared to docetaxel or cetuximab alone. These studies, however, did not preselect subjects based on genomic or pathway activation.

BYL719 (Novartis Pharmaceuticals Corporation, East Hanover, NJ) is an oral inhibitor that selectively targets the α isoform of class I PI3K.[162] In a phase I study of BY719 in patients with *PIK3CA*-mutated tumors, SCCHN patients were among those with an observed partial response and demonstrated the greatest reductions in tumor volume.[163] Based on preclinical data,[164] a phase I/II study of BYL719 and cetuximab in patients with recurrent or metastatic SCCHN is currently ongoing (NCT01602315).

mTOR Inhibitors

Everolimus (Afinitor, Novartis Pharmaceuticals Corporation, East Hanover, NJ) is an mTORC1 inhibitor and is being tested as part of a phase I/II study

investigating induction chemotherapy with weekly everolimus, carboplatin, and paclitaxel in locally advanced SCCHN (NCT01333085). Preliminary data suggest that treatment is well tolerated with an overall response rate of 79%.[165] Temsirolimus (TORISEL, Wyeth Pharmaceuticals Inc., Madison, NJ), another mTORC1 inhibitor, was added to carboplatin and paclitaxel in a phase I study in patients with recurrent/metastatic SCCHN and achieved an objective partial response rate of 22%.[166] In a phase II study in patients with recurrent or metastatic, platinum-refractory SCCHN, the combination of temsirolimus plus erlotinib was poorly tolerated and prematurely aborted providing some caution in employing EGFR and mTOR targeting.[107]

Cyclins D1 Function and Inhibitors

The mammalian cell cycle is regulated by cyclin-dependent protein kinases (CDKs). CDKs are often hyperactivated in cancer, thus representing potential small-molecule targets in several malignancies. Retinoblastoma (Rb) pocket proteins p107 and p130 prevent the cell from replicating damaged DNA by controlling the restriction point that would allow the progression along the cell cycle through G1 into S. Rb binds and inhibits transcription factors of the E2F family, which are composed of dimers of an E2F protein and a dimerization partner (DP) protein. The transcription activating complexes of E2F–DP can push a cell into S phase. When Rb is bound to E2F, the complex acts as a growth suppressor and prevents progression through the cell cycle keeping the cell stalled in the G1 phase. However, in response to a mitogenic signal, the cyclin D1–CDK4 and cyclin D1–CDK6 complexes are activated. These induce phosphorylation of the Rb protein, resulting in release (and therefore activation) of E2Fs and thereby promoting transcription of genes that trigger S phase entry. On the other hand, the CDKN2A gene encodes for the protein p16, an inhibitor for the cyclin D1–CDK4 complex that mediates senescence and differentiation. Consequently, the interplay between the cyclins, CDKs, and their inhibitors determines whether the restriction point can be passed.[167]

Increased expression and gene amplification of cyclin D1 have been observed in 68% and 58% of SCCHN of the tongue, both findings associated with a worse disease-free and overall survival.[168,169] Similarly, loss of p16INK4A has been reported in 55% of anterior tongue tumors and has also been associated with worse outcome.[168] Preclinical studies have reported that

deregulated cyclin D1 overexpression may be associated with resistance of HNSCC to the EGFR kinase inhibitor gefitinib.[169] Therefore, inhibitors of cyclin D1 and other regulatory CDKs are attractive agents to developed in SCCHN.

Seliciclib (CYC202; R-roscovitine) is an orally available inhibitor of CDK2/E, CDK2/A, CDK7, and CDK9 that has been shown to enhance apoptosis in head and neck cancer cells in preclinical studies.[170] It was the first CDK inhibitor to enter the clinic, and two phase I studies were developed using continuous and intermittent doses of seliciclib in patients with solid tumors. Both trials treated a total of 77 patients, but there was only one objective response seen in one patient with hepatocellular carcinoma. No patients with SCCHN were treated in either trial.[171,172] Another small trial evaluated seliciclib in 14 patients with nasopharyngeal carcinoma, reporting grade 3 liver toxicity in one patient and grade 2 vomiting on another at doses of 800 mg twice daily, but no significant toxicities were experienced in 13 patients treated at 400 mg twice daily. Seven of 14 evaluable patients had clinical evidence of tumor reduction. Some of these responses were associated with increased tumor apoptosis, necrosis, and decreases in plasma EBV DNA posttreatment.[173] Another orally bioavailable CDK inhibitor, LEE011, that targets cyclin CDK4/6 is currently being tested in patients with solid tumors and amplifications or mutations of CDK4/6.

Apoptosis and Poly(ADP-Ribose) Polymerases (PARPs) Inhibitors

In the presence of DNA damage, a normal cell will prompt cell cycle arrest while the potential for repair is assessed. If the damage exceeds repair capacity, the cell will then undergo programmed cell death (apoptosis). Whereas an immune-mediated pathway can trigger antigen-induced cell death, an intrinsic or mitochondrial pathway can also activate apoptosis in response to unrepaired DNA damage. Poly(ADP-ribose) polymerases (PARPs) are a family of enzymes involved in DNA repair for cell survival and apoptosis. PARP1 is the most studied of these enzymes and accounts for at least 85% of maximally activated cellular PARP activity. Their main role is to detect and signal single-strand DNA breaks (SSB) and consequently recruit proteins responsible of the enzymatic machinery of DNA repair. The

typical activation pathway for PARP1 is triggered by DNA breaks caused by ROS/RNS species, UVB, or ionizing radiation. Once PARP detects an SSB, it binds to DNA and begins the synthesis of a poly(ADP-ribose) chain (PAR) as a signal for DNA repair enzymes such as DNA ligase III and DNA polymerase beta.[174] Because survival of cancer cells depends on their ability to continually repair their own DNA, blocking the antiapoptotic regulators of the intrinsic pathway with novel PARP inhibitors represent a potentially attractive new therapeutic option in a range of malignancies, including SCCHN.

Inhibition of PARP blocks the repair of spontaneous SSB, leading to the formation of double-strand breaks through mechanisms such as stalled replication forks. These double-strand breaks become lethal in cells that are deficient in double-strand break repair (such as those with mutations in BRCA1 or BRCA2).[175] PARP inhibitors can also trap the PARP1 and PARP2 enzymes at damaged DNA. With unrepaired SSB, the trapped PARP–DNA complexes are highly cytotoxic and can induced block of DNA replication.[176] Thus, several PARP inhibitors are currently being evaluated in clinical trials as single agents or in combination with other cytotoxic agents or radiation therapy. PARP1 protein has been found to be highly expressed in nasopharyngeal carcinoma cell lines and the level of expression strongly correlates with nasopharyngeal carcinoma disease stage. In preclinical studies, the PARP inhibitor olaparib (AZD2281) can increase DNA damage, cell cycle arrest, and apoptosis in nasopharyngeal carcinoma cells challenged with ionizing radiation or temozolomide, as well as enhance the tumor inhibitory effects of ionizing radiation in animal xenograft models.[175] Double-strand breaks (DSBs) are repaired mainly by homologous recombination during replication. Some SCCHN have been reported to have a deficiency in homologous recombination, a characteristic that can act phenotypically as a BRCA germline mutation. The presence of this abnormality in some SCCHN cell lines has been correlated to susceptibility to PARP inhibitors, especially with rucaparib.[177] Moreover, when used in combination with radiation therapy, PARP inhibitors have synergistic activity enhancing apoptosis in vitro and in vivo, as compared with radiation alone.[178,179]

Veliparib (ABT-888, NSC 737664) is an orally available PARP inhibitor that has been combined with carboplatin and paclitaxel in a phase I trial. The

combination was found to be well tolerated and with a safety profile similar to the chemotherapy doublet without veliparib. Of the seven patients with SCCHN that were included, one had a partial response.[180] Studies using olaparib concurrently with radiation for patients with locally advanced SCCHN are in development.

Angiogenesis

Angiogenesis plays an essential role in tumor growth and metastasis; therefore, controlling tumor-associated angiogenesis is now a key tactic in limiting cancer progression. VEGF is a subfamily of structurally related growth factors that can increase vascular permeability and promote proliferation and survival of endothelial cells. All members of the VEGF family can stimulate cellular responses by binding to the VEGFRs on the cell surface, causing dimerization and subsequent activation through transphosphorylation, but VEGF-A is the most important mediator of angiogenesis and contributor to pathogenesis in many cancers.[181] VEGF-A promotes angiogenesis mainly via VEGF receptor 2 (VEGFR2). The binding of VEGF to VEGFR2 leads to dimerization of the receptor, followed by intracellular activation of a cascade of different signaling pathways such as Raf/MAPK and phosphatidylinositol 3′ kinase (PI3K)-Akt pathways.[182]. In SCCHN, VEGF protein overexpression has been associated with a worse OS in SCCHN patients.[183,184] In a preclinical study, the inhibitors of VEGFR2 and PDGFR sorafenib and sunitinib lead to a statistically significant down-regulation of PDGFR α/β in HPV-positive SCCHN cell lines, but not in HPV-negative tumor cells. HPV-positive HNSCC, consequently, might exhibit a higher sensitivity to antiangiogenesis drugs compared to HPV-negative HNSCC.[185]

Several antiangiogenesis drugs are currently approved and in clinical use for the treatment of malignancies, but none so far in SCCHN. Bevacizumab, a monoclonal antibody directed against VEGF, is approved in the United States and Europe for use in metastatic lung cancer, colorectal cancer, and glioblastoma. Interestingly, in non–small cell lung cancer (NSCLC), bevacizumab is only approved for its use in nonsquamous histology because of the bleeding risk associated with squamous cell carcinomas of the lung. Bevacizumab has been studied in SCCHN in the metastatic setting added to chemotherapy with pemetrexed. A phase II trial enrolled 40 patients with

recurrent and metastatic SCCHN and using bevacizumab added to chemotherapy with pemetrexed. The median OS was 11.3 months and the ORR was 30%.[186] There were, however, bleeding events in 15% of the patients, but not all of them were considered treatment related. VEGF signaling is up-regulated by EGFR expression, and up-regulation of VEGF has been associated with resistance to cetuximab.[187,188] Thus, cotargeting of EGFR and VEGF has been attempted in patients with SCCHN. Bevacizumab was combined with cetuximab in a phase II trial enrolling 46 patient, reporting a disease control rate of 73% and ORR of 16%.[186] Median PFS and OS in the trial were 2.8 and 7.5 months, respectively, and <10% of the patients had grade 3 to 4 adverse events. Similar results were seen in a phase I/II trial that combined erlotinib with bevacizumab, where an RR of 15% and OS of 7.1 months were seen in the 48 patients enrolled.[69]

An alternate approach to block angiogenesis is using low molecular weight inhibitors of the tyrosine kinase domain of VEGFR2. Several of these inhibitors are commercially available and approved for diseases as renal cell carcinoma, hepatocellular carcinoma, and refractory thyroid cancer. Vandetanib (ZD6474), a multikinase inhibitor of EGFR, VEGFR2, and RET, has demonstrated antitumor activity on nude mice bearing an established xenograft of SCCHN cells by inducing apoptosis and decreasing angiogenic activity.[189] Vandetanib was also combined with docetaxel in a phase II trial that treated patients with metastatic/refractory SCCHN. The trial randomized 29 patients that failed platinum-based therapy to docetaxel every 3 weeks with or without vandetanib orally daily. There was no difference between PFS or OS, although a small statistically significant difference in response rate was noted.[106] Another phase I/II study added vandetanib with radiation therapy with or without cisplatin in patients with locally advanced disease and enrolled 33 patients. All the 29 patients that were evaluable for efficacy achieved a complete response and of the 17 patients that completed a 2-year follow-up at the time of the presentation, 6 recurred, and 11 remained free of disease.[190] Four of the 18 patients that received vandetanib discontinued therapy due to adverse events.

Sorafenib is another small molecular inhibitor of VEGFR, PDGFR, and Raf kinases. It was evaluated in the recurrent/metastatic setting in a phase II trial that enrolled 41 patients, reporting a median PFS of 4 months and OS of 9 months, but with only 2% of RR. The most common side effects included

fatigue, anorexia, stomatitis, hand–foot syndrome, and hypertension.[110] More encouraging results were seen on another phase II trial that combined sorafenib with paclitaxel and carboplatin, achieving an RR of 55%, disease control in 84%, and median OS of 22 months.[191] Grade 3 adverse effects included hand–foot syndrome, neutropenia, elevated lipase, amylase, and anemia.

Sunitinib is also a multikinase inhibitor with activity against VEGFR2, PDGFR, RET, and c-KIT. Two A phase II trial evaluated sunitinib monotherapy in patients with recurrence metastatic SCCHN. The first one treated 38 patients, reporting a disappointing OS of 3.4 months and partial response in one patient and grade 3 or more bleeding episodes in 16% of the patients treated.[192] The second study accrued 22 patients, achieving a patient response in one.[111]

Immunotherapy for SCCHN

Another manner of targeting SCCHN has aimed at targeting the immune system. Therapies that modulate the immune system in SCCHN may be particularly active as these patients are deemed relatively immunosuppressed. Patients with SCCHN, compared to healthy controls, demonstrate lower absolute numbers of CD3+, CD4+, and CD8+ T cells,[193] dysfunctional antigen-processing machinery,[194,195] and impaired natural killer cell activity.[4] As seen with other malignancies, patients whose cancer cells elicit an immune response appear to have a better prognosis; for example, the presence of tumor-infiltrating lymphocytes (TIL) has been identified as a good prognostic factor for SCCHN patients.[196,197] Regulatory T cells (T-regs) modulate the immune system and maintain tolerance to self-antigens by down-regulating the induction and proliferation of effector B and T cells.[198] An increase in the concentration of T-regs found in the periphery of patients with SCCHN appears to correlate with an improved prognosis.[199] Furthermore, chronic HPV infection plays a strong role in a subset of SCCHN patients, and it is well known that the same mechanisms that enable a chronic infection also promote malignant transformation. After an infection with HPV, the virus is usually cleared in the majority of individuals through T cell–mediated immunity. In a subset of patients, the infection persists, leading to chronic inflammation, inhibited cell growth, and immune

tolerance, which subsequently can lead to cellular malignant transformation.[200] The virus down-regulates the immune system through a variety of mechanisms. The viral proteins E5 and E7 down-regulate the expression and cell surface concentration of class I HLA.[201] Similarly, E6 and E7 reduce the effects of alpha and beta interferon (IFN).[202] Tobacco-related malignancies share a similar chronic inflammatory cellular milieu, which can contribute to and accelerate the malignant transformation.[203]

In order for a cancer to continue its growth, it has to succeed at modulating and suppressing a natural immune response. All cancer cells have genetic and epigenetic alterations that can present antigens that the immune system can exploit to attack while distinguishing malignant cells from benign ones. The mechanisms cancers employ to evade and avoid destruction by the immune response are extremely complex and involve multiple pathways including mechanisms of evasion, direct suppression, and indirect suppression. Evasion of the immune response can be achieved by a number of mechanisms, which include decreasing the expression of surface MHC class I molecules[204] or impairing antigen-processing machinery.[194] Direct immune suppression occurs through the expression of receptors normally found in immune cells that induce an antiapoptotic pathway or an inhibitory signal such as the Toll-like receptor 4 (TLR-4),[205] galectin-1,[206] FasL,[207] TRAIL,[208] and PD-L1.[209,210] Finally, indirect suppression and modulation of the immune response can be mediated through recruiting and directing a cellular network of cells such as tumor-associated macrophages, myeloid-derived suppressor cells, immature dendritic cells (DCs), regulatory T cells, and natural killer cells.[204]

The goals of immunotherapy are to reverse the mechanisms of immune resistance and augment the antitumor immune response as a therapeutic strategy. Immunotherapies can be divided in cytokine, antibody, and cell-based therapies. Cytokine therapies regulate and coordinate the response of the immune system and generally augment the response of an ongoing active immune system. Antibodies use antigens expressed by tumor cells to induce antibody-dependent cell–mediated cytotoxicity (ADCC), interfere with cell signaling by modifying the interaction of cell membrane receptors and its ligands, deliver a dose of chemotherapy or radiation to a specific target, or finally activate the complement system. In cell-based therapies, autologous immune cells are harvested from patients, activated in vitro, expanded, and

subsequently returned to the patient to elicit an immune response.

Although targeting the immune system with vaccines and other immune-stimulating agents has been a strategy employed for years in many tumor types, this strategy has not been met with much success in SCCHN, and some therapies also had considerable toxicity. However, recent breakthroughs with the immune checkpoint inhibitors have generated renewed enthusiasm in immunotherapy due to observed dramatic sustained tumor regressions, reasonable tolerability, and improvements in survival in solid tumors that had not been considered amenable to immune targeting, such as NSCLC.[211,212] Preliminarily, responses to the immune checkpoint inhibitors appear to be more prominent in those NSCLC patients with squamous cell histology[213] that share biologic similarities to SCCHN. The inflammatory milieu observed in SCCHN tumor specimens, the relative immunosuppression in SCCHN patients, and the limited effective systemic therapies available for recurrent or metastatic SCCHN support the exploration of, and renewed interest in, therapies targeting the immune system in SCCHN. An exhaustive list of immune therapies that have been attempted or examined will not be discussed—however, some of the more promising immunotherapies and immunotherapy trials will be presented.

Cytokines

Cytokines are a large family of proteins that are essential for cell signaling. The term cytokine is a general term used to describe chemokines, interferons, interleukins, lymphokines, and tumor necrosis factors. Cytokines modulate inflammation and contribute to mediation of an immune response. Cytokines administered systemically have been used to elicit an immune response in malignancies such as melanoma and renal cell carcinoma. Despite antitumor responses and activity, they are associated with significant toxicities. In SCCHN patients, a number of cytokines have been explored and some of the notable cytokines of interest are subsequently presented; however, adoption of cytokine therapy in this patient population has been largely limited due to tolerability.

Systemic IL-2 administration coupled with IFN-alpha led to two partial responses in 11 heavily pretreated SCCHN patients; however, adverse events were substantial with grade 3 hypotension and fatigue being the most common reasons for discontinuing study therapy.[214] Local administration of

IL-2 appeared to be better tolerated; in a phase III trial, 220 patients underwent direct local administration of low-dose (5,000 U/day) perilymphatic recombinant IL-2 administered pre- and postoperatively in resectable SCCHN (T2 to T4, N0 to N3, M0); patients in the experimental arm had an improvement in both PFS and OS. Moreover, after a median follow-up of 64 months, the median OS for the experimental arm was not reached, in contrast to a median OS of 75 months in the standard of care arm ($p = 0.03$).[215] However, despite its low toxicity and improvements in survival demonstrating a role for immunotherapy in SCCHN, no tumor responses were observed, limited immunologic correlates were performed, and immunologic endpoints were not assessed, which hampered the adoption of IL-2 in this setting.

To optimize the delivery of IL-2, other formulations have been explored such as ALT-801. ALT-801 is a fusion protein that contains IL-2 coupled with a single chain T-cell receptor domain that targets tumors that overexpress the p53 gene. This therapy in a dose-escalating phase I study of 26 patients with a variety of solid tumors demonstrated lesser toxicities than those experienced in high-dose IL-2, with demonstrated biologic and immunologic correlative effects such as interferon-γ induction and encouraging clinical activity with stability in 10 patients lasting over 11 weeks. Notably, administration of two doses of ALT-801 at 0.04 mg/kg to a heavily pretreated progressing SCCHN patient led to disease stability for >8.5 months with no other anticancer treatment.[216]

Other active cytokines such as IL-12 and IL-15 were explored for their immunostimulatory effects with hopes of less toxicity. Il-12 injected into the primary tumor of 30 SCCHN patients in a phase II study showed immunologic correlative effects with a redistribution of NK cells, lymphocytes, and monocytes from the peripheral blood to lymph nodes and increased lymph node IFN-gamma expression levels. However, significant toxicity was experienced and no clinical responses were seen.[217] As preclinical in-vitro studies of IL-12 appeared to enhance the antitumor activity and ADCC effects of cetuximab and in vivo xenograft models demonstrated synergistic tumor regressions,[218] this combination is being currently investigated in a phase I/II study in SCCHN patients (NCT01468896). IL-15 is a cell growth factor that induces the activation and proliferation of CD8+ T cells as well as NK cells. It maintains long-term

memory T cells with relatively less effect on T regulatory cells and inhibits activation-induced cell death.[219] A phase I study is currently exploring the subcutaneous administration of IL-15 in patients with a number of solid malignancies, including SCCHN (NCT01727076).

Other cytokines such as interferon-alpha demonstrated promise but were limited by feasibility. Preliminary results of interferon-alpha coupled with isotretinoin and vitamin E administered in 45 SCCHN patients in a phase II trial demonstrated a 5-year progression-free survival rate of 80% and a 5-year overall survival rate of 81.3%.[220] Unfortunately, an ECOG-led phase III trial of this regimen was terminated due to poor accrual. IRX-2 is a product that contains a physiologic combination of cytokines that includes IL-2, IL-1-beta, IFN-gamma, and TNF-alpha. It is administered subcutaneously in the neck area just above and adjacent to the lymph nodes draining the head and neck. It demonstrated promising activity in a neoadjuvant phase II study of 42 SCCHN patients with 3 complete responses and 10 partial responses. A phase III study is under way in patients undergoing surgery for oral cavity cancers.[221]

Another class of agents that can potentially have a therapeutic effect in SCCHN are the Toll-like receptor (TLR) agonists. TLRs are also important mediators in the immune response that can have an immunostimulatory effect and antitumor activity. TLR agonists induce a potent innate and adaptive immune response and can enhance the ADCC activity of therapeutic monoclonal antibodies.[222,223] Preclinically, potent immunologic anticancer effects were observed with the TLR agonists in SCCHN models.[224–226] VTX-2337 is a small molecule TLR8 agonist that activates myeloid dendritic cells, monocytes, and natural killer (NK) cells. A phase Ib study with escalating doses of VTX-2337 and a fixed dose of cetuximab in 12 patients with previously treated SCCHN demonstrated a response rate of 16.7% and a disease control rate of 50%.[227] This encouraging study formed the basis for a subsequent randomized phase II study comparing 5FU, a platinum agent, and cetuximab versus the same regimen plus VTX-2337 in the first-line setting for SCHNN patients (NCT01836029).

Oncolytic Virus Therapy

Oncolytic viruses exploit the ability of a viral infection to target specific

cells. Viral therapy can induce cell lysis of infected cells and an acute vascular disrupting effect or provoke antitumor immunity.[228] Reolysin is a proprietary variant of a reovirus, an acronym for respiratory enteric orphan virus, based on phase I/II results demonstrating tolerability and activity in advanced solid malignancies.[229] Reolysin is being evaluated in a double-blind phase III study in combination with paclitaxel and carboplatin in platinum-refractory SCCHN (NCT01166542). Despite a preliminary press release[230] from the company indicating that in an intent-to-treat analysis, there was promising improvement in PFS for the experimental versus the control arm (p = 0.0072, HR = 0.5360); confirmatory data, overall survival endpoints, and trial details have not been released or published to date. A genetically modified adenovirus, Onyx-015, was evaluated in a phase III clinical trial, which did not show any improvement in overall survival, halting its development in the United States.[231] A similar virus, H101, has been approved by regulatory agencies in China for the treatment of SCCHN. The approval was based on a phase III trial, with a 79% response rate in patients receiving H101 by intratumoral administration in combination with cisplatin and 5-fluorouracil (5FU); however, its effect on survival is unknown.[41] The development of a new version of H101, H103, including a heat shock protein designed to attack metastatic tumors, is currently under way.[231]

Antibodies Inhibiting Cytokines

Hepatocyte Growth Factor/c-MET Pathway.

The secretion of HGF promotes tumor growth and metastases through c-MET signaling and inhibition of dendritic cell maturation.[232] The HGF/c-MET pathway is expressed and up-regulated in SCCHN,[122] and its activation leads to resistance to both chemotherapy and radiation.[233,234] Ficlatuzumab and rilotumumab are antibodies against the HGF that are in different stage of development against a variety of malignancies. Protocols to study them in SCCHN patients are currently in development.[235]

TGF-Beta.

TGF-beta is found to be significantly elevated in the serum of patients with HPV-negative SCCHN. In a xenograft model, the addition of an antibody

against TGF-beta with cetuximab improved antitumor efficacy when compared to treatment with cetuximab alone. Fresolimumab is an antibody against TGF-beta currently in development that could potentially be beneficial for SCCHN patients.

Immune-Stimulating Agonistic Antibodies.

For T-cell stimulation and activation, there are a number of accessory surface costimulatory receptors that are involved in the priming of the immune system, cytolysis, and memory cell differentiation. Agonistic antibodies to a number of costimulatory T-cell receptors such as CD40, OX40, and CD137 are in early-phase clinical trials and may have activity in SCCHN. These antibodies could also be additive or synergistic with chemotherapy, radiation, other targeted antibodies, and other immunotherapies, including the immune checkpoint inhibitors. The binding of CD40 to its ligand on activated CD4+ T cells can enhance antigen-presenting cell priming, secrete immunostimulatory cytokines, and up-regulate antigen-processing and cytotoxic T-lymphocyte priming. A patient with refractory SCHNN demonstrated a long-term complete response in a phase I trial of a recombinant CD40 ligand agonist.[236] This pathway seems to be actively involved in SCCHN immune evasion and merits further exploration and development in SCCHN.

OX40 signaling is involved in the survival, expansion, and memory of T helper cells and stimulating inflammatory cytokine production and decreasing suppression by T regulatory cells.[237] Patients with SCCHN have lower levels of circulating T cells that express OX40 and CD137 compared to controls.[238] OX40 antibodies have demonstrated antitumor activity in a number of solid tumor preclinical models. A phase I study in a select number of solid tumors including SCCHN is currently under way (NCT02221960). CD137 also has immunostimulatory attributes, and activation on NK cells helps enhance the ADCC effect of cetuximab and NK cell–mediated direct cytotoxicity. Preclinically, cetuximab induces CD137 up-regulation on NK and enhances its cytolytic activity in SCCHN models.[239]

Antibodies against Immune Checkpoints

To prevent autoimmune reaction and to protect healthy tissues when the immune system is activated, T cell activation is highly regulated, and several inhibitory pathways are expressed in immune cells. Cancer takes advantage

of this inhibitory signaling to prevent T-cell activation and escape the immune response.

Cytotoxic T-lymphocyte A-4 (CTLA-4).

The recognition of antigens presented by the major histocompatibility complex is not enough to turn on a T-cell response, and a second signal delivered by the B7 costimulatory receptor is required. When B7 binds to CD28, it provides an activating signal. In contrast, if it binds to CTLA-4, an inhibitory signal is provided. Ipilimumab and tremelimumab are antibodies that inhibit the CTLA-4 inhibitory signaling. Ipilimumab is FDA approved for the treatment of metastatic melanoma due to its benefits on overall survival.[240] An ongoing phase I trial at the University of Pittsburgh is exploring 3 courses of ipilimumab after treatment with cetuximab and intensity-modulated radiation therapy (IMRT) for SCHNN patients with high- or intermediate-risk AJCC stage III/IV (excluding T1N1) cancer of the oropharynx, hypopharynx, and larynx for tolerability and potential efficacy (NCT01935921).

Programmed Death 1 Checkpoint Blockade.

Programmed death 1 (PD-1) can be expressed by T cells, B cells, and myeloid dendritic cells (DC). It is highly expressed in T-regs, which are commonly found to be infiltrating tumors and may contribute to suppressing effector immune responses.[241] Its ligand (PD-L1) is inducible and constitutively expressed in several malignancies including SCCHN.[210] Interactions between PD-1 and PD-L1 in the tumor microenvironment lead to inhibition of the immune response against the tumor through several mechanisms including the inhibition of effector T cells, the induction of tolerance mediated by T-regs,[242] and the activation of an antiapoptotic pathway signaling (**Fig. 32.1**).[243]

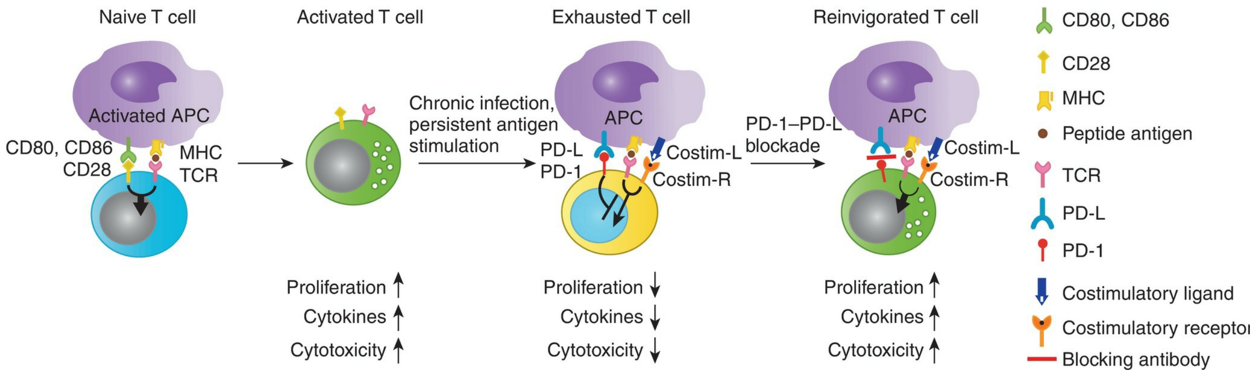

Figure 32.1. PD-1 and PD-L1 blockade—a strategy for immunotherapy in SCCHN. (Adapted and modified from Sharpe AH, et al. *Nat Immunol*. 2007;8:239.)

PD-L1 is frequently expressed in SCCHN. Three sets of retrospective case series have established that PD-L1 expression is more commonly found in HPV-related than in HPV-negative SCCHN: 62.5% versus 40%,[244] 49.2% versus 34.1%,[245] and 70% versus 29%.[246] This increase in PD-L1 expression contributes to a local immune resistance that allows HPV to infect and may contribute to the malignant transformation process.[246] Studies of various malignancies have been discordant in terms of correlation of expression of PD-L1 and prognosis,[241] and the same is true for SCCHN.[244,247,248] These differences may be methodologic in that PD-L1 measurement has not been standardized (different antibodies, different cutoff levels for positivity, and different definitions of positivity whether it be on tumor cells, stroma, or tumor-infiltrating cells). Additionally, the expression of PD-1/PD-L1 may be dynamic and fluid through time, subject to changes in the microenvironment, and even potentially up-regulated with therapy.[210]

Treatment with anti-PD-1 and anti-PD-L1 monoclonal antibodies in phase I trials initially included multiple solid tumor types and demonstrated unprecedented durable tumor responses.[212] Currently, a number of different anti-PD-1 and anti-PD-L1 antibodies are being developed (**Table 32.1**). As most of the reported data have been in early-phase studies, the differences between anti-PD-1 and anti-PD-L1 agents or the use of IgG1 or IgG4 backbones have not been elucidated. Moreover, different agents may have different efficacy and tolerability in different tumor types. It is important to note some theoretical differences. PD-L1 inhibition only inhibits the binding of PD-L1 to PD-1; in contrast, antibodies against PD-1 inhibit both PD-L1

and PD-L2 signaling. This subtle difference could translate into increased toxicity for anti-PD-1 therapy as both PD-L1 and PD-L2 have been implicated in playing an important role in maintaining immune homeostasis. Another theoretical difference is that targeting PD-1 can saturate this T-cell receptor in the periphery, which obviates the need for antibody penetration into sites such as the CNS.[249]

Table 32.1 Seven Companies Developing PD-1 Checkpoint Inhibitors

Anti-PD-1 Antibodies			
Nivolumab	Bristol-Myers Squibb	IgG4	Phase 3
MK-3475	Merck & Co	IgG4 (humanized)	Phase 3
Pidilizumab	CureTech	IgG1 (humanized)	Phase 2
AMP-224	AstraZeneca/MedImmune	PD-1/B7 Fc fusion protein	Phase I
AMP-514		IgG	Phase I
	Novartis (CoStim)	IgG	Phase I
Anti-PD-L1 Antibodies			
MPDL3280A	Genentech/Roche	IgG1	Phase 3
MEDI-4736	AstraZeneca/MedImmune	IgG1	Phase 2
MSB0010718C	EMD Serono (Merck KGa)	IgG	Phase 1

www.clinicaltrials.gov, Accessed May 12, 2014.

In SCCHN, several clinical trials have been ongoing with some preliminary findings reported. In a phase Ib study of pembrolizumab, MK-3475, an antibody designed to block the PD-1 interaction with its ligands PD-L1 and PD-L2, patients with recurrent or metastatic SCCHN that were positive for expression of PD-L1 (1% on tumor cells or stromal cells) were treated. Of 104 patients screened for PD-L1 positivity, 81 (78%) were positive of which 60 received ≥1 dose. A preliminary analysis showed that the drug was well tolerated and had an overall response rate of 20% (n = 11/56 evaluable patients) with a response duration that ranged from 8+ to 41+ weeks (median had not been reached).[250] Preliminary results of the anti-PD-L1 antibody, MEDI4736, also demonstrated durable responses in 14% (n = 4/29) of recurrent or metastatic SCCHN patients.[251] Currently, seven different companies have inhibitors of PD-1 or PD-L1 that are being tested in phase I to III clinical trials for a variety of malignancies.

The use of PD-L1 as a predictive biomarker to determine who will respond or should be treated with immunotherapy is not well established. In melanoma, NSCLC, and other solid tumors, patients with stronger expression

of PD-L1 tend to have higher response rates to these agents; however, responses and clinical benefit have been seen in patients whose tumors are negative for PD-L1 expression.[252] Therefore, development of predictive biomarkers is likely to be more complex than PD-L1 positivity alone. Gene arrays, tissue immune infiltration scores, and peripheral immunologic markers are being explored.

What is notable about the PD-1/PD-L1 inhibitors is the highly tolerable toxicity profile that enables long-term administration. Mild toxicities such as fatigue, pruritus, rash, and infusion reactions have been commonly observed. In SCCHN, the rate of reported adverse events ranges from 39% to 58%, the majority of them being grade 2 or less,[250,251] whereas severe toxicities are infrequent and, in contrast to the experience with CTLA-4 blockade, immune-related toxicities are rare.

The immune-related toxicities experienced with the CTLA-4 and PD-1/PD-L1 inhibitors appear to occur more frequently in responding patients and range in severity from mild to fatal, generally appearing late, 8 to 10 weeks after initiation of therapy. Toxicities can also be long lasting, even months after discontinuation of therapy, and may even potentially affect the toxicity profile of subsequent therapies. Most adverse events that are considered immune adverse events can generally be treated with steroids and immunosuppressants with resolution.[253] Despite their rare incidence, immune-related toxicities with the PD-1 checkpoint inhibitors can affect any organ system, and toxicities of diarrhea, rash, liver enzyme changes, endocrine abnormalities, renal dysfunction, and musculoskeletal abnormalities have been reported. Early detection and management are important to avoid severe consequences. Algorithms for the management of toxicity have been established for the CTLA-4 inhibitor, ipilimumab, in melanoma; the toxicity management of the PD-1 checkpoint inhibitors is still in evolution and has yet to be fully defined. The sensitivity and tolerability to immune checkpoint inhibitor toxicity may vary in different solid tumor populations, especially in SCCHN patients who may have smoking- or alcohol-related comorbidities.

Cell-Based Therapies

T-cell therapies involve the harvesting of a patient’s own tumor antigen-specific cells followed by different types of manipulation in vitro with the

goal of priming them prior to reintroduction into the patient. This is a complex and laborious methodology; however, impressive results have been reported in several tumors, including a complete response in a patient with SCCHN.[254] In HPV-related tumors, T cells specific against the HPV antigens E6/E7 have been expanded in vitro, and a recent reported trial in patients with refractory cervical cancer showed one partial response and two complete responses.[255] This strategy is currently being tested in an ongoing phase II study of HPV-positive cancers, including HPV-positive SCCHN (NCT01585428).

Defining Mechanisms of Resistance to Immunotherapy

Although promising results have been seen in SCCHN, most patients do not respond to immunotherapy and those who do eventually acquire resistance and tumor growth. In the case of immune checkpoint inhibition, rechallenging patients with the same therapy after an initial response can reinduce tumor regression, but it does not do so consistently in all patients.[256,257] Another strategy in nonresponders or patients that progress is to induce response and an inflammatory tumor milieu with infiltrating T cells via the use of combination strategies—either sequential or concurrent with chemotherapy, radiation therapy, targeted therapies, or other immunotherapies. These approaches are being explored in early-phase trials, and their efficacy and toxicity, optimal administration, and sequencing are yet not determined. Several ongoing clinical trials are combining forms of immunotherapy such as the use of cancer vaccines along with checkpoint inhibitors and the use of costimulatory T-cell receptors and CTLA-4 antibodies (**Fig. 32.2**).[258]

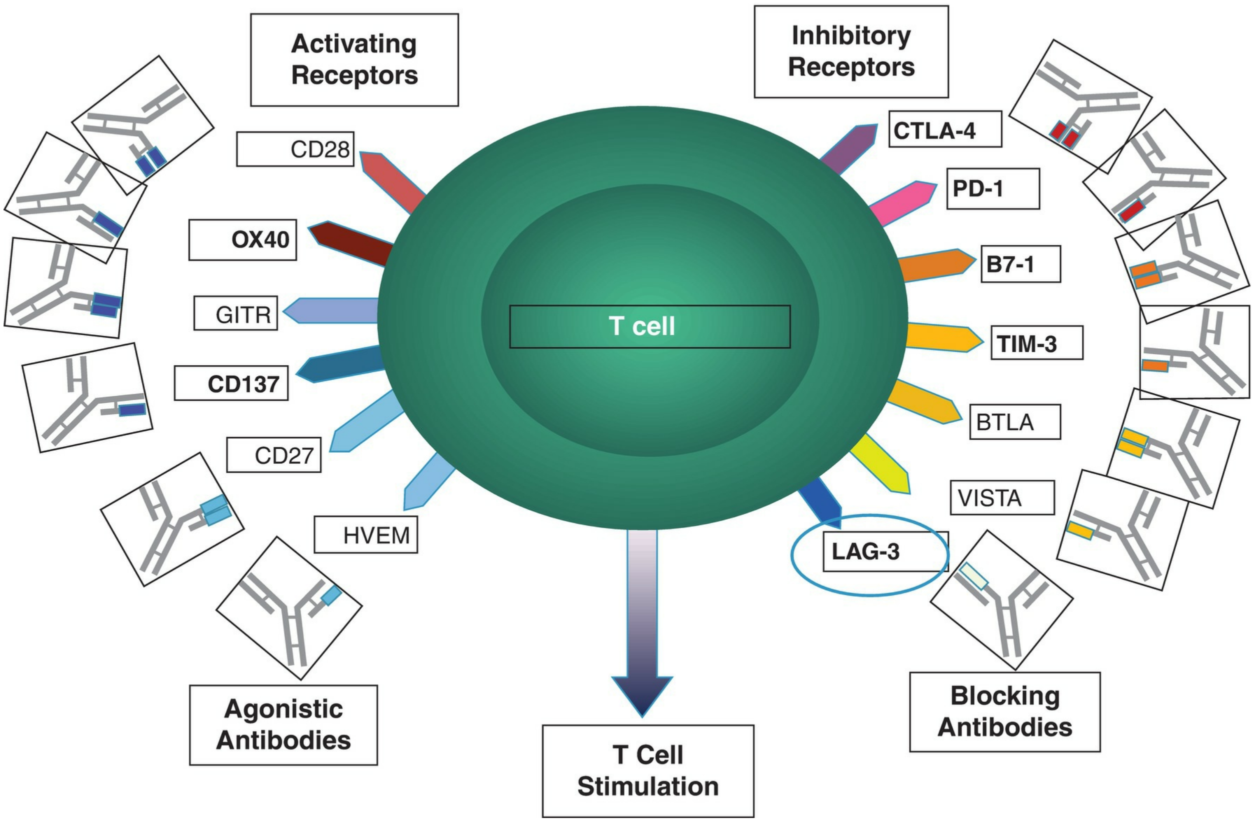

Figure 32.2. T-cell immune checkpoints as targets for immunotherapy. (Adapted and modified from Mellman I, et al. *Nature*. 2011;480:480–489.)

Interaction of Targeted Therapies with Radiation for SCCHN

Radiation therapy is a cornerstone of multidisciplinary care in patients with SCCHN, especially those with locally advanced disease. Therefore, targeted therapies are often studied in the context of radiation therapy or for their radiosensitizing properties. EGFR inhibitors and radiation therapy were discussed in detail elsewhere in this chapter, but multiple other agents have been investigated in SCCHN although the only approved targeted agent thus far is cetuximab.

Angiogenesis

The molecular mechanism through which HPV mediates tumor angiogenesis has been well established. The HPV virus integrates into host DNA and the E2 reading frame is disrupted leading to lack of repression of E6 and E7. E6 inactivates tumor suppressor protein p53. Decreased p53 causes subsequent

up-regulation of TSP-1 and VEGF. E7 inactivates tumor suppressor protein Rb. VEGF is then in turn up-regulated by HIF-1-alpha, which leads to angiogenesis. Macroscopically, abnormal vascular markings can be easily seen during direct laryngoscopy in patients with invasive SCCHN.

Bevacizumab is a recombinant monoclonal antibody that inhibits VEGF, which is responsible for angiogenesis. Ferrara's laboratory was the first to isolate and sequence VEGF.[259–261] In 1993, Ferrara reported that a mouse anti–human VEGF monoclonal antibody inhibited the growth of several tumor cell lines in nude mice.[259–261] In 1997, the anti-VEGF antibody was humanized and Genentech initiated the first phase I trials. A phase III trial of bevacizumab in addition to 5FU chemotherapy in metastatic colorectal cancer conferred a statistically significant overall survival benefit and led to FDA approval in 2004.[262] Since then, bevacizumab has had great clinical success in a wide range of different tumor types. Bevacizumab has been tested in combination with radiation. Willett et al.[263] established the safety of bevacizumab in patients with locally advanced rectal cancer who received combination of chemoradiation.

Given the relationship between HPV and angiogenesis, it is natural to imagine that bevacizumab would play a role in SCCHN. RTOG 0615 examined the use of bevacizumab concurrently with radiation and cisplatin in a phase II trial of patients with nasopharyngeal carcinoma. The addition of bevacizumab to standard chemoradiation treatment for patients with nasopharyngeal cancer showed feasibility and potentially might delay the progression of subclinical distant disease.[264] Interestingly, nasopharyngeal cancer is known to be caused by Epstein-Barr virus (EBV) rather than HPV, so the molecular mechanism for which EBV and angiogenesis are related is unclear.

Oncolytic Viruses

Preclinical literature supports the hypothesis that oncolytic viruses are effective in treating SCCHN.[265] Oncolytic viruses have synergistic effects with chemoradiation therapy.[266] In particular, vaccinia has shown efficacy above other poxviruses specifically in SCCHN.[267]

GLV-1h68 is a genetically modified, attenuated form of recombinant vaccinia that has been intensively investigated in HNC. Preclinical studies

show that GLV-1h68 infects and lyses HNSCC in vitro and in vivo.[268] Mansfield et al. have shown that cell killing by GLV-1h68 is dose and time dependent, with infectivity increasing in S-phase and sub-G1 cells.[266] In addition, radiation augments vaccinia-mediated cell death, apoptosis, and tumor xenograft regression.[266] A phase I trial in previously untreated stage III to IVB head/neck cancer at UC San Diego has found that intravenous GL-ONC1 is safe and well tolerated when delivered concurrently with radical chemoradiation therapy at radiation doses of 70 Gy and cisplatin 100 mg/m^2 delivered triweekly. Currently, there is a phase I trial of attenuated vaccinia virus delivered intravenously with concurrent cisplatin and radiation therapy in patients with locoregionally advanced SCCHN.

Histone Deacetylase Inhibitors

Histone deacetylase (HDAC) inhibitors are becoming important antineoplastic agents, which have been observed to alter transcription, differentiation, cell cycle, and apoptosis. Recent preclinical studies suggest that they have an important role in radiosensitization.[269] De Schutter et al.[270] investigated the use of HDAC inhibitors in SCCHN and found radiosensitizing doses induced histone hyperacetylation and reversal of gene silencing and increased radiation-induced cell cycle arrest. CUDC-101 is a multitargeted agent designed to inhibit EGFR, HER2, and HDAC and was tested in a phase I dose escalation study in patients with locally advanced head and neck cancer showing preliminary evidence of antitumor activity and was well tolerated.[271]

mTOR Inhibitors

Preclinical studies have shown that everolimus and other mTOR inhibitors increase efficacy of cisplatin in cancer cell lines. Everolimus has been tested in a phase 1 study with cisplatin and IMRT for head and neck cancer and was shown to be both safe at therapeutic doses of 5 mg/day.[272]

PI3K Pathway Inhibitors

Rigosertib has been shown to inhibit the PI3K pathway in many different cell lines.[273] PIK3CA alterations have been shown in SCCHN (see above). A current phase I study is testing whether rigosertib when added to

chemoradiation will improve PFS in patients with HPV-positive intermediate– or high–risk SCCHN. Preliminary data show promising activity and minimal toxicity.[273] A phase II study is currently under way in the metastatic setting.

Ras/Raf/MEK/MAPK Inhibitors

Sorafenib is a small molecule inhibitor of multiple different tyrosine kinases including Raf, VEGFR, and PDGFR and induces autophagy. In 2006, the FDA-approved sorafenib for advanced renal cancer and then for hepatocellular carcinoma in 2007. Sorafenib has been shown to sensitize SCCHN to ionizing radiation in preclinical studies.[39] Sorafenib is thought to sensitize tumor cells to chemoradiation therapy by down-regulating DNA repair proteins ERCC-1 and XRCC-1 as well as blocking angiogenesis.[274]

Immunotherapies

Preclinical models of radiation and anti-PD-1 antibodies have been shown to suppress tumor growth at both radiated and nonradiated sites and enhance the radiation therapy-induced abscopal effect.[275] The biologic mechanism for this abscopal effect is thought to be due to radiation inducing antigen-specific immune responses. In a mouse model, radiation therapy altered the immunophenotype of tumor cells and increased antigen presentation resulting in increased primary tumor control and abscopal effects outside of the radiation field.[276] The RTOG is currently developing an upfront phase II trial of cisplatin with or without nivolumab or cetuximab with or without nivolumab in intermediate-/high-risk HNSCC.

The evolution of molecularly targeted therapy in SCCHN has been rapid. Just in the last decade, we have witnessed the approval of an EGFR-directed antibody, cetuximab, and a tremendous increase in the understanding of SCCHN biology. There are currently several agents in phase III testing covering a plethora of drugs and mechanisms. The hope of all these trials is to improve long-term outcomes and cure rates in this disease.

33 Rehabilitation of Swallowing and Speech in Patients Treated for Cancer of the Head and Neck

Jan S Lewin.

INTRODUCTION

Unlike past decades in which functional rehabilitation of speech and swallowing was often considered an afterthought once definitive treatment of the head and neck cancer was completed, functional preservation, that is, the ability to eat, drink, and speak normally, shares a primary goal with cure and survival in the contemporary management of patients with cancer of the head and neck. Patients who were once satisfied if not grateful to be cured of their cancer, whether or not they could eat or speak, currently expect that verbal communication and the ability to swallow without aspirating will remain intact after treatment, with a spontaneous ability to return to a normal daily routine once they have recovered from treatment. Unfortunately, as organ-sparing treatment alternatives for head and neck cancer have intensified, and their ability to cure the disease has improved, the short and long-term effects on speech and swallowing have become even more severe. Treatment regimens have become stronger, frequently combining surgical and nonsurgical alternatives, given in regimens and doses that often result in significant anatomical defects, severe fibrosis, and long-term neuropathies that can cause irreversible damage to the upper aerodigestive tract (UADT), that in some instances, relegate the patient to a tracheostomy and gastrostomy tube dependence.

The diagnosis of cancer of the head and neck, the tumor itself, and the consequences of its treatment can impart a tremendous impact on the individual’s physical, physiologic, psychological, and social functioning. The

diagnosis itself will almost certainly be associated with concerns regarding body image, self-concept, self-esteem, and the ability to return to work and social interactions. However, in all cases, cancers of the head and neck will, to some degree, affect speech and swallowing function that will require accurate evaluation and targeted rehabilitation from clinicians with critical expertise and experience managing patients with cancer of the head and neck. Pretreatment evaluation and counseling and posttreatment intervention must be timely and precise to optimize patient outcomes and successful recovery. Hence, treatment based on limited knowledge and inaccurate interpretation of evaluations remains ineffective and useless.

Over the past two decades, there has been a paradigm shift away from ablative surgery to organ preservation with an associated emphasis on quality of life, function, and the cost of treatment. For patients with early cancer of the larynx, the treatment dichotomy generally remains a decision to use laser excision of the cancer or to treat with radiation therapy. For patients with advanced cancer of the larynx, the contemporary focus is also to preserve the larynx. Unfortunately, elevated rates of speech and swallowing dysfunction prevail. Hence, in some cases, questions have arisen as to the true benefit of organ preservation versus total organ resection using contemporary surgical–prosthetic methods of voice restoration and early swallowing exercise regimens to maintain acceptable oral communication and prevent long-term dysphagia.

Likewise, for patients with cancer of the oropharynx, the question regarding the optimal treatment alternative also continues to be investigated and debated. Today’s patient with cancer of the oropharynx is generally younger than his or her older counterpart, often in the fourth or fifth decade of life, with a better prognosis for survival, and is adamant about the ability to return to a normal routine of work and social activities after treatment. Thus, posttreatment morbidity and function have become primary considerations in decisions regarding the contemporary treatment of cancer of the oropharynx. Despite ongoing investigation, the clear advantage of new endoscopic surgeries (eHNSs) of the head and neck using laser and robotic resections versus nonsurgical alternatives that use intensity-modulated radiation therapy (IMRT) with photon or proton beams, or adaptive radiation protocols, to preserve function, is still being investigated.

What we have learned over the past several decades is that patients’ goals

have not changed significantly; their posttreatment expectations continue to be able to eat and swallow by mouth, to speak using their natural laryngeal voice, and to keep their appearance unchanged. Patients' self-perception of their ability to eat and drink is often inaccurate and incongruous with the findings seen on instrumental tests; that is, what is seen on objective examination does not always corroborate the patients report. Experience and investigation have demonstrated that in patients who have been treated with radiation therapy, severe dysfunction, primarily dysphagia, often occurs late, years after the cancer treatment has ended, and is most often refractory to current standard methods of behavioral dysphagia therapy. Likewise, high rates of aspiration that are often silent (without patient awareness) and result in aspiration pneumonia and chronic gastrostomy tube dependence remain common occurrences and are also associated with elevated rates of dysphonia and vocal fold paralysis particularly after surgical treatment for cancers of the head and neck. Finally, data demonstrate that anatomical preservation does not ensure functional preservation nor is the potential for recovery a guarantee for successful functional results. Likewise, outcomes will vary in terms of both the response to the cancer treatment as well as the long-term speech and swallowing results. Thus, the exact predictors of functional outcomes still remain unknown.

Normal Speech and Swallowing Function

Speech and swallowing are highly complex processes that depend on a series of neuromuscular events that rely on rapid, highly coordinated, and precisely executed movement. The sequence of the motor events involved in both speech and swallowing is fairly predictable, although in the case of swallowing, investigators have shown that the relative timing of these events varies, depending on the size and consistency of the bolus of food or liquid being swallowed.[1–3] In general, speech production is affected primarily by cancers that involve the oral tongue or other structures of the oral cavity, whereas swallowing can be affected by any cancer within the aerodigestive tract. However, in most instances, the greatest impact on swallowing occurs from tumors that affect the base of the tongue or pharynx.[4]

Speech production and intelligibility depend on precise sequences of movement and contact by the articulators of the oral cavity, mainly the lips, tongue, and soft palate, that rapidly change the configuration of the vocal

tract. Although articulation is the main contributor to speech intelligibility, speech understandability is also influenced by voice quality and resonance. Hence, any cancer that affects structures other than the tongue, such as those that impact the larynx, specifically vocal fold function, or fill the recesses of the naso-, oro-, or laryngopharynx, will result in changes in the quality of the voice (loudness, pitch, resonance) and also indirectly influence speech intelligibility. The place of articulatory contact may be bilabial (m, p, and b) or it may be velar (k and g). Whether the sound is nasal or voiced depends on the valving action from the velum, which requires a lowering of the soft palate for nasal sounds (m, n, and ng) or valving from the larynx that involves the opening or closing of the vocal folds to produce the voiced distinction between various sounds (p and b, t and d, k and g). In the case of vowels, the shape and height of the tongue are the key determinants of sound distinction. Thus, a cancer that involves the oral cavity, pharynx, or larynx will have some effect on speech and voice production and ultimately on conversational intelligibility.

The act of swallowing can be divided into four unique stages, the oral preparatory, oral, pharyngeal, and esophageal phases that involve more than 30 pairs of muscles and six cranial nerves. Each of these stages depends on intact neurologic function and anatomy with the triggering of each successive stage dependent on the timely occurrence of the previous one. Variations in normal anatomy that affect size, shape, or symmetry have little significant impact on swallowing in healthy individuals but may result in impaired swallowing or further decompensation including aspiration in an otherwise debilitated patient.[5] In general, the oropharyngeal swallow begins at the lips and ends as the bolus enters the cervical esophagus at the level of the cricopharyngeal inlet and involves both voluntary and involuntary control mechanisms, and the entire oropharyngeal swallow should take no longer than 1 to 2 seconds in normal individuals.[6] Only the oral preparatory, oral, and pharyngeal stages can be addressed by behavioral therapies, as the esophagus is a relatively less complex muscular tube, for which the main therapeutic maneuver is dilation. Although the gastrointestinal radiologist and the speech pathologist work together to diagnose abnormalities associated with swallowing function, diagnosis of abnormalities associated with the esophageal stage of swallowing remains the responsibility of the diagnostic radiologist.

Risk and Predictors of Dysfunction

Tumor site and extent and treatment intensity are the key clinical predictors of functional outcomes after organ preservation.[7] Data demonstrate that among cancer sites treated with radiation or chemoradiation regimens, cancers of the hypopharynx portend the worst functional outcomes. Both cancer of the hypopharynx and combined regimens of chemotherapy and radiation are associated with the highest rates of swallowing-related dysfunction including dysphagia, stricture, and pneumonia when compared to other cancer sites such as the tongue, larynx, and oropharynx or single-modality treatments or a combination of surgery and radiation therapy.[8] Although data suggest that the staging of the primary cancer of the head and neck carries a prognostic significance per TNM criteria, T stage appears to be the most consistent staging variable that impacts long-term function, often predicting the severity of dysphagia, gastrostomy dependence, and aspiration after treatment of cancer of the head and neck. Oropharyngeal primary cancers have the second highest risk of dysphagia after treatment. A 39% to 64% prevalence of long-term dysphagia has been documented in patients with cancer of the head and neck treated with combined regimens of chemotherapy and radiation.[8,9]

Changes in voice remain the primary complaint in more than 75% of patients treated for early laryngeal disease (T1-T2) regardless of the treatment modality, and although subjective reports of long-term vocal outcomes are generally comparable, better acoustic and perceptual measurements have been reported in patients treated with radiation therapy.[10] Swallowing is generally not a complaint of patients treated for early cancer with a similar reported quality of life for both groups. However, the increased financial impact for patients treated with radiation therapy and the patient burden of missed work hours, travel time and distance, and the number of hours associated with treatment delivery are often concerns of patients selected to receive radiation therapy, in favor of surgical alternatives such as endoscopic laser procedures.

For patients with early cancer of the larynx who have been treated with radiation therapy, a continued history of smoking after completion of treatment has been shown to be associated with lower fundamental frequency changes in the voice and poorer vocal quality when compared with results in

nonsmokers.[11] Cancers that affect the anterior commissure generally result in patient complaints related to weak, breathy vocal quality and problems with pitch variation similar to the complaints of patients who have received larger volumes and doses of radiation (>60 Gy).[12] In contrast, superficial cancers of the true vocal folds have been shown to result in better vocal outcomes after laser resection than do cancers that are deeply invasive into the muscle of the true vocal fold. Large bulky cancers that invade the vocal fold or involve the anterior commissure put the patient at risk for poor vocal quality that is often weak in intensity and breathy in quality because of the large postoperative glottic defect that results in glottic incompetency for voice production. Unfortunately, there are few options for vocal improvement, behavioral or surgical, in these instances, and practice has shown that patients often experience better vocal outcomes after radiation therapy in lieu of a large defect that limits the ability to compensate or restore the voice after resection. Our anecdotal experience suggests that most patients still remain more willing to accept a poor voice in favor of the decreased patient burden associated with laser resection.

Alternatively, patients with advanced (T3-T4) cancer will experience greater and more severe functional debilitation particularly after organ preservation. More than 90% of patients will complain of dysphonia, of which ~25% will report severe vocal disabilities. Up to 10% mortality rates associated with aspiration pneumonia have been reported in treated patients with advanced cancers of the head and neck.[13] Late-occurring dysphagia and aspiration remain common with reported rates of silent aspiration as high as 70% in patients who aspirate[14,15] and rates of percutaneous gastrostomy (PEG) tube placement between 70% and 80% with long-term dependence >12 months between 5% and 15%.[7] Unfortunately, early recovery of swallowing may be misleading because of the delayed fibrosis and neuropathy that can eventually result in laryngopharyngeal dysfunction inhibiting the ability to swallow by mouth.

The cancer-related risk factors for long-term swallowing dysfunction generally have included advanced T stage, primary cancers that involve more than 50% of the base of tongue,[9,16,17] cancers that involve the tonsil and extend to the pharyngeal wall, and cancers with advanced cervical lymph node metastases. Patients who are nutritionally compromised and who demonstrate pretreatment changes in diet, G-tube placement, weight loss, or

malnutrition are at significant risk for long-term dysphagia. In addition, patients with persistent or recurrent cancer who require salvage procedures such as surgery or who present with comorbid diseases such as chronic obstructive pulmonary disease (COPD), diabetes, neuromuscular degenerative disease, substance abuse, or continued smoking, among others, also remain at high risk for poorer swallowing outcomes.

We are just beginning to understand the risk factors associated with long-term dysphagia after radiation or chemoradiation treatment. Studies have demonstrated that patients who have difficulty swallowing before treatment are also at higher risk for chronic dysphagia and permanent feeding tube dependency.[18] Likewise, prolonged intervals of nothing per oral (NPO) longer than 2 weeks during radiation or chemoradiation treatment are associated with poorer swallowing outcomes.[19] Therefore, it is important that patients are encouraged to eat and swallow as much as possible throughout the course of treatment, and even brief periods of NPO should be avoided.[20]

Finally, the viewpoint and preferences of the patient and the support of family and friends are essential components of treatment acceptance and compliance and ultimately long-term functional success. The psychological/psychosocial characteristics such as patient attitude, the attitude of the physician, particularly the surgeon, and the speech pathologist, and the attitude/support of the spouse or significant other have been found to be strongly related to successful functional outcomes. When the views of important others are nonsupportive, patients are less likely to achieve successful outcomes because of the detrimental effect on patient motivation, treatment adherence, and encouragement.[21–23]

The Interdisciplinary Team

Patients with cancer of the head and neck face multiple, often severe functional and psychological challenges associated with the diagnosis and treatment of their disease. Successful treatment for cancer of the head and neck and posttreatment rehabilitation depend on a strong, collegial interdisciplinary team for management. This is a point that cannot be overemphasized. Pretreatment evaluation and planning for functional rehabilitation should begin immediately after diagnosis and involve the entire oncologic care and rehabilitative team. After assessment and diagnosis by the

surgeon, the patient should, at minimum, meet with the radiation oncologist, medical oncologist, dentist or maxillofacial prosthodontist, speech pathologist, nurse, dietitian, and social worker. Specialists from other disciplines such as physical therapists and psychologists, among others, may also be needed and should be called to help when indicated. In particular, the need for speech and swallowing therapy is often an unexpected recommendation that both the patient and family frequently find difficult to accept because the ability to speak and swallow after treatment is commonly anticipated to be regained automatically without need for intervention. Experience has shown that recovery and rehabilitation are optimized when there is ongoing dialogue between all members of the interdisciplinary team and information is similarly provided to the patient by all members of the group.

Evaluation

Standardized functional assessments remain a critical component of comprehensive patient care and outcomes research. Pretreatment examination should establish a baseline for treatment planning and later posttreatment comparison. Baseline evaluation is critical because it documents pretreatment function and often is helpful in predicting long-term outcomes. A complete functional examination includes clinical assessment that depends on clinician appraisal during physical examination, such as the bedside swallowing examination, cranial nerve examination, and oral motor assessment among others. Clinician-driven examinations also include instrumental and imaging studies, as well as clinician-rated scales. In addition, a comprehensive functional examination must also recognize patient perception and therefore include patient-reported outcomes (PROs) such as quality-of-life questionnaires and symptom performance inventories.

Rehabilitation, and even more important, rehabilitative planning, should begin at the time of cancer diagnosis with patient counseling and a thorough baseline evaluation provided by a speech pathologist who is an expert in the evaluation and treatment of functional disorders associated with head and neck malignancies and their treatment. Baseline swallowing evaluation that includes instrumental examination, such as the modified barium swallow (MBS) study or flexible endoscopic evaluation of swallowing (FEES), documents important functional elements such as the presence of aspiration

and airway protection that have been found to be strongly predictive of long-term swallowing dysfunction. Aspiration, vocal fold paresis, feeding tube dependence, and tracheostomy prior to treatment have been reported as adverse prognostic indicators of posttreatment functional recovery.[7] Moreover, aspiration of thin liquids sufficient enough to necessitate dietary modifications before cancer treatment or an NPO status prior to beginning treatment significantly predicts swallowing dysfunction requiring NPO status in long-term laryngeal cancer survivors.[18] Additionally, it is important to determine the pretreatment effect of the cancer on swallowing as a decline in swallowing after radiation or chemoradiation treatment may not be related to fibrosis or posttreatment deconditioning but in fact may represent the loss of compensation for a cancer-related dysfunction once the cancer has been cured.

Most important is that pretreatment baseline assessment provides critical information in select patients for whom survival is comparable regardless of surgical or nonsurgical alternatives but whose function, swallowing and voice, may be improved with one of either modalities. Baseline evaluation also helps to identify those patients with pretreatment dysphagia or who are at significant risk for posttreatment swallowing dysfunction to ensure therapeutic placement of gastrostomy tubes as opposed to the common practice of prophylactically placing feeding tubes in all patients. Recent data indicate that patients with pretreatment dysphagia, whether self-reported or documented by instrumental evaluation, treated with radiation ± chemotherapy for cancer of the oropharynx, experience more frequent placement and longer gastrostomy tube duration beyond 6 months than do patients with adequate oral intake prior to treatment ($p < 0.001$).[24]

Finally, the results from baseline evaluation provided during patient counseling offer realistic posttreatment functional expectations that frequently facilitate patient understanding, acceptance, and compliance with both cancer and rehabilitative treatment recommendations. Baseline evaluation allows clinicians to assess outcomes and draw conclusions that cannot be determined without appropriate pretreatment functional examination. It is for these reasons, among others, that pretreatment referral to speech pathologists for baseline functional evaluation has been recognized as best practice for all patients particularly for patients treated with nonsurgical organ preservation.[25,26]

METHODS OF EVALUATION

Clinical/Bedside

The clinical evaluation is useful because it is based on observation in a more natural, relaxed environment that is often representative of actual patient routine. However, it is important to remember that clinical observation lacks the sensitivity of instrumental examination. The most common clinical assessment of swallowing is often referred to as the bedside examination. The bedside swallowing examination always precedes the instrumental (MBS, FEES) study. It provides a basic screening to identify patients who have a “functional” swallow and who do not require instrumental examination. The clinical examination also allows the clinician to help determine the timing or readiness to begin oral intake. Not all patients require instrumental examination as these tests are often expensive and impractical and are associated with a resource burden that can be avoided when clinical examinations are performed accurately and in a timely fashion.

The clinician should obtain a thorough case history and perform a comprehensive evaluation of motor speech functioning that allows the development of a hypothesis of swallowing competency and dysfunction related to neurologic functioning and patterns of movement. Again, clinical examinations provide important information that is critical to the patient’s functional status. However, it is important to remember that bedside observation of swallowing function cannot reliably determine or rule out silent aspiration. Nor can observation reliably diagnose pharyngeal swallowing disorders because the problems that occur during the pharyngeal stage of swallowing must be inferred by the clinician. Despite this limitation, the examiner can detect signs and symptoms suggestive of pharyngeal swallowing impairments during clinical observation and evaluation. The goal of the clinical examination is to synthesize the overt as well as the subtle observations and use this knowledge to make recommendations including the need for further, more objective swallowing assessment.

Patient-Reported Outcomes

A variety of assessments are available to assess both speech and swallowing that include both quality-of-life and symptom performance scales. Measures

of patient report rely on patient perception of functional status. Data, however, have shown that patients' report of their functional status is frequently unreliable and more often does not accurately reflect physiologic performance and actual abilities.[27] Patients frequently report normal swallowing despite abnormal findings of silent aspiration shown on MBS examination.[28,29] Conversely, patients also report abnormal swallowing function associated with radiation-induced xerostomia despite functional MBS findings. Several noninstrumental tools have been shown to be good indicators of functional status particularly in patients with cancer of the head and neck. The Performance Status Scale for Head and Neck (PSS-HN) assesses three areas, normalcy of diet, understandability of speech, and eating in public, and is a simple clinician-rated tool that can provide valuable indicators of both speech and swallowing function.[30] The MD Anderson Dysphagia Inventory (MDADI) is a 20-item patient-reported instrument, scored on a scale from 1 to 5, consisting of global, emotional, functional, and physical subscales that evaluate the effects of dysphagia on quality of life (QOL) from the patient's perspective.[31] Alternatively, the Functional Oral Intake Scale (FOIS)[32] is another simple, validated tool that helps quantify the functional status of the patient with regard to feeding tube dependence and level of oral intake.

In addition, a variety of assessments are available to evaluate vocal functioning. Among them are the Voice-Related Quality of Life (V-RQOL),[33] the Voice Symptom Scale (VoiSS),[34] and the Voice Handicap Index (VHI-30)[35] and its shortened version VHI-10.[36] The Consensus Auditory–Perceptual Evaluation of Voice (CAPE-V)[37] is a frequently used measure of voice perception that provides clinician-rated assessment of such vocal parameters as roughness, asthenia, breathiness, and strain.

Although there are multiple tools for assessing voice and swallowing function, there are relatively few assessments specifically designed for evaluation of speech intelligibility. The Speech Handicap Index has been validated for use in the head and neck population.[38,39] Although the Assessment of Intelligibility of Dysarthric Speech[40] has not been standardized for use in patients with cancer of the head and neck, it provides valuable information regarding articulation for therapeutic planning that is often beneficial for patients with cancer of the head and neck. In addition, the understandability of speech component of the PSS-HN provides a simple and

quick clinician-rated assessment of the intelligibility of speech production that is graded by a single score (0 never understandable to 100 always understandable).

The importance of patient experience and opinion as critical components of functional recovery and performance should not be disregarded. However, only instrumental examination, such as the MBS study or FEES, in the case of swallowing function, and direct observation of vocal fold function using endoscopy or stroboscopy, can provide physiologic information that ultimately identifies the etiology of dysfunction. Both anecdotal experience and research findings support the recognized discrepancy between patients' perception of their handicap versus instrumental evaluations that examine physiologic aspects of function. Therefore, comprehensive examination should include both the findings from PRO measures along with those from instrumental evaluations of speech and swallowing abilities to ensure accurate interpretation of functional status.

Modified Barium Swallow Study

The most widely used and likely still the gold standard of instrumental swallowing evaluations remains the MBS examination, also referred to as the videofluoroscopic assessment of swallowing. This is because the MBS study evaluates the entire oropharyngeal swallow, from the point at which the food passes the lips to the time it enters the cervical esophagus. The MBS study is performed jointly by a speech pathologist and a radiologist. The examination should be performed in standard fashion including the use of radiopaque liquids, pastes, and solid consistencies as swallowing physiology will vary depending on the consistency and the amount of food presented. The MBS study is the examination of choice for swallowing assessment versus the traditional barium swallow study or esophagram, the purpose of which is to evaluate the structural integrity of the pharyngoesophagus and identify aspiration during continuous swallowing of a large liquid bolus. Furthermore, the barium esophagram does not provide the information necessary to identify dysfunction of oropharyngeal swallowing nor do the results allow a differential diagnosis of the etiology of aspiration.

The primary purpose of the MBS examination is to understand oropharyngeal swallowing physiology as it relates to swallowing dysfunction. A number of important observations can be made from the MBS study that

include the presence of penetration of swallowed material into the laryngeal vestibule and the degree of aspiration into the trachea using the validated Penetration–Aspiration Scale.[41] The efficiency of the swallow can also be measured and quantified with the oropharyngeal swallowing efficiency (OPSE) score.[42] In addition, the Dynamic Imaging Grade of Swallowing Toxicity (DIGEST) scale offers a novel grading schema that summarizes the interaction between swallow safety measured by penetration aspiration events and swallowing efficiency estimated by pharyngeal residue, in a psychometrically validated scale. One of the advantages of the MBS study is that the examiner can immediately assess the effectiveness of selected swallowing techniques and strategies to relieve the dysphagia during study administration.[43] Most important, videofluoroscopic findings during MBS examination document swallowing physiology, laryngeal sensation, and aspiration and have been reliably associated with health risk prediction rates particularly for pneumonia.[29]

Figure 33.1 shows a lateral radiographic view of normal oropharyngeal anatomy prior to swallow initiation during the MBS study. No evidence of aspiration or residue is seen following swallowing completion as shown in **Figure** 33.2. **Figure** 33.3 demonstrates aspiration associated with disordered swallowing function.

Figure 33.1. Lateral radiographic view of normal oropharyngeal anatomy seen during MBS examination.

Figure 33.2. Normal swallowing results during MBS examination. Note the lack of tracheal aspiration or oropharyngeal residue after the swallow is completed.

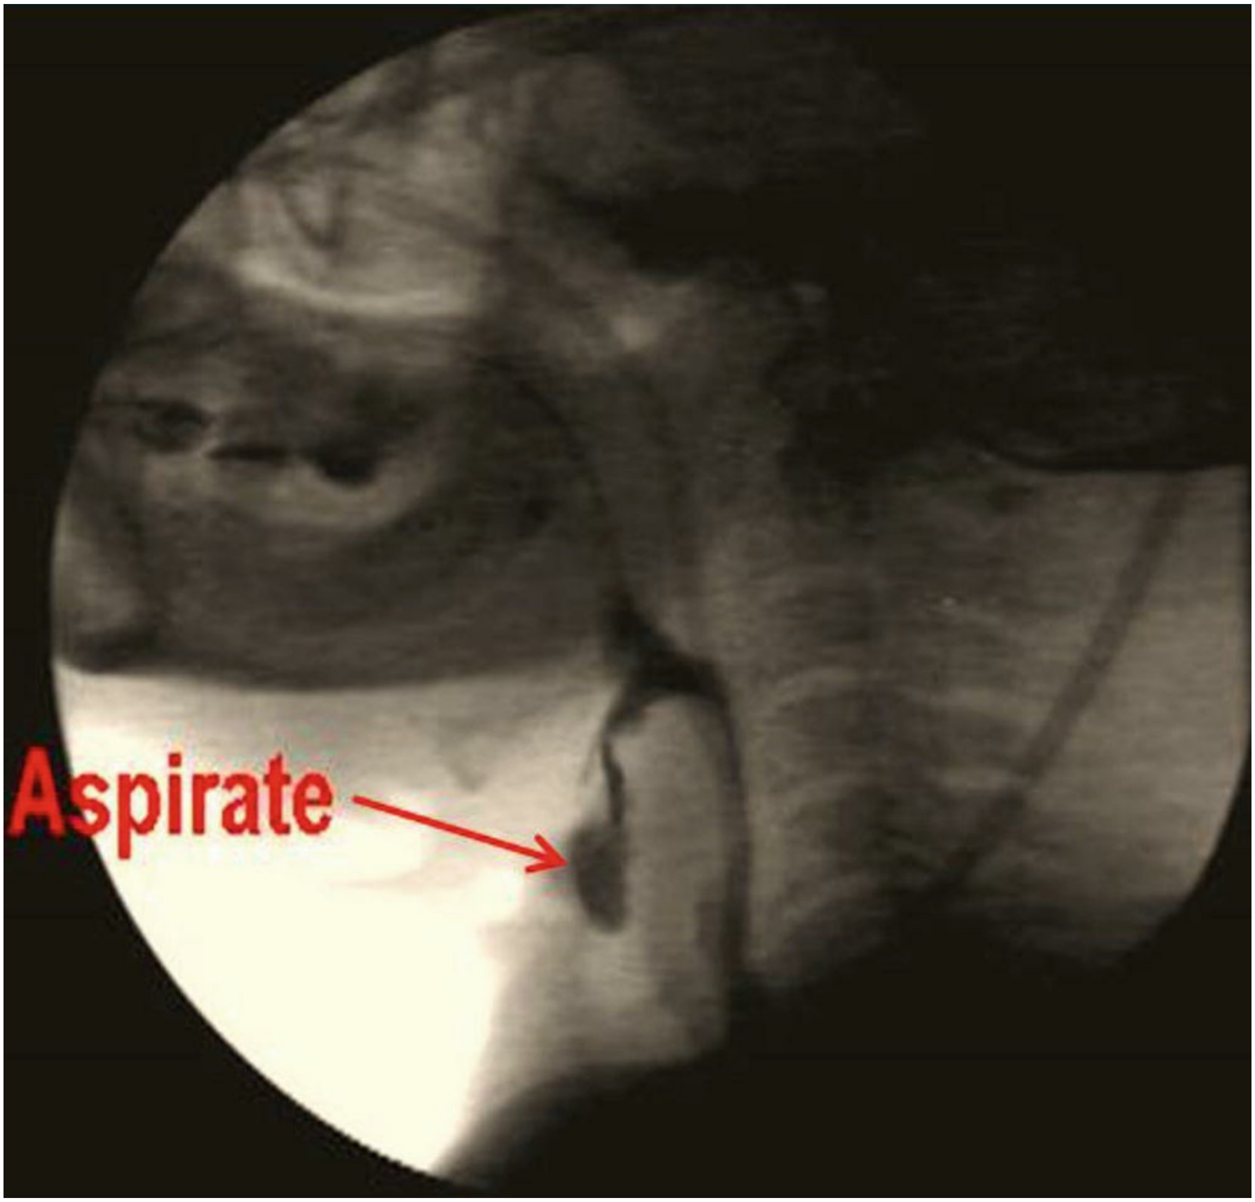

Figure 33.3. Aspiration is shown on MBS examination.

Flexible Endoscopic Evaluation of Swallowing

In some cases, FEES provides an excellent alternative to the MBS study because it can be easily performed as a clinical procedure or at bedside for patients who cannot tolerate or are not candidates for videofluoroscopic examination of swallowing. FEES uses a flexible endoscope placed transnasally to examine the pharyngeal swallow while providing direct visualization of laryngeal anatomy. FEES has been shown equally effective to the MBS study in detecting aspiration and does not expose the patient to

radiation.[44] It is often preferred for patients who have cancer of the larynx because it provides the best view of glottic competency, including airway protection and vocal fold mobility. An additional advantage of FEES is that it can be paired with simple sensory testing to help determine laryngeal sensitivity unlike the MBS study in which this is difficult to do.[45] Furthermore, it provides the patient with immediate biofeedback and visualization that are often useful during therapy sessions.

Unfortunately, the disadvantages of FEES often preclude its use for swallowing assessment in patients with cancers of the head and neck, particularly those that involve the oral cavity and the oropharynx. Neither the oral preparatory nor the oral phases of the swallow can be visualized during FEES. Thus, dysfunction must be inferred or presumed because of the "white-out" that occurs at the onset of the pharyngeal stage of swallowing that obscures visualization during the peak of deglutition. **Figure** 33.4 illustrates the laryngopharyngeal anatomy observed during FEES. Significant swallowing dysfunction is seen in **Figure** 33.5 during an FEES examination.

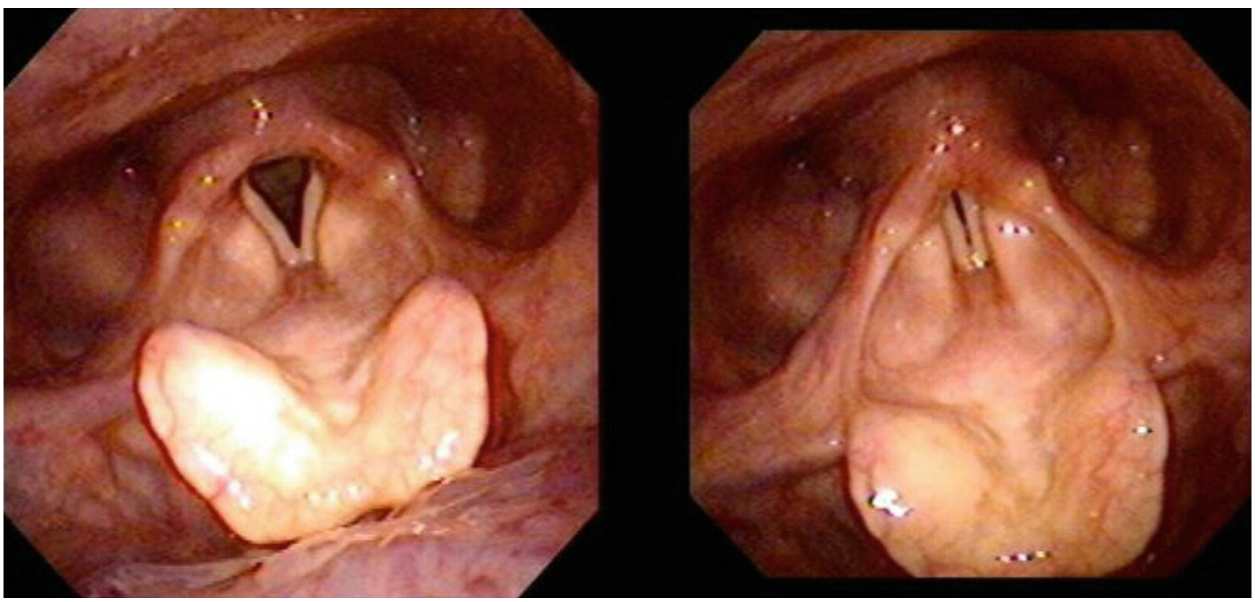

Figure 33.4. Fiberoptic view of laryngopharyngeal anatomy seen using FEES.

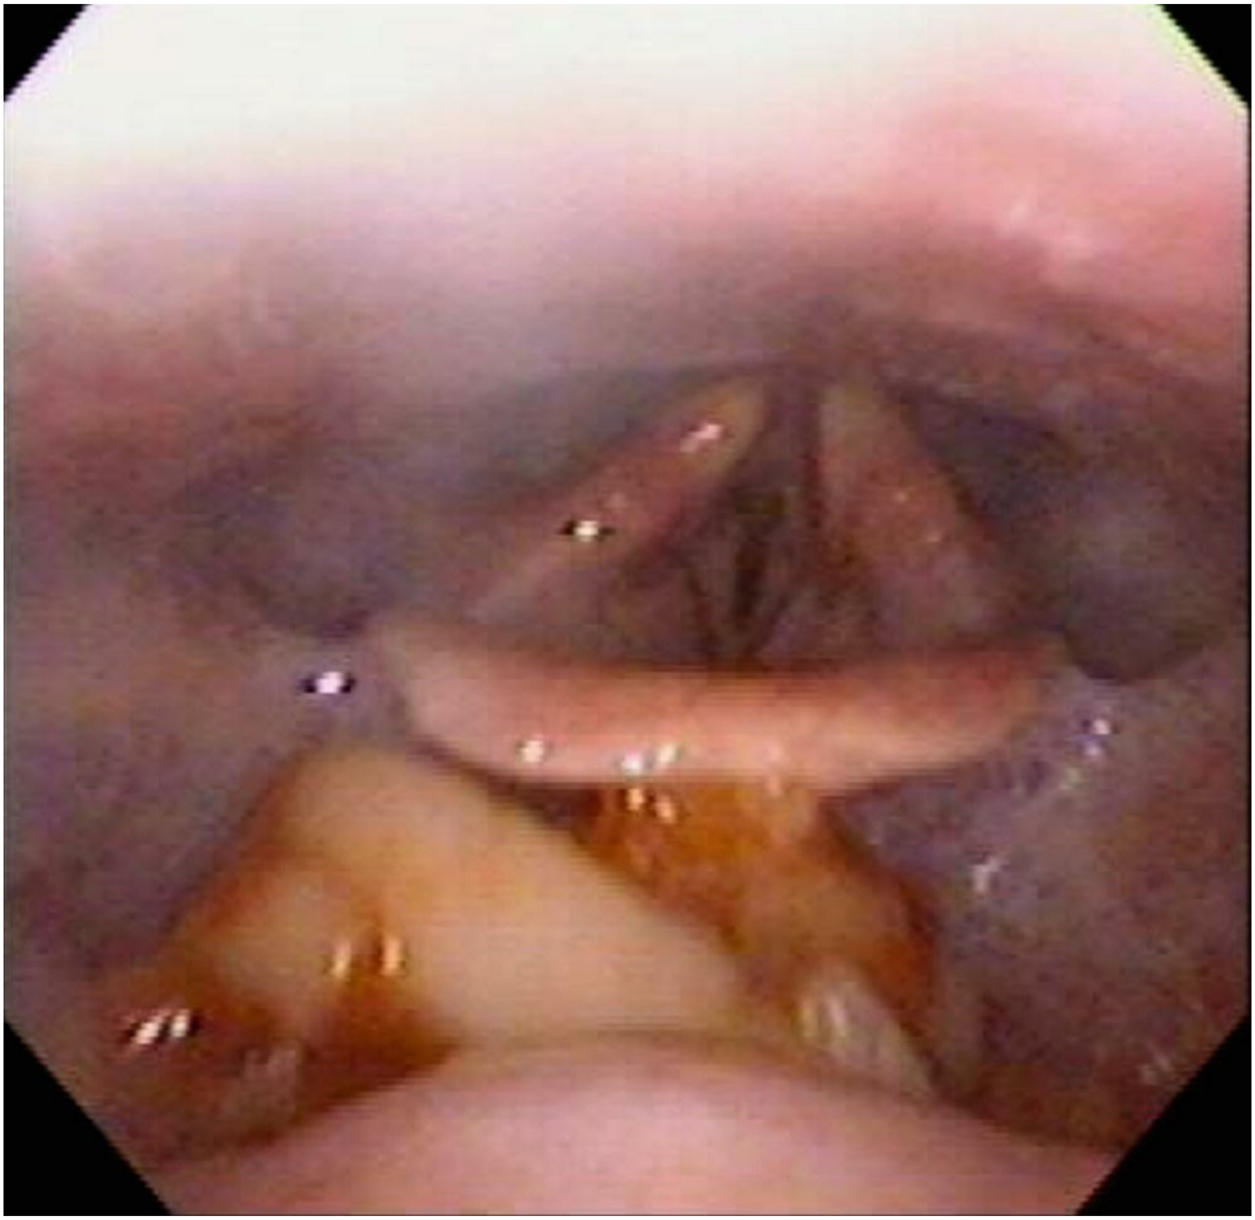

Figure 33.5. Abnormal FEES examination showing remaining significant amount of food in vallecular region after the swallow.

Laryngeal Videostroboscopy

Traditionally, evaluation of glottic functioning has relied on mirror examination of the larynx. Laryngeal videostroboscopy builds on the technique of mirror examination to visualize the glottis but also allows detailed examination of true vocal fold vibration to assess voice production. Laryngeal videostroboscopy should be coupled with acoustic and aerodynamic measures to accurately capture and document dysphonia. Most

critical is that laryngeal videostroboscopy remains one of the most useful tools to examine patients with cancer of the head and neck and vocal abnormalities because it exploits the limitations of observation with the unaided eye.

Videostroboscopic assessment employs the use of an endoscope that is placed transorally or transnasally and emits a straight and pulsed light to assess vocal fold movement and vibration. Videostroboscopy is generally performed as an office procedure. It affords a clinical measurement of movement that provides an illusion of slow motion and is a key diagnostic tool to visually assess pathology and function. Videostroboscopic imaging is not simply a photo, but rather it provides documentation of known disease and visualization of overall laryngeal anatomy and glottic functioning. It allows serial documentation and monitoring of change related to the treatment of laryngeal cancers. Because of the ability to evaluate vibratory function layer by layer, the trained examiner has an improved ability to determine the depth of vocal fold, superficial versus deep, that is prognostically important for decisions regarding surgical or nonsurgical treatment selection particularly for glottic cancers. In some instances, an early change seen on videostroboscopic examination may provide early indication of a cancer that would otherwise be invisible to the naked eye using indirect endoscopic visualization.

Finally, the use of videostroboscopy in the head and neck clinic often complements the images seen on CT scans because of the limitation in detection of subtle disease seen in the true vocal folds. The addition of laryngeal videostroboscopy frequently offers a greater capability for improved diagnostic accuracy of vocal fold disease. **Figure** 33.6 shows the image shown using a straight light during indirect visualization compared with **Figure** 33.7 that shows the vibration resulting from generation of a mucosal wave that can be seen using videostroboscopy.

FUNCTION AFTER SURGERY

Postoperative speech and swallowing function basically depend on the primary site of tumor, the surgical approach, the type of reconstruction, and the extent of neck dissection. The addition of radiotherapy or chemoradiation as an adjuvant treatment after definitive resection of cancers of the oral cavity can exacerbate postsurgical effects because of the associated postradiation fibrosis and neuromuscular insult that will, in turn, impact laryngopharyngeal function.

In most cases, the extent of the cancer resection and the resulting surgical defect will determine the need for and the type of reconstruction. However, in general, larger defects that are reconstructed with adynamic, bulky flaps that

overfill the surgical defect will result in worse speech and swallowing outcomes. Primary closure generally is associated with the best postoperative function in selected reconstructions of the oropharynx.[46,47] Because of the increased use of nonsurgical organ preservation procedures in contemporary practice to improve locoregional control and preserve function for many patients with advanced cancer of the head and neck, the use of ablative surgeries has dramatically declined. Therefore, the popularity of traditional open surgeries such as the supraglottic laryngectomy and vertical partial laryngectomy that were often associated with increased complications and longer, more difficult rehabilitation and recovery has waned. Thus, open surgeries are primarily reserved for use as salvage procedures in cases of residual or recurrent cancers of the larynx and pharynx. As demographics change with an increasing percentage of head and neck cases being HPV-related oropharyngeal cancers, patients are now younger and healthier with a better prognosis for long-term survival. Hence, minimally invasive procedures that offer oncologic equivalency but result in quick recovery and rapid return to normal routine have become an expectation and a preference of today's patient with cancer of the head and neck.

Oral Cavity

Surgical resection remains the primary treatment modality used for cancers of the oral cavity.[48,49] In cases of cancer of the oral cavity, resection of critical structures of the oral cavity disrupts oral physiology and will result in problems with the oral stage of swallowing such as mastication and lingual propulsion. In addition, surgery that significantly impacts lingual structure and excursion are also associated with poorer swallowing outcomes. Surgical defects of the oral cavity are challenging to reconstruct because they require enough tissue to separate the oral cavity from the neck, prevent pooling, preserve remaining mobility, and restore anatomical configuration, but at the same time, they must avoid overcorrection with tissue bulk that obstructs oral swallowing function. Data have shown that the best swallowing outcomes result from partial resections that remove less than half of the tongue that are closed primarily.[50] Despite the ability to restore some sensation using new surgical techniques with innervated cutaneous free flaps, the ability to restore movement and function continues to be challenging, and no consensus has been reached regarding the functional benefit to both speech and swallowing

in patients who have undergone reconstruction with sensate flaps.[51]

Cancers of the oral cavity particularly those that involve the tongue most commonly impair articulation. However, in most cases, speech remains largely intelligible [sentence level (blinded rating): 92% to 98% intelligible] for surgically treated patients with advanced-stage cancer of the oral cavity (T stage ≥2) including cancers involving the tongue, but articulatory errors are common. Again, most patients will ultimately acquire good intelligibility after partial or hemiglossectomy that preserve half or more of the native tongue, but outcomes are more variable after subtotal and total glossectomy.[52] Besides articulatory defects, treatment of cancers of the oral cavity often affects oral speech resonance. Resection of cancer of the maxilla generally results in some degree of hypernasality until successful prosthetic obturation or surgical reconstruction of the defect is achieved.[53,54]

Swallowing efficiency (prolonged bolus transit times and incomplete bolus clearance) is commonly impaired after surgical management of advanced-stage cancers of the oral cavity, but chronic aspiration is less common (12% to 25% prevalence). Moreover, most patients with cancer of the oral cavity malignancies report the greatest degree of difficulty swallowing dry or hard foods.[55]

Oropharynx

Cancers of the oropharynx arise in a region of the UADT critical to swallowing function, and thus, pharyngeal dysphagia is the primary functional deficit after treatment. Minimally invasive surgery, specifically transoral robotic surgery (TORS), is fast becoming a preferred alternative over open surgical procedures or definitive chemoradiation for the treatment of oropharyngeal tumors. Likely, the primary advantage of TORS is the ability to preserve the suprahyoid muscles, which are critical for swallowing. Tracheostomy, typically required for airway management after open resection, is also avoided in most TORS cases (70% to 100%). Furthermore, lower rates of PEG tube placement (18% to 23%) and chronic PEG dependence (0% to 7%) after TORS are lower than those reported in patients receiving definitive chemoradiation. Finally, data suggest that 9% to 27% of patients treated initially with TORS avoid postoperative radiotherapy, and 34% to 45% avoid chemoradiotherapy.[17,56–59]

Larynx and Hypopharynx

The larynx plays a key role in both speech and swallowing function. It is the primary source of phonation for speech production. Its ability to move both superiorly and anteriorly is key to preventing saliva and food from entering the airway, thereby directing it into the cervical esophagus and on to the stomach. Thus, two of the most significant problems that affect swallowing following laryngeal surgery are the inability of the larynx to vertically and anteriorly elevate and to close. In addition to airway protection, these movements are essential to open the upper esophageal sphincter (cricopharyngeus) so that spillage into the trachea is avoided and food is directed into the esophagus. Hence, any surgery that impedes or limits laryngeal excursion or any of its valving mechanisms will result in swallowing dysfunction.

Most patients with early-staged cancer do not complain of significant swallowing problems postoperatively. Rather vocal dysfunction (dysphonia) is the primary complaint in the majority of patients who are treated surgically for early glottic cancer.[60–62] The increasing popularity of the use of transoral laser microsurgery (TLMS) instead of radiation therapy for early glottic cancers has provided significant benefit to carefully selected patients in terms of both vocal outcomes and reduced patient burden (missed work, reduced travel time to appointments, number of treatment sessions). Pretreatment videostroboscopic assessment provides valuable information regarding treatment selection, surgery versus radiation therapy, for patients with otherwise comparable survival outcomes for whom function becomes the determining criteria. Experience has shown that the depth of invasion and the glottic site of the cancer are key determinates in treatment selection. Cancers that deeply invade the vocal cord or ones that involve the anterior commissure are often better treated with nonsurgical alternatives that avoid large defects and impede vocal fold closure, resulting in glottic incompetency, poor vocal quality, and risk of aspiration. Unfortunately, there are few to no alternatives to augment or correct large, fibrotic defects of the glottis thereby resulting in poor quality of life for patients who are cured of their disease and for whom the prognosis for long-term survival is good.

Alternatively, surgical treatment for advanced cancer of the larynx is generally associated with problems of both voice and swallowing. Contemporary treatment for advanced cancer of the larynx includes larynx-

preserving resections that are often accompanied by adjuvant regimens of radiation therapy alone or in combination with chemotherapy. Although more ablative open surgery such as total laryngectomy and pharyngolaryngectomy are less frequently performed, they remain viable alternatives for the treatment of advanced cancer of the larynx that is not treatable with conservation alternatives and as salvage procedures for patients with persistent or recurrent laryngeal cancer.

Total Laryngectomy

Despite the contemporary goal of organ preservation, for some patients, this is not possible, and total laryngectomy remains the procedure of choice to enable cancer cure and survival. Despite the profoundly ablative nature of the surgery, total laryngectomy continues to be regarded as a quick, safe procedure with a high percentage of an ultimate cure of the disease. The surgical creation of a tracheal stoma and the loss of laryngeal voice represent the two major disadvantages of total laryngectomy. Despite these drawbacks, most patients who have had a laryngectomy report ultimate satisfaction particularly following successful tracheoesophageal (TE) voice restoration that is associated with recovery of a nearly normal ability to verbally communicate.[63–65]

Because total laryngectomy separates the trachea from the esophagus, the risk of aspiration is also avoided unless patients have also undergone tracheoesophageal puncture (TEP) for alaryngeal voice restoration. The ability to speak through a TEP depends on the surgical creation of an anatomical passageway between the esophagus and the trachea for the transfer of pulmonary air for sound production and hence reestablishes a potential site for tracheal aspiration of saliva and food. Recent data show that enlargement of the TEP may occur in up to 20% of patients. TEP enlargement can result in food and salivary aspiration around the TE voice prosthesis and can be associated with such etiologies as cancer recurrence, fibrosis, malnourishment, uncontrolled diabetes, and smoking. A retrospective multivariate analysis found that a history of advanced metastases to the neck, postoperative stricture, and locoregional recurrence/distant metastasis were the most significant risk factors for enlargement of the TEP in patients with a laryngectomy who were irradiated. Patients with advanced metastases to the neck who require extended neck

dissections are also at risk for TEP enlargement.[66]

Patients who have undergone total laryngectomy do not routinely complain of significant swallowing problems and in most cases return to a normal diet postoperatively. The majority of patients who have had a laryngectomy with dysphagia report slower swallowing that is primarily the result of pharyngeal dysmotility, cricopharyngeal dysfunction, and reduced strength of movements of the base of the tongue following resection of the larynx and hyoid bone. Patients frequently report an initial reduction in their sense of taste immediately after surgery. However, they generally indicate improvement in taste with healing.[67,68]

RADIATION THERAPY

Regardless of the clinical intent of radiation therapy as a definitive treatment modality, whether given in combination with chemotherapy for organ-preserving alternatives, as an adjuvant therapy following surgery, or for palliation of patients with incurable cancer, radiation produces tissue changes that, in many cases, result in long-term alterations in speech and swallowing function. In general, radiation has a greater effect on swallowing than it does on speech. Patients who have swallowing problems before treatment are at higher risk for chronic swallowing disability after treatment, and they are at higher risk for permanent feeding tube dependence.[69,70] The addition of chemotherapy and accelerated schedules of radiation can exacerbate the problems, particularly during the early phases of recovery. The magnitude of the effect will generally be influenced by the field or distribution of dose over the structures of the UADT, the radiation dose as it relates to the sensitivity of the structure to damage, the duration of treatment, and the fraction of treatments as the dose per treatment is associated with greater damage to function, particularly swallowing.

As the treatments for cancer of the head and neck have intensified in an attempt to improve both cancer cure and survival while still preserving the organ, so too have the treatment-related morbidities such as dysphagia, stricture, and pneumonia. Anecdotally, a late onset of radiation-associated dysphagia is relatively uncommon. However, a high prevalence (38.5%) is reported for dysphagia persisting more than 1 year after the completion of radiation therapy defined by chronic gastrostomy dependence, aspiration on

MBS, aspiration pneumonia, and/or stricture.[9,71]

When late radiation dysphagia occurs, the level of dysfunction is most often intense and debilitating. Recent data have shown that late, severe dysphagia is refractory to standard, nonsurgical therapies relegating patients' gastrostomy dependent and at high risk for aspiration pneumonia. Eighty-six percent of 29 long-term (≥5 years) cancer of the head and neck survivors with late dysphagia treated with radiation or chemoradiation therapy aspirated and developed pneumonia in a small case series study from a single institution. Sixty-two percent experienced recurrent pneumonias, and 21% ultimately underwent elective total laryngectomy to eliminate aspiration. Despite short-term benefit from standard rehabilitative efforts, no patient achieved durable improvement across all functional measures. Ultimately, 66% of these patients were gastrostomy dependent as a result of aspiration or malnutrition.[72]

Data have shown that early swallowing recovery from radiation therapy may be misleading because of the delayed development of fibrosis and cranial neuropathies that cause neuromuscular dysfunction and impede swallowing physiology resulting in long-term swallowing deterioration. Findings support the neuropathic contributions to posttreatment dysphagia as a result of the denervation of the suprahyoid musculature following radiation therapy.[73] Late-swallowing dysfunction and aspiration have been reported in up to 60% of patients treated with radiation therapy, and up to 70% of patients who aspirate do so silently without coughing or clearing their throat. It has been estimated that between 15% and 30% of patients who aspirate will require a feeding tube for nutrition. Persistent dysfunction has been reported after treatment, months or even years later.[74–76] Although stricture has mostly been seen in areas that receive high-dose radiation, stricture has also occurred in areas treated with lesser radiation doses. Thus, authors have suggested that decreased swallowing frequency may also be associated with increased risk of fibrosis.[77] Rather than stricture, it is therefore more likely that the commonly reported problems associated with dysphagia including reduced pharyngeal contraction, limited base of tongue retraction, incomplete epiglottic inversion, decreased laryngeal excursion, and abnormal esophageal opening are more likely the primary contributors to late, severe radiation-associated dysphagia.[72] A rate of 16.7% pharyngoesophageal stricture was reported in patients treated with IMRT using photon beam therapy compared

with 5.7% in patients treated with conventional radiation therapy, again suggesting an effect of treatment intensification despite normal tissue sparing and protection.[78] Recent findings have shown increased beam path toxicity from higher doses of IMRT delivered to nontargeted structures including the brainstem and oral cavity, compared with that associated with the administration of 2D conventional radiation.[79] In all cases, the avoidance of specific organs at risk is important to swallowing preservation.[80–82] Newer treatment techniques including IMRT and IMPT (protons) that target the cancer with set radiation doses while limiting the dose to adjacent structures may reduce radiation-related morbidity. Thus, dose-limiting constraints to organs at risk may avoid long-term swallowing dysfunction.

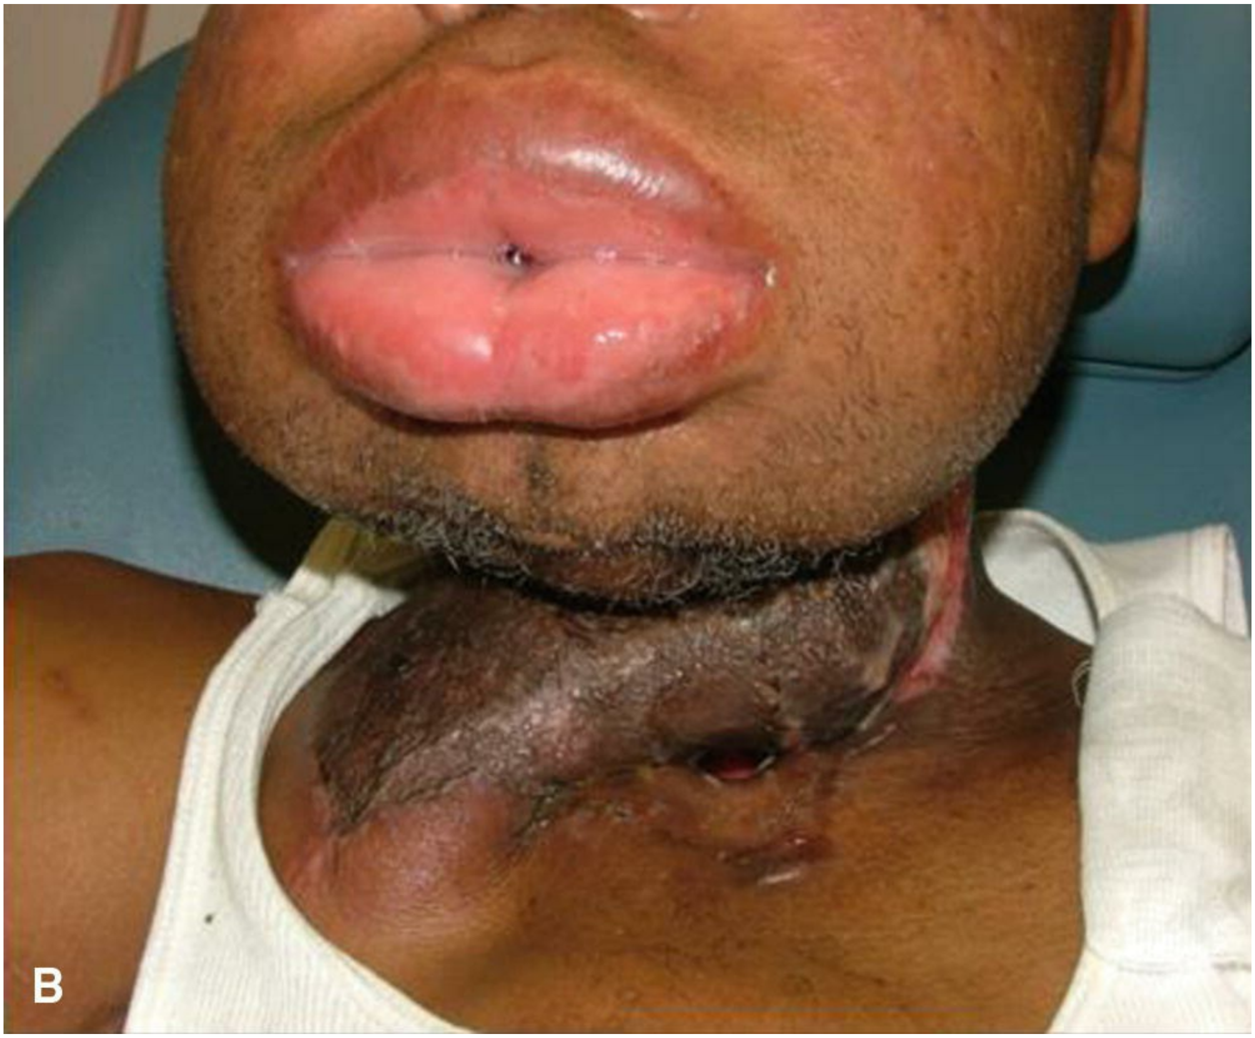
COMMON COMPLICATIONS OF TREATMENT

Two of the most common complications resulting from radiation-induced damage to the salivary glands and mucosal tissue of the UADT are xerostomia and mucositis. Xerostomia is one of the most disturbing complaints of patients treated with radiation as there are no good, effective long-lasting management strategies to mitigate dry mouth. Acute mucositis is also associated with long-term dysphagia and has been reported to be a major dose-limiting toxicity of standard chemoradiation regimens. High-grade mucositis resulting from intensive regimens of chemotherapy generally occurs early, lasts longer, is more severe, and may result in scarring and organ dysfunction. Patients experience thick, ropey secretions that are difficult to swallow or expectorate and result in gagging, regurgitation, and, in some cases, aspiration.[83] Patients who receive oral irradiation and experience mucositis and xerostomia often present with reduced lingual speed, slow oral transit of food, aberrant tongue movements, and slowed triggering of the swallow reflex.[84] Other complications from radiation therapy that affect speech and swallowing function include trismus, dys- or ageusia (changes in or loss of taste), and dysosmia (changes in smell). These problems often begin acutely and worsen throughout treatment.

Head and neck lymphedema (HNL) is another common sequela of HNC treatment that is associated with symptom burden, functional deterioration,

and poor quality of life in HNC survivors.[85,86] Although interest in HNL has increased, unfortunately HNL continues to be an underrecognized and undertreated functionally debilitating consequence of treatment that has been estimated to occur in at least 50% of treated HNC patients.[87,88] HNL is characterized by tissue swelling resulting from the blockage of normal drainage pathways in the lymphatic system. Although most often associated with radiation effects that impair vessel contractility (“lymphangiomotoricity”), surgery that removes lymph nodes as well as the tumor itself may cause vessel obstruction. In some cases, infection such as recurrent cellulitis may further impair lymphatic functioning.[89,90] If left untreated, chronic edema along with permanent fibrosis can result in significant long-term cosmetic, functional, and psychosocial consequences that are often irreversible, including discomfort and difficulties associated with speech, respiration, voice, and swallowing.[91] **Figure** 33.8 represents typical presentations of patients with HNL after treatment of their head and neck cancer.

A



B

Figure 33.8. A–C: Typical presentations of HNL after treatment for cancer of the head and neck.

A recent analysis of over 1,200 survivors of cancer of the head and neck with HNL showed that 68% of patients with functional complaints reported swallowing problems. Swallowing dysfunction is readily illustrated in the radiographic views shown in **Figure** 33.9. Furthermore, 60% of patients showed dramatic reduction in HNL regardless of complete or partial adherence to complete decongestive therapy that was mostly self-administered by the patient through a home program after training by a certified HNL therapist.[92] Dramatic results after treatment for HNL can be seen in **Figure** 33.10.

PREVENTION AND TREATMENT

Prevention of Dysfunction

Intact oral, pharyngeal, and laryngeal anatomy and physiology are critical to speech and swallowing function. The lips, oral tongue, and soft palate play critical roles as the articulators of the oral cavity and are essential for speech production. Speech intelligibility depends on a highly precise sequence of rapidly changing vocal tract shapes resulting from exquisitely precise movements and articulatory contacts. The valving action of the velum determines the nasality of sounds. Laryngeal valving requires the opening or closing of the vocal folds to produce the voiced distinction between sound pairs. Consequently, speech intelligibility can be significantly impaired by partial, subtotal, or total glossectomy but can be improved with speech therapy even after major or total resection.[93,94]

Likewise, the same structures are also essential to the efficiency and safety of normal swallowing including the lips to contain the food, tongue to propel it through the oral cavity into the pharynx, palate to prevent nasal regurgitation, and larynx to avert aspiration. Cephalad laryngeal excursion leading to epiglottic closure and adduction of the vocal folds is a critical component of glottic airway protection. The primary correlates of swallowing dysfunction include poor retraction of the base of the tongue, pharyngeal dysmotility, poor laryngeal excursion, and impaired airway closure (glottic or neoglottic). Thus, treatment of cancer of the head and neck that avoids or reduces damage to these structures will, in effect, help prevent long-term problems as any insult to these structures or their physiology can impair both speech and swallowing function.

Conformal plans using IMRT have been proposed to prevent the burden of dysphagia by limiting radiation dose to the base of the tongue, pharyngeal constrictor muscles and autonomic neural plexus, and the larynx, essentially sparing swallowing-related organs at risk.[81] The unnecessary radiation of the uninvolved larynx has been strongly discouraged in contemporary radiation treatment planning.[95,96] There are different techniques used during IMRT. Some treat the entire neck with IMRT, or split the field, and treat the lower neck with an anterior supraclavicular field that essentially blocks or limits larynx dose and is associated with lower aspiration rates, a potential benefit over other radiation techniques for the prevention of swallowing dysfunction.[80]

Research findings show that delaying the placement of a feeding tube until it is needed may in fact help preserve long-term swallowing function. The practice of prophylactic feeding tube placement for patients with cancer of the head and neck has changed within the last decade as evidence has shown that patients who receive prophylactic G-tubes are more likely to have late esophageal toxicity and dysphagia, leading to long-term dependence on enteral feedings and often depression that ultimately complicates recovery.[19,97,98] Recent findings suggest that reactive versus prophylactic feeding tubes are associated with favorable swallowing outcomes and thus may help to prevent dysphagia requiring long-term feeding tube dependence. Furthermore, experience has shown that reactive feeding tube placement is in fact possible without increasing the rate of breaks in cancer treatment. In a study of 474 evaluable patients with oropharyngeal cancer of whom 293 patients (62%) required placement of a g-tube during the study period; no patient required a treatment break for g-tube placement.[24]

Data clearly demonstrate that early therapeutic regimens of swallowing exercises that are designed to strengthen musculature, increase the precision of movements, and maintain range of motion provide the best prevention of long-term swallowing dysfunction in patients who have undergone radiation or chemoradiation therapy for cancer of the head and neck.[99,100] Because even brief NPO intervals (≥2 weeks) portend poorer swallowing outcomes, experience shows that it is important for patients to continue to swallow as frequently and as much as possible throughout the course of their radiation treatment, even if they have a feeding tube, to maintain swallowing ability.[19,20]

Moreover, prophylactic swallowing exercise that begins before the initiation of cancer treatment is associated with better swallowing–related quality-of-life scores,[101] superior movement of the base of tongue and epiglottis,[102] lower gastrostomy rates,[24,103] better postradiation therapy diet levels,[104] improved mouth opening,[105] and superior muscle composition on MRI.[106] Results demonstrate that both eating and exercising are associated with the best swallowing outcomes; however, eating or exercising alone results in better outcomes than does neither eating nor exercising. Moreover, findings also show that patients who adhere to their swallowing exercise regimens are 3.6 times more likely to eat a regular diet in long-term survivorship than do those who do not adhere.[107]

Treatment and Rehabilitation

Impaired voice production associated primarily with the treatment for cancer of the larynx, including both surgical and nonsurgical management, can range from breathiness or hoarseness to complete aphonia. Depending on the etiology, speech therapy alone or in combination with any one of a variety of surgical procedures designed to improve and optimize voice production may be recommended, particularly in cases of unilateral vocal fold paralysis. In appropriately selected cases, injection medialization laryngoplasty (thyroplasty) offers temporary augmentation for relief of acute aspiration related to glottic incompetence. For patients whose paralysis is long standing, permanent medialization thyroplasty offers the opportunity for return of near-normal vocal function and efficient glottic airway protection.[108,109]

Probably the most significant voice disorder requiring specialized expertise is the rehabilitation of voice after total laryngectomy. Total laryngectomy results in a variety of cosmetic and functional changes; however, the most debilitating is the loss of verbal speech production. Verbal communication is restored using three major approaches: (1) the artificial larynx or electrolarynx, (2) esophageal speech production, and (3) surgical prosthetic voice restoration, of which the most common and contemporary method is TE voice restoration with a removable voice prosthesis. Not every patient is a candidate for all of the alaryngeal speech alternatives, and selection should be made on the basis of careful evaluation. The advantages of each alaryngeal speech alternative should be reviewed and discussed with the patient prior to surgery. Recommendations should be based on the individual's specific needs and interest, medical/surgical history, physical capabilities, level of independent functioning, family support, motivation, and access to and compliance with rehabilitation. In the case of TE voice restoration, the ability to acquire replacement prostheses is a consideration that is frequently neglected. Access to well-trained, expert clinicians who can help manage issues related to placement of the TE prosthesis or who can problem-solve difficulties encountered by the TE speaker is often challenging. In addition, the cost of prostheses may be prohibitive for patients who have limited funds and for whom TE prostheses are not a covered benefit of their insurance policies.

The choice of an alaryngeal method is primarily a function of the patient's ability to choose based on his or her physical and medical status and

personal preference, and the decision regarding the best alaryngeal speech alternative should never be made solely by the physician, speech pathologist, or family. In large part, clinician experience and familiarity with the specific alaryngeal voice alternative will significantly impact the patient's overall success in acquiring alaryngeal speech production. Thus, it is important that alaryngeal speakers seek out rehabilitation from experienced clinicians who are familiar with the nuances of multiple available methods and who are not unfamiliar with the unique complications and problems often experienced by alaryngeal speakers.

CONCLUSIONS

Cancer of the head and neck and its treatment result in unique problems that require clinician expertise and familiarity with the disease, the treatment and its effects, and the rehabilitation and restoration of associated speech and swallowing dysfunction. Contemporary focus on quality of life and functional preservation, surgical and nonsurgical, will likely play a key role in future decisions regarding treatment for cancer of the head and neck as today's survivor is typically younger, healthier, and better informed, with a greater chance for increased survival, and an expectation for functional success along with a quick return to a normal premorbid routine. Late treatment effects associated with intensive treatment regimens, especially those associated with radiation, are not generally common, but when they occur, they can be devastating. Thus, current intervention to protect the ability to speak and swallow must be targeted and aggressive based on the findings of functional examinations that start early and are rigorously monitored to ensure progress and avoid complications. It is critical that ongoing and future investigations into treatments for cancer of the head and neck ensure cure and survival, but avoid crippling speech and swallowing function in our survivors.

34 Supportive and Palliative Care

Ahmed Elsayem Eduardo Bruera

INTRODUCTION

Palliative care is a discipline that strives to alleviate the physical and psychological suffering of patients and their families and to allow them to express their maximum potential during the course of their illness.

Patients with cancer of the head and neck may suffer from severe symptoms, including pain, anorexia, fatigue, cachexia, dyspnea, and psychological distress. In addition, cancer treatments such as surgery, radiation, chemotherapy, and immunotherapy have adverse effects such as mucositis, neutropenia, infection, neurocognitive dysfunction, and psychological distress due to extensive surgical procedures. The purpose of this chapter is to discuss the assessment and management of these complex symptoms in patients with cancer of the head and neck at all stages of their disease.

SIGNS AND SYMPTOMS ASSOCIATED WITH CANCER OF THE HEAD AND NECK

Cancer of the head and neck is frequently associated with many physical symptoms related to the cancer itself or to associated treatment. Surgery and radiation therapy are the main modes of treatment, although chemotherapy is frequently used.[1] Radiation therapy doses sufficient to produce tumor regression are associated with mucositis and xerostomia (dry mouth).[2] In addition, significant disfigurement and functional loss often accompany surgical interventions.[3] Many vital functions such as taste, speech, mastication, and swallowing can be affected.[4] Late effects of treatment,

particularly radiation ports that include incidental brain exposure, may cause significant cognitive impairment.[5] Cancers of the head and neck are particularly problematic because of their impact on the airway and gastrointestinal tract, which results in significant compromise of breathing and nutrition. **Table** 34.1 describes the incidence of the most common symptoms of advanced cancer of the head and neck.

Table 34.1 Incidence of Common Signs and Symptoms of Advanced Cancer of the Head and Neck

Symptom	Approximate Percentage
Pain	79
Weight loss	79
Feeding difficulties	74
Dysphagia	74
Cough	66
Communication	53
Bleeding	47
Candida	47
Fistula	21
Aspiration	10

Modified from Forbes K. Palliative care in patients with cancer of the head and neck. *Clin Otolaryngol.* 1997;22:117.

Pain

Pain is a common symptom in this patient population. In most patients with advanced cancer, chronic pain is due to direct stimulation of afferent nerve structures by the primary or metastatic cancer. Pain associated with direct tumor involvement occurs in 65% to 85% of patients with advanced cancer.[6] Cancer therapy accounts for 15% to 25% of pain syndromes.[7] Pain

syndromes are categorized as nociceptive or neuropathic. Nociceptive pain is further divided into somatic and visceral. For example, nociceptive pain related to cancer of the larynx or bony metastases results from activation of pain receptors in these tissues and organs. Neuropathic pain, such as trigeminal or glossopharyngeal neuralgia, results from direct injury to the peripheral or central nervous system. Somatic pain is usually localized and tender to pressure; neuropathic pain is often described as burning or shooting.[8]

Patients with advanced cancer often have chronic, constant pain intermittently punctuated by acute breakthrough pain. Patients may have acute pain following certain procedures, such as postoperative pain or radiation-induced mucositis. Incidental pain is usually acute and may be triggered by certain maneuvers such as swallowing, mastication, or speech.

Weight Loss

Cachexia–anorexia occurs in more than 80% of patients with advanced cancer and is a major factor contributing to morbidity and mortality.[9] Patients with cancer of the head and neck are particularly susceptible because of the effects of cancer and its treatment on eating, including altered taste and difficulty chewing and swallowing. Cachexia is characterized by weight loss, wasting, anorexia, and change in body image with resulting asthenia and psychological distress.

Fatigue

Fatigue is the most frequent symptom of advanced cancer.[10] It is characterized by unusual and profound tiredness after minimal effort, accompanied by an unpleasant sensation of generalized weakness. Cancer-related fatigue, unlike fatigue in a person who is not ill, does not improve with rest.

Psychological Distress

Patients with cancer of the head and neck face enormous psychological distress because of the structural and functional deficits associated with the cancer and its treatment. Facial disfigurement and loss of taste, speech, and sometimes sight result in altered body image, low self-esteem, and possibly

depression.[11] Moreover, patients with cancer of the head and neck often have a history of chronic alcohol and tobacco use[12] accompanied by physical and neurocognitive disabilities.[13] It is estimated that 80% of patients with cancer of the head and neck have such a history, which may complicate their care and rehabilitation.[14]

ASSESSMENT OF SIGNS AND SYMPTOMS

Pain

Lack of expertise among health care professionals in the use of assessment tools for pain and other symptoms is the main reason for poor management of symptoms.[15] Patient self-reporting should be the primary source of information for the measurement of symptoms. Observer ratings of symptom severity correlate poorly with patient ratings. Simple tools such as the visual analogue scale (VAS), numeric rating systems (NRSs), and verbal descriptor scales have proved to be effective and reproducible means of measuring pain and other symptoms.[16] Other scales include the Memorial Symptom Assessment Scale (MSAS).[17] The Edmonton Symptom Assessment System (ESAS) is the most common clinical tool for the assessment of pain and multiple other physical and psychosocial symptoms in the clinical setting (**Fig.** 34.1). This tool is copyright-free and can be completed by the patient in a few minutes. Pain in cancer patients is frequently complicated by a high level of distress.[18] The emotional suffering experienced by cancer patients manifests itself as fear, anxiety, and depression, which result in increased sensitivity to pain and other symptoms.[19] Therefore, a unidimensional approach to pain that considers 100% of the pain complaint as nociceptive may not address other treatable conditions, thus depriving the patient of appropriate additional therapies.

Figure 34.1. Edmonton Symptom Assessment System. (From Bruera E, Kuehn N, Miller MJ, et al. The Edmonton Symptom Assessment System [ESAS]: A simple method for the assessment of palliative care patients. *J Palliat Care*. 1991;7:6–9.)

Assessment of pain should address the cause of the pain and should measure the intensity, onset, duration, location, character, and factors that aggravate and relieve it. Regular reporting in the patient's medical records of the patient's pain and other symptoms assists the team that is treating the patient in monitoring these symptoms and providing appropriate treatment. The ESAS (Fig. 34.1) graphically displays the most common symptoms reported among cancer patients.[20–22]

A positive history of alcoholism may be associated with a higher risk for the use of medications to cope with emotional distress.[23,24] Well-validated tools are available for quantifying alcohol use, both current and past,[25]

although there are limitations to the accuracy of any self-report questionnaire about alcohol use. Some groups have found that a history of alcoholism is an independent prognostic factor for the development of opioid dose escalation and opioid-related neurotoxicity[26] and that such a history predisposes the patient to preexisting cognitive deficits.[27] Simple bedside screening of alcohol intake shows a very high frequency of undocumented alcoholism. These patients are at a higher risk of chemical coping with opioids.[28] Among patients with head and neck cancer, those who score positive in the CASE questionnaire are at high risk of opioid use 3 months and 6 months after completion of radiation and/or chemotherapy. Although patients with a significant alcohol history may need more frequent monitoring and counseling to achieve good pain control, a history of substance abuse or emotional problems is not an indication for limiting pain treatment.

Unfortunately, pharmacologic treatment of pain may lead to worsening of other symptoms such as opioid-related nausea, constipation, and delirium. Given the complexity of the interaction among the various physical and psychosocial domains, there is a growing acceptance that the assessment of pain in cancer patients requires a multidimensional approach.

Weight Loss

Weight loss is the main clinical finding in patients with cancer cachexia. In patients with cancer of the head and neck, this may result from local factors affecting food intake such as altered taste, smell, or swallowing. It may also be due to decreased appetite. A weight loss of 10% or more usually indicates moderately severe malnutrition.[29] The presence of edema, ascites, or pleural effusion may make the interpretation of weight loss difficult. Assessment of caloric intake can be made at the bedside by a nutritionist or a trained nurse. Anorexia is a major target of both nutritional and pharmacologic interventions.

Fatigue

Fatigue is often measured according to subjective assessment and functional capacity. Commonly used performance status scales, such as the Karnofsky Performance Scale and the Eastern Cooperative Oncology Group (ECOG) scale, do not adequately measure fatigue. Although there are a number of

tools for the assessment of the severity of fatigue, in the clinical setting, it can be monitored using multidimensional tools such as ESAS.[30]

MANAGEMENT OF SIGNS AND SYMPTOMS

Pain

Successful management of pain depends on the physician's ability to assess the patient and the pain, identify the pain syndrome, and formulate and discuss the treatment plan with the patient. A pharmacologic approach is the primary treatment provided for cancer pain. In more advanced and complex cases, in which suffering and psychological distress complicate pain perception, a multidisciplinary approach is required for effective pain management. The World Health Organization proposed a simple analgesics ladder for the pharmacologic management of cancer pain, which has been shown to be safe and effective. This ladder begins with simple nonopioid analgesics, proceeds to weak opioids, and then recommends strong opioids as the disease progresses and pain expression escalates. Most patients need opioids for the management of cancer pain. Patients should receive appropriate counseling and information regarding their pain, opioids, medication adverse effects, and the costs of treatment.

Nonopioid Analgesics

Acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) are effective analgesics for patients with mild cancer pain and can be combined with opioids such as codeine and oxycodone in patients with moderate to severe pain.[31] Acetaminophen does not inhibit prostaglandin synthesis or affect platelet function; therefore, it is widely used in the treatment of cancer pain, either alone or in combination with opioids such as codeine or oxycodone. The major toxicity of acetaminophen is its hepatotoxic effect, which is dose related. Therefore, the cumulative daily dose should not exceed 4 g. The main limitations of NSAIDs include their relatively flat dose–response curves and associated gastrointestinal, renal, and bleeding adverse effects. These effects are related to the inhibition of the enzyme

cyclooxygenase-1. Newer generations of cyclooxygenase-2 inhibitors such as celecoxib and rofecoxib have a lower frequency of toxicity and are effective when used alone or in combination with opioids.

Opioids

Opioids remain the mainstay in the treatment of cancer pain. Opioids interrupt pain perception at different levels in the central nervous system. **Table** 34.2 summarizes the general principles that apply to opioid treatment of cancer pain.

Table 34.2 Opioid Treatment of Cancer Pain
Administer around the clock.
Aggressively prevent nausea and constipation.
Consider adjuvant drugs to manage adverse effects or a specific pain syndrome.
Consider long-acting opioids when pain is better controlled.
Consider opioids as only one part of the total pain management plan.
Educate patient regarding tolerance, adverse effects, and low risk of addiction.
Make oral route the first choice.
Titrate doses individually. Allow extra doses for rescue analgesia.

Routes of Opioid Delivery.

The oral route of opioid administration is preferable because it is safe, effective, and convenient and can be used in the home setting. However, 80% of patients taking oral opioids require an alternative route of administration before death.[32] The intravenous route is more suitable for the immediate postoperative period and when the gastrointestinal route is not available

because of concerns about wound healing, vomiting, dysphagia, or mucositis. Patient-controlled analgesia (PCA), administered with different types of pumps, is a widely used technique that has proved to be effective in the treatment of pain in hospitalized patients, especially during the postoperative period.[33] Although the overuse of medication by confused or psychologically impaired patients, particularly those with a history of addiction, is possible, this is easily handled by limiting the number of doses that can be administered over a given period of time. The subcutaneous route is a safe and effective mode of opioid delivery wherein opioids can be administered by the patient or a family member with the use of a preloaded syringe.[34] The rectal route is also safe and effective, but it is uncomfortable for many patients. The transdermal route (patch) is an effective alternative to the oral route and is more suitable for patients with stable pain complaints who need a relatively small dose of opioids. Drugs such as morphine and hydromorphone can be given safely through the transdermal route.

Specific Opioids.

Patients with cancer-related pain need to be maintained on opioids in such a way that a constant blood level of the drug can be provided. In addition, patients need to have access to rescue doses of opioid for episodes of pain exacerbation. **Table** 34.3 summarizes the opioids most frequently recommended for cancer pain.

Table 34.3 Opioid Analgesics Most Frequently Recommended for Cancer Pain

Type of Opioid	Name of Opioid	Common Route	Equivalent Price ($)	Other Routes
Weak	Codeine[a]	PO	—	IV, SC
	Tramadol	PO	—	—
Strong	Morphine	PO	1	IV, SC, Supp
	SR Morphine	PO	5	—
	Hydromorphone	PO	3	IV, SC, Supp
	Oxycodone	PO	3.6	SC[b]
	SR Oxycodone	PO	6.5	—
	Fentanyl	TD	6.5	TM, IV
	Methadone	PO	0.15	IV, Supp
	Diamorphine[b]	IV	—	SC

[a]Products may contain paracetamol. Make sure the daily paracetamol dose does not exceed 4 g.

[b]Not available in the United States (available in Canada and the United Kingdom).

$, Approximate relative price when a daily dose equivalent to morphine 100 mg by mouth is used.

PO, oral; IV, intravenous; SC, subcutaneous; Supp, suppository; TD, transdermal; TM, transmucosal; SR, slow release.

Weak Opioids.

Members of this group, including codeine and tramadol, tend to have a flat dose–response curve and are frequently associated with fewer restrictions for prescriptions. Codeine is frequently combined with acetaminophen or aspirin. Propoxyphene is not recommended for long-term use in cancer pain because it includes the active metabolite norpropoxyphene, which can cause confusion and hallucinations. Recent research has demonstrated that hydrocodone is 1.5 times more potent than morphine and therefore it should not be considered a weak opoid.[35]

Strong opioids.

Morphine has been considered the strong opioid of choice. However, other opioid agonists such as hydromorphone and oxycodone exhibit similar properties. A typical starting dose of morphine is 5 to 10 mg every 4 hours in patients who have not taken opioids previously. The starting dose may not be sufficient, and relatively rapid titration may be needed, particularly if pain is severe. When the effective dose of short-acting morphine has been established, patients may be maintained on this preparation, or at this point, a slow-release preparation may be administered every 12 or 24 hours. When a patient is switched from one opioid to another, or when one opioid is substituted for another, it is important for the clinician to calculate the equianalgesic dose of the previous opioid to determine the correct dose of the new opioid.

Hydromorphone is a semisynthetic derivative of morphine that is approximately five to six times more potent. It is well absorbed from the gastrointestinal tract. Usually, it is given as an immediate-release preparation every 4 hours, although in some countries such as Canada, slow-release preparations are available.

Methadone is a synthetic opioid with good bioavailability; it is inexpensive and less constipating than other opioids, making it a suitable

drug for the treatment of chronic cancer pain. It has no active metabolites; therefore, it is particularly useful in patients with renal failure. However, methadone has a prolonged and unpredictable half-life and complex pharmacokinetics, making it relatively difficult to titrate. Currently, the practice of starting treatment with methadone should be limited to physicians who are experienced with its use.

Fentanyl is available as a transdermal patch with ~3 days duration of action. A disadvantage of fentanyl is the difficulty associated with titrating the dose when a steady state is not reached.

Meperidine should not be used on a long-term basis for cancer pain because of the associated production of a neurotoxic metabolite, normeperidine, which can cause seizures and other central nervous system adverse effects.

Adverse Effects Associated with Opioids.

A number of adverse effects are associated with the use of opioids for cancer-related pain. In most patients, these adverse effects can be managed easily through patient education, selection of the appropriate route of administration, and the use of additional drugs such as antiemetics and laxatives. **Table** 34.4 summarizes the main adverse effects of opioids.

Table 34.4 Common Adverse Effects of Opioids

Problem	Suggested Intervention
Cognitive slowing	Consider opioid rotation, improved hydration; review current psychoactive medications and educate family.
Constipation	Start laxative concomitantly (e.g., senna products). Titrate the dose.
Nausea	Start metoclopramide 10 mg every 4 h around the clock for 3 d, then as needed.
Pruritus	Give antihistamine.
Respiratory depression	Reduce the opioid dose for mild depression. If moderate or severe, treat with opioid antagonists (e.g., naloxone).
Sedation	May improve spontaneously with continued use. If it persists, consider psychostimulant (e.g., methylphenidate).

Sedation, constipation, and nausea are the most common adverse effects. Sedation and nausea usually improve spontaneously in about 3 days. Sedation can be exacerbated by coadministration of alcohol or benzodiazepines. If sedation persists, the administration of a psychostimulant such as methylphenidate may improve arousal during the day.[36] Nausea is caused by

the opioid effect on the chemoreceptor trigger zone and by delayed gastric emptying. Antiemetics such as metoclopramide are effective against both mechanisms.

Constipation is the most common adverse effect of opioids. Opioids act at multiple sites in the gastrointestinal tract to decrease both peristalsis and intestinal secretions. Unlike sedation and nausea, tolerance to constipation develops very slowly. Therefore, patients will most likely require regular laxative treatment for the duration of opioid therapy. A major myth is that constipation is a normal response to poor oral intake. Health care providers should be educated about the physiologic shedding of the lining of the gastrointestinal tract and bacterial proliferation in the colon, both of which contribute to the formation of stool.

Opioid-induced cognitive dysfunction can be a problematic adverse effect of opioids. A variety of opioids such as morphine, hydromorphone, and meperidine contain active metabolites that can cause excessive sedation, cognitive slowing, hallucinations, delirium, and seizures. These active metabolites, such as morphine-3-glucuronide, bind to opioid receptors in the brain. The concentration of these metabolites is affected by opioid dose, length of treatment, dehydration, and renal failure. The first steps in treating neurotoxic adverse effects without compromising pain relief are to (1) change the type of opioid that is being administered (opioid rotation), (2) hydrate the patient to enhance excretion of the drug and its metabolites, and (3) provide appropriate support to the patient and the family. In rare cases in which severe agitation, hallucinations, or delusions develop, haloperidol may be required.

Rotation of opioids is a safe and reliable method of alleviating symptoms in patients who develop opioid-induced neurotoxicity, although the ideal alternative opioid has not been determined. If the patient is taking morphine, a trial of hydromorphone, oxycodone, or fentanyl is usually effective. The dose of the second opioid should be determined according to guidelines that determine an equianalgesic ratio.

Other less common adverse effects resulting from opioid use include sweating, pruritus, urinary retention, and pulmonary edema. Respiratory depression is a rare and serious complication of opioid use, especially when it occurs in patients with no previous history of opioid use who have not developed tolerance to the respiratory depressant effect of the drug.

Pain in Special Situations

Incidental Pain

Incidental pain is sudden and severe pain provoked by special maneuvers such as swallowing or movement. An increase in opioid dose during episodes of incidental pain may result in excessive sedation after the pain episode has subsided. In such cases, attempts should be made to increase the local control of pain with the use of techniques such as radiation therapy, orthopedic procedures, and neurosurgical procedures.

Neuropathic Pain

Neuropathic pain is usually caused by damage to the nerves from direct tumor effect or its treatment. The pain can be burning or shooting. Neuropathic pain responds less to opioid therapy than does somatic or visceral pain, although it is generally alleviated by opioids to some degree. These patients frequently require the administration of adjuvant drugs in addition to opioids. The most commonly used drugs are tricyclic antidepressants, gabapentin, carbamazepine, clonazepam, baclofen, and corticosteroids.

Mucositis

Mucositis in patients with cancer of the head and neck usually results from the effects of chemotherapy, radiotherapy, or both. Pain is usually moderate in severity and the condition is self-limited in most cases, although rarely, pain can be severe and dose limiting. Mouth ulcers lead to dehydration from infection and decreased oral intake, especially among neutropenic patients receiving chemotherapy. Rehydration, local antiseptics, and oral opioids can frequently control the condition, although in severe cases, intravenous opioids may be required.

Nonpharmacologic Interventions

Some patients have severe pain that does not respond adequately to pharmacologic intervention; others develop intolerable toxicity. In these patients, adjuvant nonpharmacologic interventions should be considered

(**Table** 34.5). Approaches such as transcutaneous nerve stimulation and physical therapy can be attempted in most patients because of their relatively limited adverse effects and low costs. Radiation therapy should be considered in patients with bony metastases. Single large fractions may be as effective as multiple fractions and may reduce the patient's discomfort as well as treatment costs.[37] In difficult pain syndromes, some anesthetic procedures performed by neurosurgeons, anesthesiologists, or pain specialists, such as cordotomy, rhizotomy, and different nerve blocks, may be helpful.

Table 34.5 Nonpharmacologic Methods of Treating Cancer Pain
Acupuncture
Anesthesiologic Anesthesiology procedures
Biofeedback
Cognitive–behavioral therapy
Hypnosis
Neurosurgery
Occupational therapy
Orthopedic surgery
Physical therapy
Radiotherapy
Relaxation techniques
Transcutaneous electrical nerve stimulation (TENS)

A number of psychological techniques can be very effective adjuvant treatments for enhancing pain control. These include relaxation therapy, cognitive therapy, biofeedback, and hypnosis.[38] These techniques can affect both the sensory aspects of pain and the psychological distress that many patients in pain experience. In addition, they tend to be of relatively low cost and free of adverse effects.

Cachexia–Anorexia

Until recently, cachexia was believed to be the result of an energy imbalance caused by the combination of increased energy consumption by the cancer and decreased energy intake due to tumor-related factors affecting the satiety center in the brain. Attempts to reverse cachexia associated with cancer by administering parenteral or enteral nutrients led to no significant improvement.[39] The emerging view of cachexia associated with cancer is summarized in **Figure** 34.2. A recent review describes the roles of cytokines such as tumor necrosis factor (TNF), interleukins 1 and 6 (IL-1, IL-6), and interferon-alpha. Long-term administration of these cytokines can cause many of the classic features of anorexia.[40]

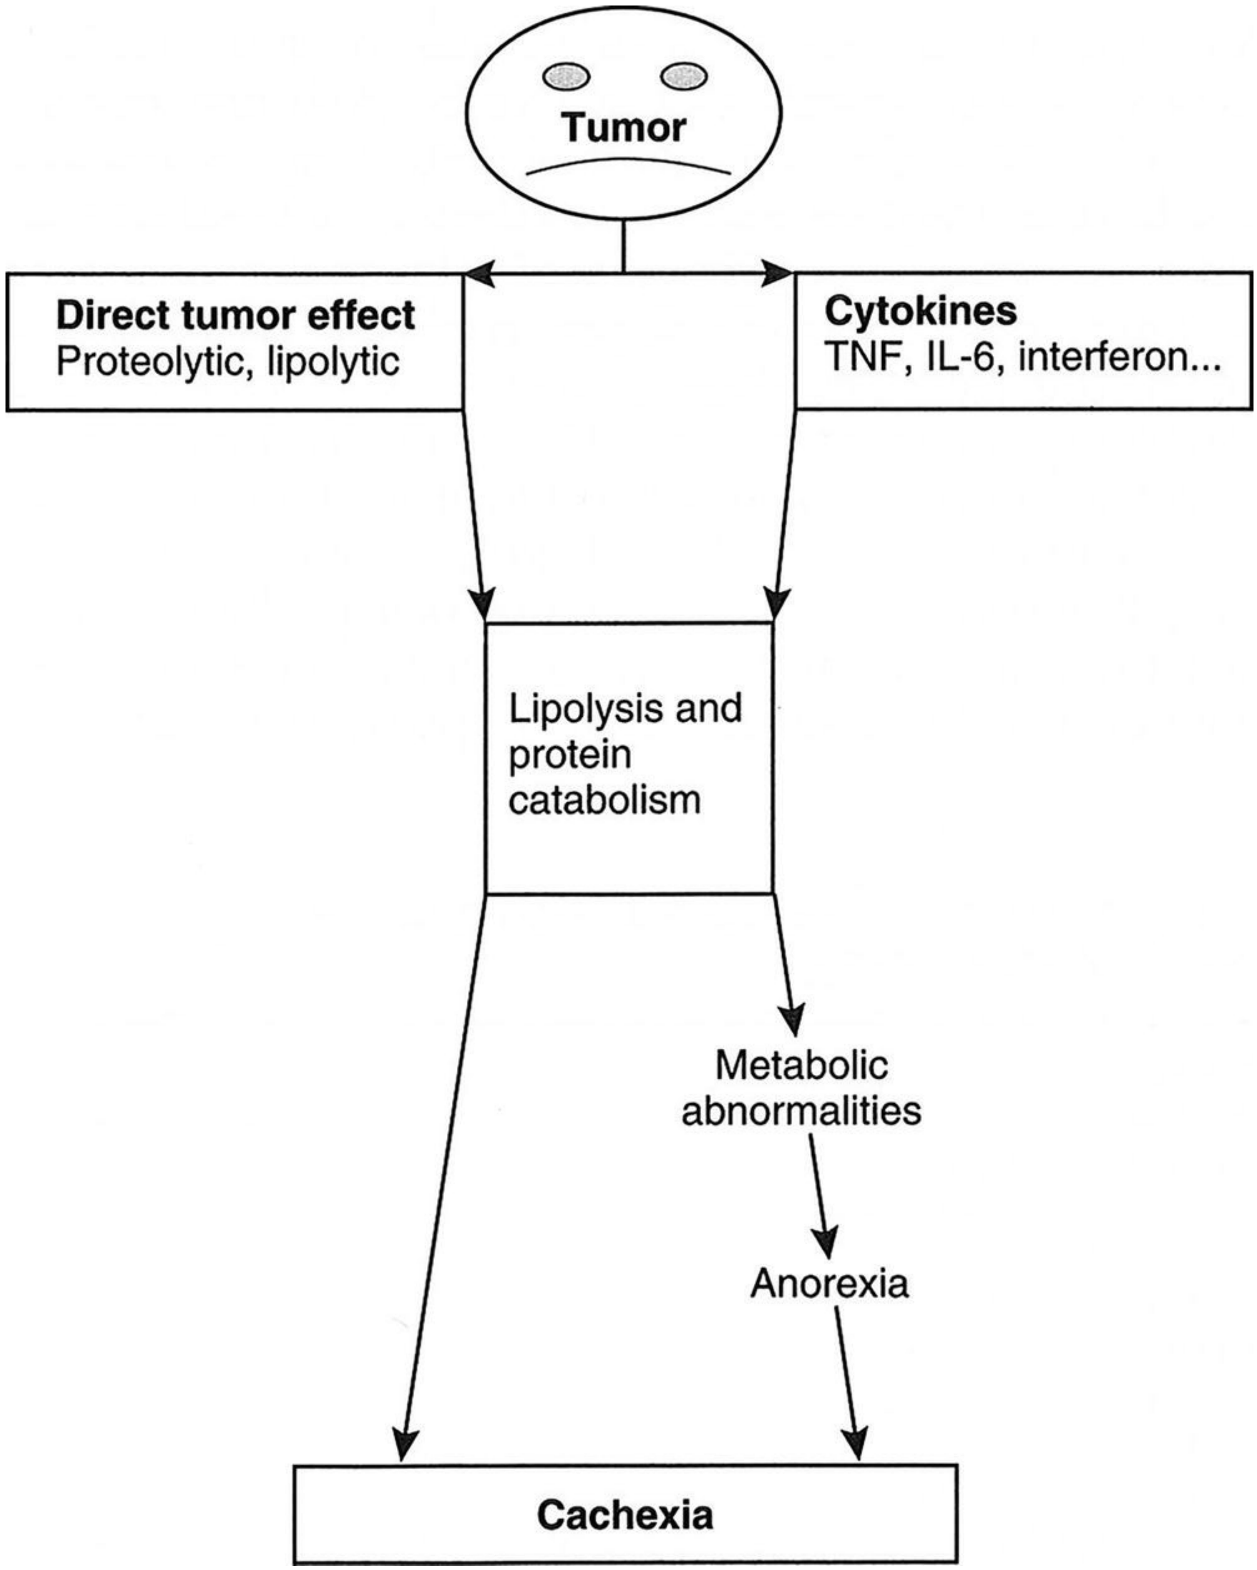

Figure 34.2. Mechanism of cachexia. (TNF, tumor necrosis factor.)

Anorexia is the most frequent distressing symptom in patients with

cachexia associated with cancer. Profound anorexia adds a nutritional deprivation component to the metabolic abnormalities. This deprivation is more severe in patients with dysphagia related to cancer of the head and neck. Anorexia is also worsened by nausea caused by tumor by-products, decreased gastric emptying, constipation, and pain medications. Moreover, patients with cancer of the head and neck can suffer from alterations of taste and smell that result in anorexia.

Management of Cachexia

One of the main challenges in the management of cachexia is defining a properly reasonable outcome for nutritional and pharmacologic interventions. A reasonable goal is to improve general comfort and ease the symptoms of anorexia, nausea, fatigue, and constipation.

Nutritional Approach.

Nutritional counseling may help improve daily caloric intake in many patients; however, it is unlikely to reduce weight loss in most patients. Adequate counseling of patients and their families about the metabolic mechanism of cachexia helps to alleviate the anxiety of family members that their relatives are starving to death.

Parenteral nutrition has no advantages over enteral nutrition and is more expensive. Enteral nutrition is safer and can be administered at home. Patients with cancer of the head and neck who have dysphagia or difficulties with mastication or swallowing may benefit from gastrostomy tube placement. This tube may also be used for administration of medications.

Pharmacologic Approach.

Table 34.6 summarizes the most useful drugs for the treatment of cancer cachexia. Promising research is under way to evaluate the possible beneficial effects of anticytokine therapies such as pentoxifylline, thalidomide, and melatonin. Multimodal interventions including anti-inflammatories, exercise, and nutritional improvement can help alleviate and/or reverse some of the effects of cachexia.[41]

Table 34.6 Drugs Useful for Treatment of Cachexia

Drug	Comment
Metoclopramide	Most effective in patients with chronic nausea and autonomic failure, and those on opioids.
Corticosteroids	Effect is short-lived (up to 1 mo). Suitable for advanced cancer. Significant adverse effects.
Megestrol acetate	Associated weight gain. Drug of first choice. Use associated with thromboembolism. Expensive.
Medroxyprogesterone acetate	Associated thromboembolic disease

Fatigue

Cancer-related fatigue is characterized by persistent and unusual tiredness occurring after usual or minimal effort, accompanied by an unpleasant anticipatory sensation of generalized weakness that is not relieved by rest. The three main mechanisms associated with fatigue are direct tumor effects, tumor-induced by-products, and medical complications, including anemia, paraneoplastic syndromes, and chronic infection. **Figure** 34.3 depicts the major causes of fatigue.

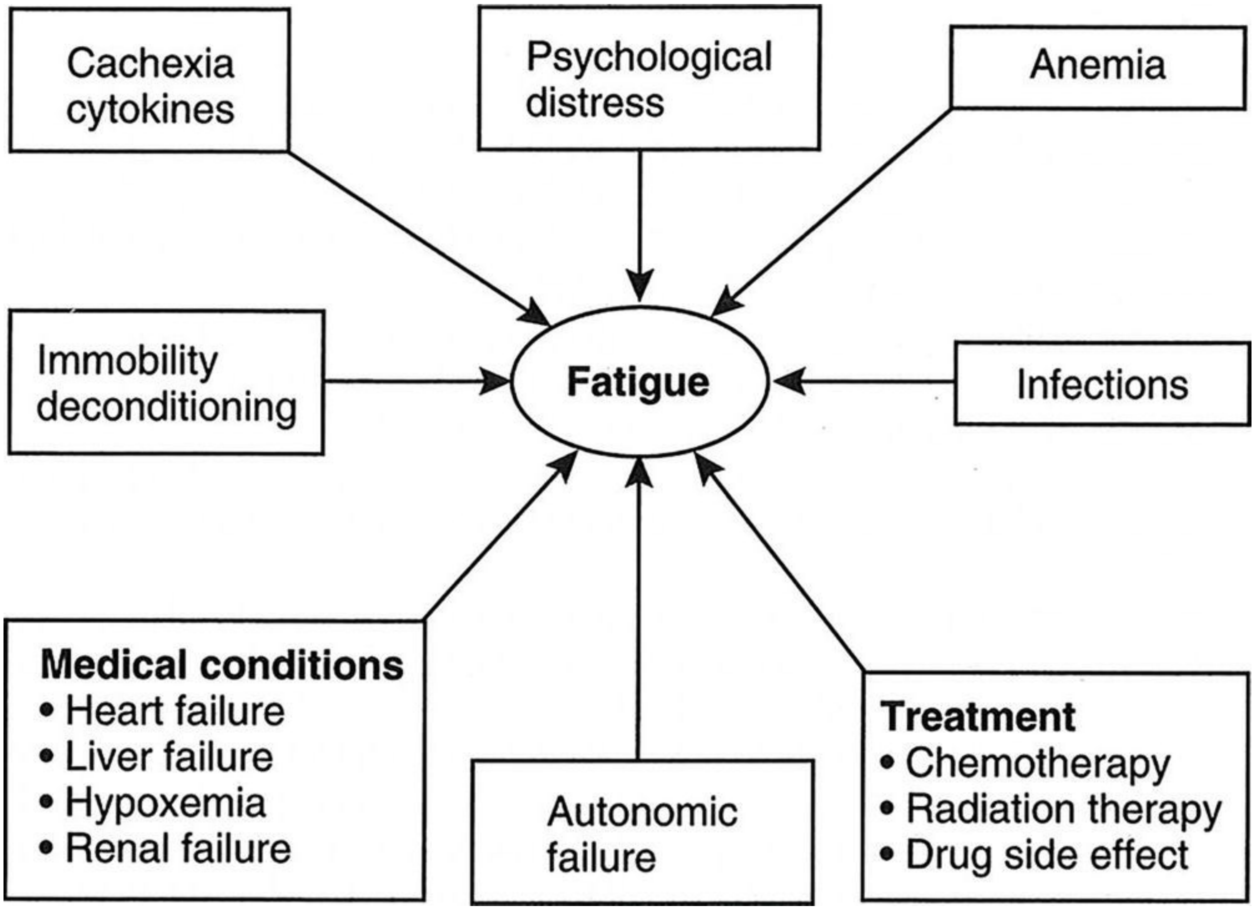

Figure 34.3. Causes of fatigue.

The relationship between fatigue and cachexia is complex; most patients with advanced cancer experience both. However, some patients with advanced cancer may have fatigue without malnutrition, whereas patients with conditions such as anorexia nervosa may experience severe malnutrition with no fatigue.

Management

Figure 34.4 presents a clinical approach to the management of fatigue. If specific causes can be identified, their correction will lead to significant improvement. General nonpharmacologic measures, such as adapting activities of daily living and providing physical therapy and occupational therapy, help in matching clinical function and symptom status with the expectations of patients and their families.[42] Counseling and appropriate pharmacotherapy may help patients in whom fatigue is exacerbated by an affective disorder such as anxiety or depression.

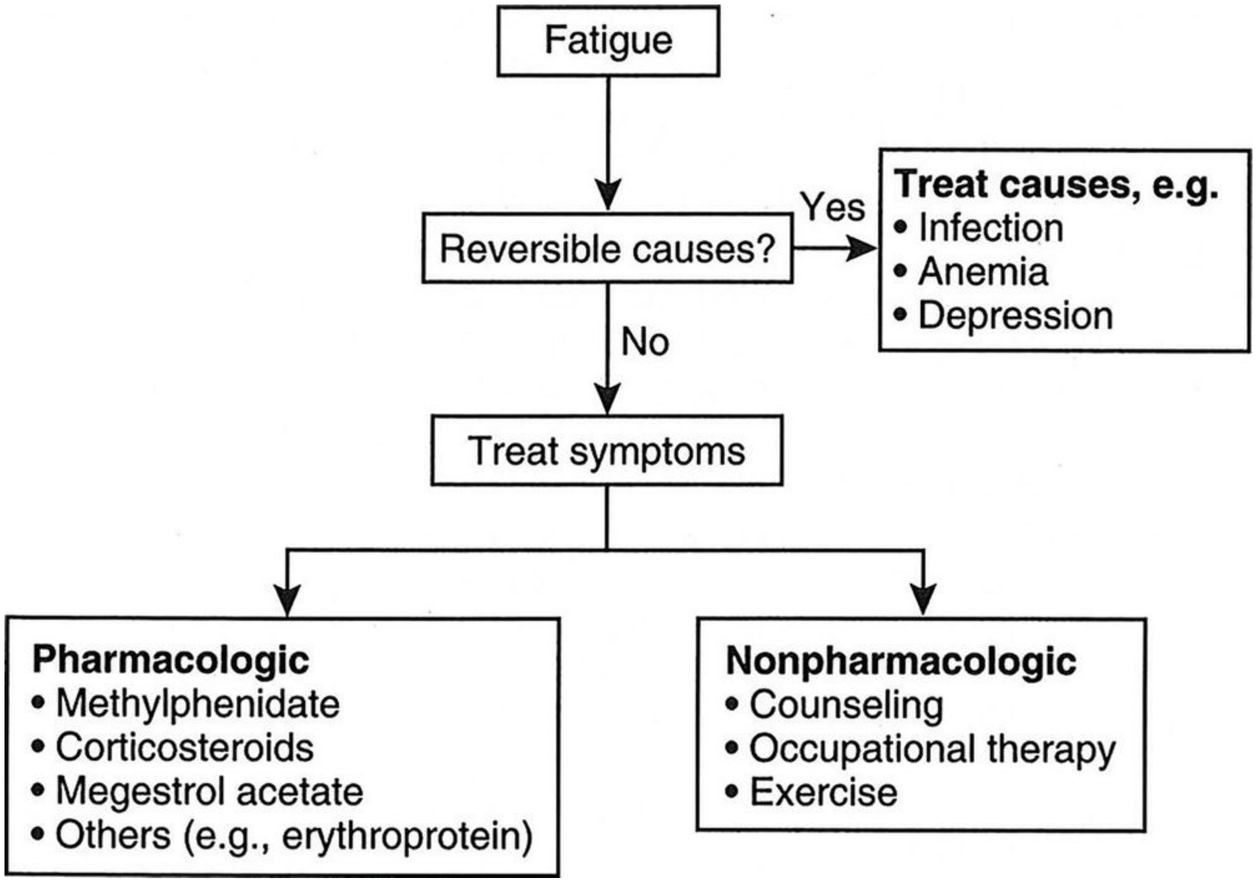

Figure 34.4. Algorithm for the management of fatigue.

Dyspnea

Dyspnea has been defined as an uncomfortable awareness of breathing. It is an unpleasant subjective sensation and cannot be measured by any physical abnormalities. **Figure** 34.5 summarizes the causes of dyspnea in cancer of the head and neck.

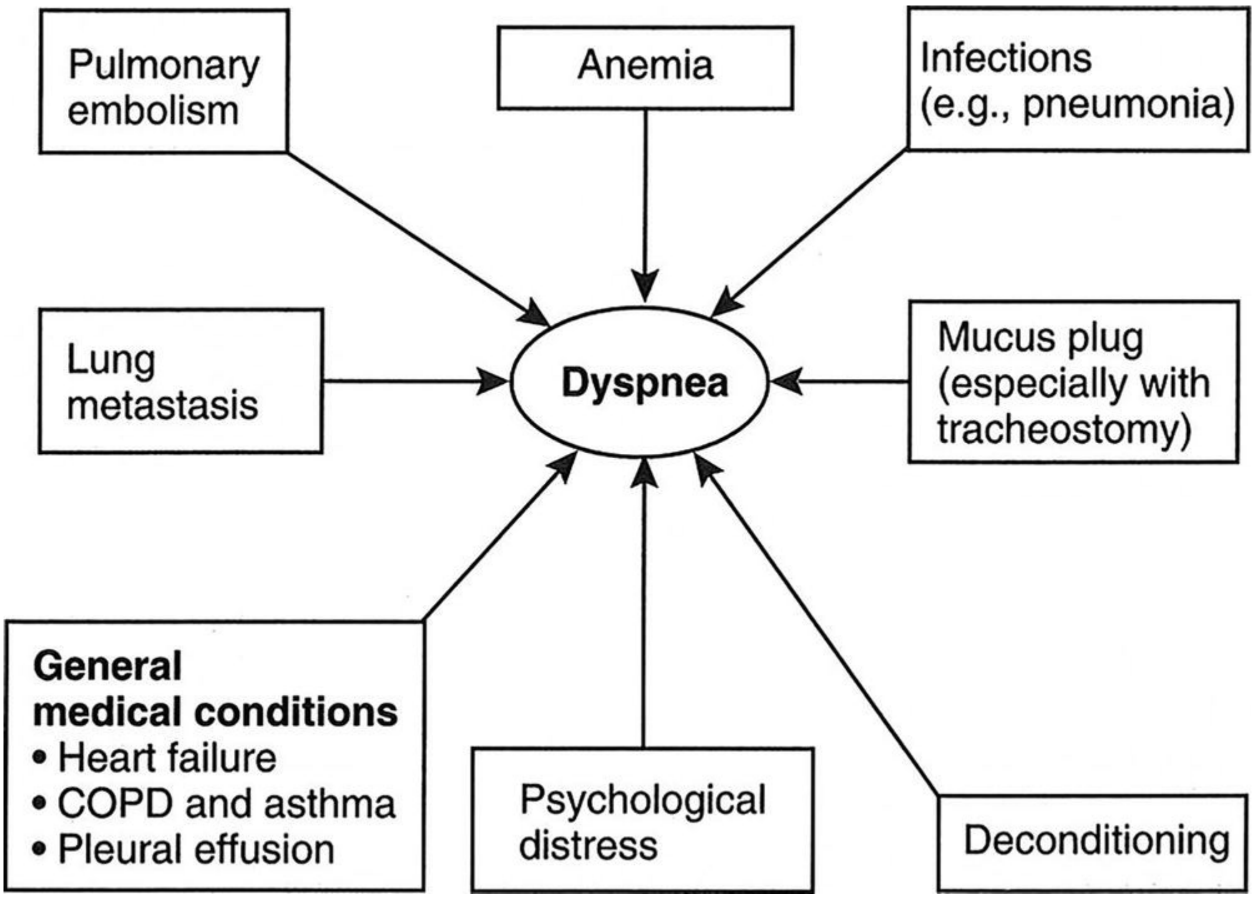

Figure 34.5. Causes of dyspnea in head and neck cancer. (COPD, chronic obstructive pulmonary disease.)

Patients with a tracheotomy have special problems related to accumulation of secretions and blockage of the stomal lumen due to enlargement of the tumor. The lumen can also be blocked during removal of the tracheotomy tube for cleaning. This can result in significant distress for the patient. In addition, caregivers often are stressed by caring for patients with tracheotomy.[43]

Many of the causes of dyspnea improve with treatment of the underlying condition, such as antibiotics for pneumonia, anticoagulation for pulmonary embolism, or blood transfusions for anemia. The symptoms of dyspnea are treated with oxygen, opioids, and behavioral strategies. Several randomized, controlled trials have shown that opioid therapy is beneficial for cancer dyspnea.[44] Corticosteroids are effective in the management of dyspnea associated with carcinomatous lymphangitis; they are also frequently used in the management of superior vena cava syndrome.[44]

Delirium

Delirium is the most common neuropsychiatric disorder, affecting ~85% of patients with advanced cancer.[45] Patients with delirium experience a combination of cognitive dysfunction, fluctuating levels of consciousness, reversal of the sleep–wake cycle (insomnia and daytime sleepiness), hallucinations (especially visual and tactile hallucinations), delusions, and other perceptual abnormalities. The condition is frequently misdiagnosed by clinicians as anxiety or insomnia, which may lead to certain interventions that worsen the delirium, such as prescribing benzodiazepines. Hospitalized elderly patients are particularly at risk, and clinicians should maintain a high degree of vigilance when patients experience sudden alteration in mental status. Family members are particularly helpful in identifying early changes in cognitive function and mood.

Figure 34.6 highlights the causes of delirium in cancer patients. Common causes of delirium in cancer patients include infection, adjuvant medications (especially corticosteroids and opioids), and electrolyte imbalance. Delirium is classified according to psychomotor activity as hyperactive (agitated), hypoactive (hypoalert), or mixed.[46] The hyperalert type of delirium is most common and tends to have the shortest duration and the best outcome.[47]

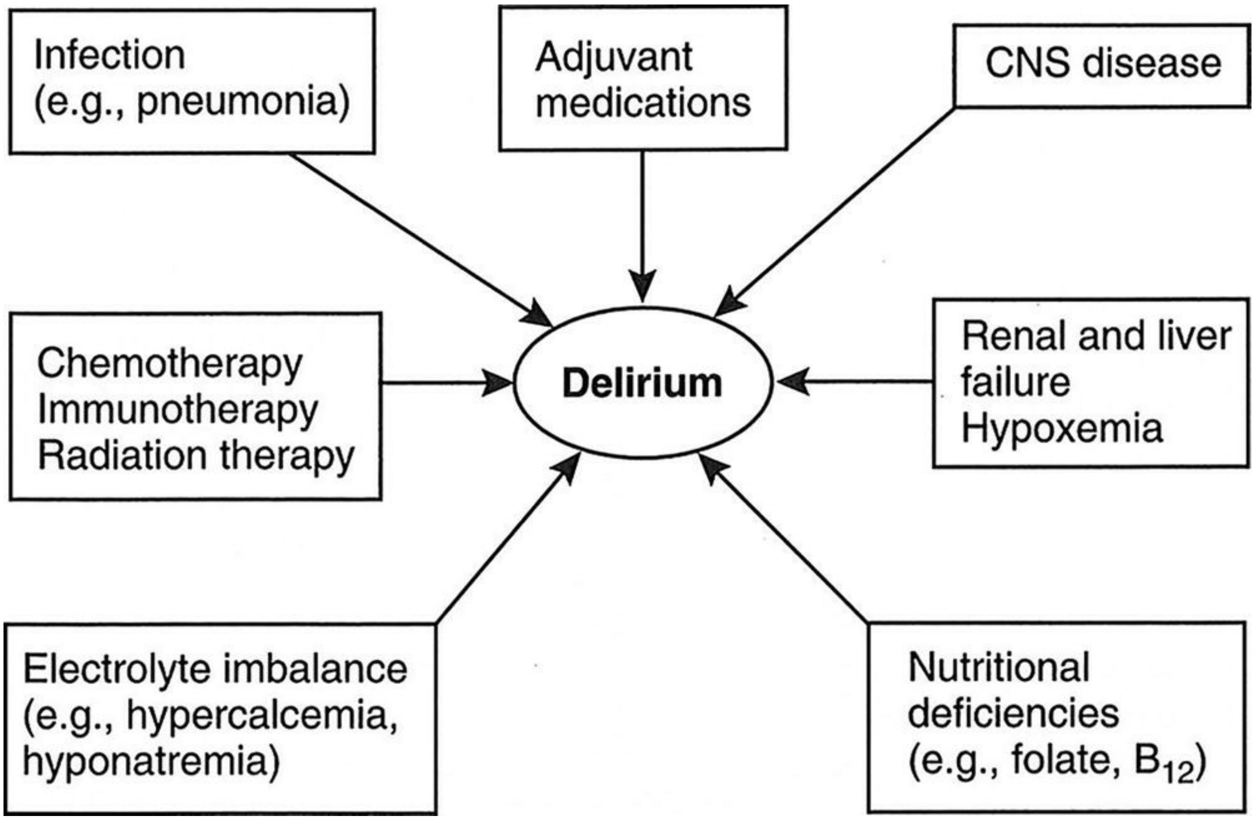

Figure 34.6. Causes of delirium in head and neck cancer.

A detailed history is of utmost importance in the diagnosis of delirium. Simple bedside tests, such as the Mini-Mental State Examination,[48] may be useful for screening patients suspected of having frank delirium, although such brief tools are not helpful in patients with focal lesions or mild to moderate cognitive dysfunction.[49] In cases of suspected but mild cognitive dysfunction, neuropsychological assessment may be useful. Neuropsychological evaluations are also useful in differentiating organic from functional disorders and in identifying early dementia unrelated to cancer.

The most important interventions in the management of delirium are to remove any contributing medications, to use opioid rotation, and to treat any contributing underlying medical conditions. Haloperidol can be used for symptomatic management of delirium. In about two-thirds of patients, delirium can be reversed and patients return to their baseline level of mental function.[50] Patients treated with haloperidol tend to have a shorter duration of this distressing state.[47]

Cannabinoids and Medical Marijuana

Cannabis has been used in medicine for more than 2,000 years. The interest in the potential medical effects of these compounds decreased after it became illegal. In recent years, the interest in cannabis has increased since the discovery of an endocannabinoid system. Many countries around the world have legalized the use of marijuana and other cannabinoid products both for medical and nonmedical reasons.

Cannabinoids have antiemetic effects that are mild as compared to those of the currently available potent antiemetic agents for chemotherapy-induced vomiting.

It has limited effects on appetite. There is stronger evidence regarding the role of cannabinoids for pain, particularly neuropathic pain.

The main limitations of these agents are the significant CNS side effects, especially highly debilitated patients who are also receiving opioids and other drugs. It has an addictive potential that is comparable to that of benzodiazepines but lower than the addictive potential of opioids, alcohol, or tobacco.

At the present time, there are limited indications for the use of cannabinoids in palliative care. More research is needed to better characterize the potential efficacy of these agents as adjuvants in the management of refractory pain and perhaps in selected cases of refractory emesis.[51]

SUMMARY

Patients with cancer of the head and neck suffer from multiple devastating physical and psychological symptoms. Pain, fatigue, cachexia, dyspnea, delirium, and psychological distress are precipitated by cancer and cancer treatment. These symptoms worsen the quality of life of patients with cancer of the head and neck and complicate their treatment. A history of alcoholism or poor psychosocial support may further complicate care. Multidimensional assessment of cancer-related symptoms is essential in helping to avoid complications, in providing early interventions, and in helping the patient and family cope better with the disease and its treatments. Palliative care, which can result in the provision of successful multidimensional care to patients with cancer of the head and neck and their families during the complete

course of the disease, should be integrated early in the trajectory of the illness.

35 Quality of Life in Head and Neck Cancer

Allen C. Sherman Stephanie Simonton-Atchley

INTRODUCTION

Cancer of the head and neck (HNC) and its treatments are associated with considerable burdens. Traditional clinical endpoints such as tumor control and survival provide little indication of the marked changes that patients experience in their day-to-day lives. Efforts to understand these challenges have become a more central concern. Thus, over the past few decades, health-related quality of life (QOL) has been recognized as a salient endpoint in clinical trials. Information about QOL outcomes is also important in clinical care. This information helps to inform patients and their families about what to expect during the course of care and facilitates decision making among treatment options. QOL data also assist clinicians in identifying common problems that must be monitored over time and inform the development of more effective screening and intervention services.

QOL research in HNC has grown dramatically over the past 20 years.[1,2] This chapter reviews some of the recent work in this area. We summarize some of the major difficulties that confront HNC patients at different phases of treatment and recovery. We review some of the important clinical and personal factors that may influence QOL outcomes. We examine interventions developed to enhance QOL among HNC patients. We discuss methods to assess QOL, and finally, we consider future directions for this field.

SYNOPSIS OF QOL CHANGES

HNC confronts patients with multiple challenges. Common concerns include disconcerting changes in functional capacity, disruption in daily roles, and uncertainty about the future. Patients may struggle with increased dependency on others and a diminished sense of control over their lives. The difficulties that patients experience are colored in part by the particularities of tumor site, treatment modality, and phase in the trajectory of illness.[3] During the initial period of active treatment, for example, patients must manage an array of acute toxicities.[4,5] Notwithstanding advances in treatment, symptom burden has become more pronounced with the move toward more aggressive, multimodal treatment approaches for individuals with advanced disease. The sequelae of illness and treatment may affect basic aspects of day-to-day functioning, including speaking, eating, respiration, and sometimes facial appearance— areas that play a fundamental role in social interaction and personal identity.

As patients transition from active treatment to long-term survivorship, other challenges may become more prominent.[3] These may include difficulty reestablishing normal routines,[6] fear of recurrence,[7] and sexual or social concerns.[8] Patients may need to adapt to a range of persistent or late effects (e.g., fatigue, xerostomia, dysphagia, dental complications, etc.).[4,9,10] Some are discouraged by ongoing limitations with eating or communicating. Others may struggle with recovery from nicotine or alcohol dependence, which have elevated prevalence rates in this population.[11] Finally, individuals who develop recurrence or disease progression are confronted by a new set of demands, as they cope with more pressing existential issues, intensified symptom burden, and complex end-of-life care decisions.

Aside from the impact on the patient, HNC creates major complications for the family as well.[12] Family members must accommodate multiple medical appointments and complicated caregiver tasks. Typical roles and responsibilities must be rebalanced. The burden on family caregivers has been further intensified by cost-driven changes within the health care system, including trends toward shorter hospital stays and increased home care. Traditionally neglected in both research and clinical care, family members recently have begun to receive greater attention. Studies suggest that partners often experience levels of distress that are comparable to[13] or greater than that of the patient.[14,15] Poorer communication between the spouses (e.g., less self-disclosure, greater efforts to hide from the partner one's concerns about

the illness) has been tied to greater levels of distress.[16]

QOL CHANGES DURING INITIAL TREATMENT AND RECOVERY

Patients in the initial phase of diagnosis and treatment may experience adverse changes in multiple domains. Longitudinal studies usually depict a characteristic deterioration in physical, role, and social spheres of functioning over the first few months; these changes unfold along with a series of more specific head and neck (HN) symptoms, including problems with swallowing, social eating, speech, HNC pain, xerostomia, sticky saliva, altered sensation, and nutritional deficits.[10,17–22] As expected, the most pronounced level of deterioration occurs in the acute treatment interval, followed by a gradual improvement (for survivors) over the course of the first year. By that point, many symptoms have returned to baseline (i.e., pretreatment) levels. Notably, however, clinically meaningful deficits remain in many areas. Protracted problems often include xerostomia, dysphagia, eating difficulties, speech problems, sticky saliva, fatigue, and diminished physical functioning.[10,17–22] Observers often highlight the encouraging improvements in global or general QOL, but these gains should not eclipse attention to residual concerns.

Aside from the adverse changes in physical functioning that emerge during active treatment, patients may experience difficulties in psychosocial well-being as well. Many report clinically meaningful levels of emotional distress. Prevalence estimates have varied widely across studies, due in part to methodological considerations (e.g., differences in measures, cutoff scores, and times of assessment). More rigorous studies have used diagnostic interviews instead of self-report questionnaires to evaluate psychosocial morbidity. Rates of major depression have ranged from 17% to 29% among patients assessed during the first year after diagnosis[23–25]; these estimates are notably higher than rates for the general US population. By way of comparison, these estimates are also somewhat higher than those derived from a recent meta-analytic review involving patients with diverse types of cancer and varying times of assessment.[26] These findings assume additional urgency because depressive symptoms have been associated with increased risk for malnutrition and poor adherence among HNC patients[27],28 and with

increased hospitalizations, poorer health behaviors, and diminished immune function in other patient groups.[29–31] Aside from depression, patients may experience other psychological difficulties as well (e.g., posttraumatic stress symptoms, adjustment disorder, etc.). Unfortunately, psychosocial morbidity is notably underdetected and undertreated in oncology settings.[32–34]

QOL CHANGES DURING LONG-TERM SURVIVORSHIP

Growing attention has focused on the experience of HNC survivors evaluated over the longer term, 3 to 5 years after diagnosis.[1] What challenges emerge during posttreatment survivorship? In contrast to the notable shifts in QOL that characterize the acute treatment period, subsequent changes over time are more limited. Several longitudinal studies[17,35–37] suggest stable or modestly improved global QOL, along with protracted problems in specific areas, including, for example, disrupted physical and role functioning, diminished taste and smell, xerostomia, sticky saliva, and dental concerns. At 3 to 5 years, these difficulties remained more burdensome than they had been at diagnosis. However, other areas seemed to improve compared to their pretreatment levels, such as emotional functioning and depressive symptoms.[17,36,37]

Other studies have compared the experience of HNC survivors to that of healthy comparison groups, 3 years or more after treatment. As one might expect, HNC patients (with diverse anatomical sites and treatment histories) report greater problems with HN symptoms (e.g., trismus, xerostomia, diminished taste and smell) relative to age-matched population norms.[35,38] However, findings regarding broader aspects of QOL (e.g., disrupted physical functioning, mental health, and vitality) have varied across studies, with some showing extensive deficits[39,40] and others more narrow differences,[38,41,42] compared with healthy individuals. Overall, it appears that many long-term survivors manage well but experience persisting effects in specific domains. Helping individuals adapt during the phase of survivorship is becoming a stronger priority for oncology teams.

CLINICAL CHARACTERISTICS

ASSOCIATED WITH QOL

QOL outcomes are influenced by basic characteristics of the illness and treatment, though these findings are not as consistent as one might anticipate. In view of the limited number of randomized studies, it is often difficult to disentangle the effects of one clinical characteristic from another (e.g., disease stage vs. treatment modality). Generally however, patients with advanced disease tend to fare more poorly than do those with less disseminated disease,[17,19,24,43–47] though this is not always the case.[20,22] Individuals undergoing more aggressive, multimodal treatment usually have greater difficulties than do those who receive single-modality treatment,[17,48,49] and similarly, those who receive more extensive surgical[5,50,51] or radiotherapy[46] interventions experience greater problems than do patients treated with more limited protocols.

QOL is also shaped by the specific treatment regimens that patients receive. An important objective is to determine whether advances in therapeutic approaches are associated with meaningful improvements in daily physical and psychosocial functioning. Some of this work has focused on innovations in radiotherapy strategies. Intensity-modulated radiotherapy (IMRT), which is designed to target the tumor bed while more effectively limiting the exposure of surrounding radiosensitive tissue, has been widely adopted. Several nonrandomized studies suggest that IMRT is associated with enhanced QOL outcomes relative to conventional radiotherapy[52–55] (for a review, see Tribius and Bergelt[56]). For example, in a matched-pair comparison study (average follow-up of 23 months), patients treated with IMRT fared better with respect to physical functioning and several HN morbidities (e.g., xerostomia, sticky saliva, trismus, pain, swallowing), compared with those who had received conventional radiotherapy.[52] However, QOL benefits have been less pronounced in the few randomized studies conducted thus far. These investigations have confirmed improvements in objective endpoints such as salivary flow and clinician-rated xerostomia, but noted less consistent differences in patient-reported outcomes.[57–59] Few of these investigations have had adequate statistical power to detect QOL differences; thus, more definitive conclusions await further research.

Other investigations have examined QOL changes associated with

advances in surgery. Some of these efforts have evaluated changes in reconstructive techniques. For example, with innovations in microvascular surgery, the use of free flaps has become more prominent than the use of pedicled pectoralis major myocutaneous flaps, which had been a mainstay in reconstruction for patients with cancer of the oral cavity. Free flaps require more extended time in the operating room and more specialized skills, but there are fewer complications, briefer hospitalizations, and lower costs.[60,61] Some studies have pointed to long-term improvements in QOL, such as less pain and enhanced appearance, speech, and emotional functioning among oral cancer survivors (assessed on average more than 3 years after surgery) who underwent reconstruction with free flaps, relative to those who received pectoralis major pedicled flap reconstruction.[62,63] Recently, there also have been efforts to compare different approaches to free flap reconstruction. There are preliminary indications that anterolateral thigh perforator flaps are associated with more favorable QOL outcomes, including better appearance, improved social functioning, and fewer shoulder problems, compared with radial forearm free flaps (at an average of 3 years after surgery).[64] However, caution is required in interpreting each of these studies, because none involved randomized designs and none accounted for imbalances in clinical or demographic characteristics between the reconstruction groups.

Another approach with important QOL implications involves endoscopic surgery. Endoscopic procedures, which are usually performed with a CO_2 laser, have become more common as an alternative to open surgery or radiotherapy, especially for early-stage glottic cancer. Thus far, studies have found few differences in QOL outcomes for endoscopic surgery compared with radiotherapy in this patient group[65–67] (see Spielmann et al.[68] for a review). Findings are tentative however because these were small nonrandomized investigations, which evaluated mostly long-term survivors, who may no longer experience the same sequelae that were evident earlier in care; moreover, most of the studies were characterized by clinical or demographic differences between treatment arms. Endoscopic approaches are also used to treat selected patients with more advanced disease.[69] A recent nonrandomized study[70] focused on patients with hypopharyngeal cancer, assessed closer in time to the end of treatment (average of 10 months). Those who received transoral laser surgery demonstrated significantly better outcomes compared with the open surgery group (e.g., improved emotional

and social functioning, speech, social eating, social contact, sensation, dentition), as well as better outcomes than the chemoradiation group (e.g., fewer problems with dry mouth, social eating, social contact). Results should be interpreted conservatively in view of group differences in tumor stage and time since end of treatment. We anticipate that QOL research regarding endoscopic surgery and transoral robotic surgery will continue to expand over the next few years.

Another area that has garnered continued interest and debate involves comparisons across different treatment modalities. Considerable attention has been devoted to organ preservation protocols, such as chemoradiation, as an alternative to extensive resection, in the hope that symptom burden and QOL can be improved without compromising locoregional control or survival. Most of these efforts have focused on patients with locally advanced HNC, including advanced oropharyngeal or laryngeal cancer. Findings are inconsistent. They are also difficult to interpret in the absence of randomized trials. Nonetheless, it is clear that the chemoradiation has difficult toxicities of its own (consistent with the oft-cited observation that organ preservation is not synonymous with organ function). In general, findings suggest that each treatment modality is associated with characteristic symptoms and functional limitations (some of which are distinct and some of which overlap with those of other treatments), so selection among therapeutic options remains a complex process for many patients with advanced disease.

For example, among advanced oropharyngeal cancer survivors (assessed an average of 4.7 years after the end of treatment), the group who had been treated with concurrent chemoradiotherapy reported significantly greater difficulties with a number of symptoms, including trismus, dental concerns, xerostomia, and sticky saliva, than did those who had received surgery and postoperative radiotherapy.[9] On the other hand, the surgery group had more problems in other areas (i.e., fatigue, pain, swallowing, social eating, and social contact). Similarly, at 1-year follow-up, Oates et al.[43] reported relatively greater deterioration for the chemoradiation group in some domains (e.g., trismus, dentition, swallowing, sexuality, feeling ill), but more pronounced deterioration for the surgery and postoperative radiation group in other domains (e.g., cognitive functioning, fatigue, pain, diminished sensation). In a very small subgroup analysis of survivors of advanced cancer of the oropharynx, findings hinted at clinically meaningful benefits for the

radiotherapy group, compared with the surgery and postoperative radiotherapy group, in several areas (e.g., physical, social, role, and emotional functioning, pain, dyspnea).[71] However, interpretations are limited by considerable imbalances between the groups in time since treatment. In contrast, another subgroup analysis of advanced oropharyngeal cancer survivors (average follow-up of 3.7 years) tentatively suggested clinically meaningful advantages for the surgery group (e.g., global, social, and cognitive functioning, nausea, reliance on analgesics), though once again the sample was very small.[72] Other investigations of intermediate- to long-term survivors of advanced cancer of the oropharynx reported few group differences.[40,73] Ultimately, of course, more definitive information about differential effects on QOL will require large, multicenter randomized trials.

PERSONAL CHARACTERISTICS ASSOCIATED WITH QOL

Relationships between demographic variables and QOL outcomes have been inconsistent. Women have reported poorer QOL[17,46,47] or emotional well-being[17,74,75] in some studies but not others.[44,76,77] Older patients sometimes demonstrate better psychosocial well-being[42,77] but poorer physical functioning[17,42,47] than do their younger peers, though again many studies have reported no differences.[44,74–76]

Aside from clinical or demographic factors, the personal resources that participants bring to the illness appear to have a salient effect on QOL.[3] Thus far, these variables have received greater research attention in other types of malignancies, but they are beginning to draw closer scrutiny in the HNC literature. For example, in longitudinal studies, higher levels of optimism about life (dispositional optimism) predicted better global, role, and cognitive functioning[78] and improved emotional well-being[79] after treatment. In relatively large cross-sectional analyses, greater optimism was related to improved physical, functional, and social well-being,[80] whereas pessimism was tied to poorer physical and social functioning.[81] Coping strategies appear to be important as well. Several studies suggest that participants who engage in counterproductive responses, such as self-blame, avoidance, wishful thinking, catastrophizing, or passive coping, experience greater emotional

distress and poorer QOL.[76,82–86] It would be helpful to extend this work from cross-sectional investigations to longitudinal studies and to differentiate more clearly between cancer-specific coping efforts[82,83] versus more general coping strategies.

QOL is also colored by the social and cultural contexts in which patients live. Social support is thought to be a critical resource for cancer patients. A few longitudinal studies reported that perceived support prior to treatment predicted subsequent improvements in HN symptoms[87] and depression.[75] Similarly, several cross-sectional studies suggested that greater perceived social support was related to more favorable outcomes, such as enhanced medication adherence,[88] improved speech,[89] reduced social disruption,[89] and greater emotional well-being.[23,74,89] However, some investigations have reported null findings, especially at intervals further removed from the demands of active treatment.[42,90] There are multiple dimensions of social support, which may have complex relationships with QOL outcomes.[23,81] Investigators have begun to explore some of these other facets of support among HNC patients (e.g., received vs. available support[75]; open communication vs. protective buffering[16,91]; affirming vs. undermining relationships), which should reveal a more nuanced picture.

Identifying other modifiable factors that contribute to risk or resilience for QOL difficulties is an important priority area for future research in HNC. Findings may have significant implications for clinical care, because these factors can be targeted in interventions to improve adaptation.

EMERGING AREAS OF RESEARCH

A number of important outcomes have received minimal attention in standard QOL assessments, but are now drawing increased interest. These issues are rarely discussed in clinical encounters despite their appreciable impact on daily life. Many patients struggle with marked fear of disease progression or recurrence.[7] These concerns vary in intensity, but are evident across the trajectory of illness, from initial diagnosis and active treatment[92] through long-term survivorship.[92–95] We anticipate that these concerns may be especially pronounced in HNC, which is associated with a high risk for relapse. Interestingly, however, fear of recurrence seems less rooted in

objective prognostic factors than in patient characteristics, such as younger age,[93,95] greater generalized anxiety or distress,[92,93,95] and lower dispositional optimism.[92]

Other patients experience a sense of stigma or shame regarding their illness.[96] Despite advances in surgery, cosmetic changes are a significant hardship for some individuals. Facial disfigurement, whether rated by the patient or by an observer, has been tied to greater emotional distress, social discomfort, and isolation.[23,97,98] Individuals who are more confident in their ability to manage social situations (i.e., higher in social self-efficacy)[97] or who perceive stronger social support[23] may be buffered from these difficulties. Other patients may feel stigmatized because of overt functional deficits associated with their illness (e.g., eating or speech problems) or because of the role that health practices may have played in its etiology (e.g., nicotine or alcohol dependence or human papillomavirus (HPV) infection). Stigma has been related to greater depression and lower well-being in a number of studies.[96,98,99]

Disruptions in sexual well-being are another area of concern for many cancer survivors. In recent studies, roughly one-third to one-half of HNC patients at varying phases of recovery reported difficulties with sexual interest or sexual satisfaction.[8,19,43,100–102] Most of these investigations included only very brief measures. Thus far, few studies have examined more comprehensive aspects of sexual function among HNC patients[102] or compared findings to those of age-matched healthy individuals. More detailed studies are needed to help clarify the scope of these difficulties and their risk factors.

Most QOL research has focused on identifying burdens and morbidities. It seems clear, however, that some patients experience unexpected positive life changes as well as negative ones. They discover that life has been enriched in some ways (e.g., deepened relationships, strengthened spirituality, a renewed sense of appreciation or purpose), even if depleted in others. An exclusive focus on QOL deficits may obscure the complexities of patients' responses to the illness. Positive changes in the aftermath of adverse events have been referred to as posttraumatic growth, stress-related growth, or benefit finding. Efforts to understand these experiences have given rise to several coherent theoretical models[103,104] and a large empirical database.

Within the HNC literature, a few studies have begun to explore factors that might contribute to perceived growth. Consistent with findings in other malignancies, greater optimism[105–107] and active coping or positive reframing[105,106] have been tied to increased perceived growth. At the same time, stronger challenges (i.e., perceived disfigurement, stressful events), which are thought to prompt a reevaluation of one's life, may be related to perceived growth as well.[98] Further research in this area may help clarify the nature, durability, and correlates of positive changes in response to HNC.

Other important areas[1] that have received surprisingly little attention in HNC research include adherence,[88] decision-making processes, survivorship plans, and end-of-life care.[108]

QOL INTERVENTIONS

Treatment for HNC requires interdisciplinary care. Greater recognition of the QOL difficulties that patients experience has prompted a growing emphasis on provision of psychosocial support services. Intervention research in HNC is at an early stage of development. As yet, few randomized trials have been completed. A recent meta-analytic review of randomized studies concluded that there was insufficient evidence available to substantiate the use of psychosocial interventions for HNC patients,[109] a conclusion that seems unsurprising given the small number of studies included and the diversity of intervention strategies and measures that were employed. Nonetheless, the landscape is shifting. Some additional innovative projects have emerged, and others are in progress.

One of the largest randomized studies completed thus far examined the value of a nurse-led intervention, which encompassed six individual counseling sessions over the course of the year following completion of HNC treatment.[110] This broad-based, manualized program included ongoing screening for depression, assistance with medical symptoms, and counseling or skills training for psychosocial difficulties. At 1 year following completion of cancer treatment, the intervention group (n = 103) demonstrated significantly reduced depression scores (the primary outcome) relative to the usual care control group (n = 102). The same beneficial effects were evident for the subgroup of patients who were classified as clinically depressed at enrollment. The intervention group also reported greater improvements in

several QOL domains (e.g., emotional functioning, trismus, pain, swallowing).[111] A similar pattern of benefits was evident at the 18-month follow-up, though by 2 years after cancer treatment, there were few significant differences.

Another study sought to address problems with smoking, alcohol use, or depression, among patients who screened positive for these difficulties.[112] Participants were randomized to a usual care condition (a single assessment, which included educational handouts and referrals), or a cognitive–behavioral intervention, which included 9 to 11 telephone sessions and a workbook. Six months after enrollment, those in the intervention arm (n = 93) reported significantly greater improvements in smoking cessation, relative to those in the control arm (n = 91). There were no group differences in alcohol use or depression. Other investigators compared two treatment approaches for patients with high levels of posttraumatic stress disorder (PTSD) symptoms, anxiety, or depression.[113] Patients were randomized to six sessions of either cognitive–behavioral treatment (CBT) or nondirective supportive counseling. Participants in both conditions showed improvement over the course of 12 months, and there were no significant group differences, though the proportion of patients with clinically meaningful symptoms seemed lower in the CBT condition.

Several nonrandomized studies also provide hints about the potential value of psychosocial interventions for HNC patients. One project focused on a nurse-led psychoeducational program for patients who had completed cancer treatment.[114] Individuals were eligible for this project if they exceeded cutoff values for distress. Participants elected to receive usual care, or chose two to six sessions of individualized counseling at home, supplemented by homework, to address psychosocial difficulties. At the end of treatment, the intervention group (n = 25) demonstrated significantly greater improvement in depression, anxiety, psychosocial problems, and QOL scores compared with the control group (n = 29); most of these improvements were maintained at a 3-month follow-up. Another nonrandomized investigation evaluated a coping skills program for patients who had completed cancer treatment.[115] Participants chose their preferred format for the brief intervention: two to three individual sessions; two to three group sessions; or a workbook, with access to a clinician as needed. At the end of the intervention, multivariate analyses indicated that those who received the coping program (in any of the

three formats, *n* = 45) experienced significantly better global QOL and marginally better depressive symptoms, compared to a control group (*n* = 56). There were no group differences in other dimensions of QOL or in anxiety.

On the other hand, few benefits were evident in another nonrandomized study that evaluated a support program for patients during treatment and early survivorship.[116] Patients in the intervention arm were offered weekly individual visits with a nurse and a dietician during oncology treatment; sessions were subsequently provided monthly for 6 months and then at 1- and 3-year follow-ups. There were no improvements on multiple measures of distress or QOL for the intervention patients (*n* = 52), relative to control patients (*n* = 92) who lived further away from the facility and had been matched on several variables (age, stage, gender, and anatomical site). Indeed, the intervention group seemed to fare worse on some measures. Finally, more ambiguous results emerged from a nonrandomized investigation of a nursing intervention.[117] Intervention patients received six sessions with a trained nurse over the course of year following completion of cancer treatment. Nurses provided medical checks, screened for psychosocial problems, and offered advice and support. Prior to beginning the program, intervention patients reported greater problems than did those in the usual care control group—they scored significantly worse on most psychosocial and QOL measures. By the 6-month and 1-year assessments, the intervention patients (*n* = 80) had improved to the level of the control patients (*n* = 80). Thus, they showed stronger changes from baseline on a wide number of scores (especially at the 6-month assessment). These findings hint at intervention-related benefits, but of course, other interpretations cannot be ruled out (e.g., regression to the mean).

In sum, results have varied across studies—in general, stronger findings appear to be associated with theoretically informed, skills-based interventions administered by carefully trained clinicians, targeting patients with elevated symptoms. The optimal “dose” for different interventions has yet to be clarified, but most of the projects studied thus far have included relatively few sessions.

ASSESSING QOL

Assessment of QOL is grounded in some basic principles.[1,2] Health-related QOL is construed as a multidimensional construct—it encompasses patients' perceptions of their status across several domains of functioning, including physical, emotional, social, and spiritual well-being. Thus, the use of global or summary measures of QOL tends to obscure important differences in specific areas. QOL is typically viewed as a broader, more comprehensive concept than related outcomes such as performance status, toxicities, or symptomatology. It is grounded in the individual's personal appraisals; these perceptions are not readily captured by proxy ratings from clinicians or family members, which tend to correlate poorly with patient self-report.

Over the past 25 years, there has been a major focus on developing psychometrically sound measures of QOL for use in HNC. A large toolbox of validated instruments is available (for a review, see Ojo et al.[2]). None is ideal for use in all circumstances; rather, measures should be selected to accommodate the particular needs of the assessment.[118] Generic measures of health-related QOL (e.g., Medical Outcomes Study Short Form-36[119]) are useful in evaluating comparisons between HNC patients and healthy population norms or patients with other illnesses. Cancer-related measures (e.g., FACT-G,[120] EORTC QLQ-C30[121]) assess difficulties commonly encountered by oncology patients. In contrast, disease-specific measures (e.g., FACT-HN,[120] EORTC QLQ-H&N35,[121] University of Michigan Head and Neck QOL,[122] Head Neck Cancer Inventory,[123] University of Washington QOL questionnaire[124]) offer a more focused evaluation of problems that characterize that particular disease or tumor site. A common practice involves use of combined modules, which encompass both a general and a disease-specific measure,[118] in order to capitalize on the advantages of each (e.g., FACT-G and FACT-HN module or EORTC QLQ-C30 and EORTC QLQ-H&N-35).

HNC-specific instruments vary in their content domains, so instrument selection is sometimes based on the particular morbidities of greatest interest. Among other considerations, choices also may be driven by the need to ensure comparability across studies (when more widely used measures are more helpful than uncommon ones), the reliability of the measure (when multiple items in each domain may be more useful than single items), or sensitivity to change (when it is important to capture changes over time or treatment).

Investigators have also drawn on more narrowly targeted instruments, each geared toward a particular treatment modality (e.g., QOL-Radiation Therapy Index,[125] Neck Dissection Impairment Index[126]), HNC symptom (e.g., Xerostomia Questionnaire,[127] MD Anderson Dysphagia Inventory[128]), or anatomical subsite (e.g., FACT-Nasopharyngeal module[129]). Those who wish to assess specific psychosocial outcomes, such as emotional distress, fatigue, sleep disturbance, or sexual concerns, have a wide assortment of well-established measures from which to choose.

Recently, there have been some exciting trends in QOL assessment. One involves national efforts to develop a repository of refined measures (e.g., item banks) that can be used across a broad range of clinical settings and patient groups. For example, since 2004, the National Institutes of Health (NIH) Patient Reported Outcome Measurement Information System (PROMIS)[130] has generated a portfolio of abbreviated scales with strong psychometric properties. Using item response theory analyses, it has also expanded opportunities for use of Computer Adaptive Testing (an efficient, individualized assessment approach in which the next item administered is based on the patient's response to the previous item). Ultimately, programs such as NIH PROMIS, the NIH Toolkit, and the National Cancer Institute's Grid Enabled Measures (GRID) are expected to contribute to a common core of measures, allowing greater comparability across studies.

What does a number on a QOL questionnaire tell us?—the meaning of a score is not always apparent. Thus, another important development involves attempts to determine the clinical importance of QOL scores, instead of only their statistical significance. Several approaches have been used to enhance the interpretability of QOL findings. Population norms are available for some instruments, such as the FACT-G[131] and the EORTC-QLQ-C30.[132] Some investigators have sought to define thresholds or cutoff values, reflecting minimum scores that patients regard as acceptable.[133] Others have determined the meaning of differences in scores (i.e., the "minimal clinically important difference") by using clinical benchmarks (anchor-based methods[134]), the statistical properties of the score distributions (distribution-based methods[135]), or meta-analyses of scores from large groups of patients combined with the ratings of expert panels.[136] All of these approaches are intended to improve the practical, clinically meaningful level of information that QOL instruments can provide.

Thus far, the use of QOL assessments in routine clinical practice remains limited. Of course, the tools that are most helpful for rapid clinical screening and referral differ from those needed for comprehensive evaluation. Greater integration of patient-reported outcome measures into clinical care may be facilitated by selection of brief, symptom-focused, readily interpretable measures, perhaps administered by computerized systems that provide real-time feedback to clinicians.

CONCLUSIONS

Day-to-day life is altered in fundamental ways by HNC and its treatments. Efforts to evaluate these QOL challenges, to track changes over the course of illness, and to provide appropriate screening and intervention services are core aspects of patient-centered care. QOL research in HNC has been marked by significant advances in recent years. A growing database, based on validated instruments, has highlighted some of the physical and psychosocial difficulties that patients encounter. Studies have targeted more homogenous samples, capturing sequelae associated with specific treatments, distinct anatomical sites, and particular stages of disease. Longitudinal investigations, which illuminate patterns of deterioration and improvement over time, are becoming more common. Moreover, investigators have started to reach beyond traditional QOL endpoints to evaluate additional outcomes that are important to patients, such as fear of recurrence, stigma, sexual difficulties, and caregiver burden. Studies have begun to explore the possibility of positive life changes as well as negative ones. Research on screening and intervention is nascent but expanding. Furthermore, attention has been devoted to defining findings that are clinically meaningful instead of only statistically reliable.

As the field moves forward, some additional considerations would be important to address. Very few studies have focused specifically on the experience of individuals with HPV-related HNC or those with recurrent disease. Moreover, few have focused on patients from underserved ethnic/racial minority groups, or from rural areas, who may bring distinct needs and resources. Research directed toward these participants would make a welcome contribution.

Further progress will require attention to methodological concerns. For

example, most studies remain small and underpowered, so potentially meaningful findings may be missed. Multicenter collaborative investigations would provide greater prospects for ensuring adequate samples, especially given the high attrition rates that are characteristic among patients with a demanding illness. They would also provide greater opportunity to control for confounding factors, which are a common problem in HNC research. In addition, the great majority of QOL investigations in HNC are atheoretical. Research would be enhanced by drawing on appropriate theoretical frameworks to explore predictors of risk and resilience and to guide interventions.

Enhancing QOL for HNC patients is an important mandate. Continued developments in QOL research will make a significant contribution to the quality of care.

36 Application of Advances in Endoscopic and Robot-Assisted Approaches to the Treatment of Head and Neck Cancer

Jason G. Newman Bert W. O'Malley Jr.

INTRODUCTION

The history of medicine has included some significant milestones. From the separation of philosophy and clinical medicine in the days of Hippocrates, to the understanding of the role of microorganisms in the creation of human illness, there are some concepts and tools that have literally changed how we understand and practice medicine. These individual changes have caused massive paradigm shifts, which first disrupt and then propel forward our approach to treating the human condition. Over the last 100 years, medicine has moved forward at a breakneck pace. Surgery has taken several big steps over this time frame. Open surgery, in the age of modern anesthesia, advanced imaging, and antibiosis, has become safe and effective in most cases. This has allowed us to concentrate on even further advances in the practice of surgery. Minimally invasive approaches and now even robotic approaches are becoming standard options in the management of many surgical diseases. In this chapter, we will review the history and discuss the evolving applications of both endoscopy and robotics in the field of head and neck cancer surgery.

HISTORY OF ENDOSCOPY IN OTOLARYNGOLOGY

Endoscopy within the field of otolaryngology has followed two separate but closely intertwined paths. On the one side is endoscopy to evaluate the larynx, and on the other, the sinonasal cavities. Although each of these anatomic regions has faced its own set of obstacles and techniques, what continues to keep them linked is the reliance on technology to access and operate in these tight spaces through natural orifices.

History of Sinonasal Endoscopy

In the 1970s, an Austrian physician, Walter Messerklinger, introduced the use of endoscopes in the performance of sinus surgery. Several of his students, including Stammberger and Kennedy, continued to advance the indications for the use of the endoscope within otolaryngology.[1] Initially, the endoscope was primarily used as a tool to aid in the medical management of inflammatory sinus disease. However, the endoscope quickly became the instrument of choice for management of surgical sinus disease. Over time, as descriptions of the anatomy, surgical techniques, and instrumentation began to evolve, the capacity to advance the frontier of the endoscope has grown.

Anterior skull base CSF leaks were among the earliest advanced procedures performed transnasally with an endoscope.[2] Creating safe techniques to separate the intracranial and sinonasal spaces was paramount in creating a safe and low-risk procedure. Initially, this involved the use of free mucosal grafts, adipose tissue, and nasal packing. In the 1990s, several authors described the use of the endoscope to assist in removal of tumors of the sinonasal and anterior cranial base, often with the combination of open and endoscopic techniques.[3] In 2001, Casiano et al.[4] reviewed the first series of purely endoscopic resection of esthesioneuroblastoma. Their success and the success of other authors led to a continued interest in the expansion of the use of this technique. Creation of hemostatic agents, finer and more angulated instrumentation, and techniques for closure of skull base defects were all results of these early surgical endeavors. Free mucosal grafting, inlay grafting techniques, and pedicled flaps have all played a role in the evolution of our surgical capabilities in this area. In addition, fine-cut CT and MRI scans, intraoperative navigation, and high-definition endoscopes have all allowed surgeons to address complex lesions more safely. Since these early studies, many surgical teams have gone on to describe large series of patients undergoing endoscopic resection of sinonasal malignancies.[5,6] Most recently,

the endoscopic endonasal approach (EEA) has been expanded to include options for management of tumors in areas other than the sinonasal cavity. This includes intracranial tumors, as well as tumors in the infratemporal fossa and pterygopalatine space. The sinonasal cavity has now, in many cases, become for the endoscopic approved corridor to the region of primary concern.

History of Laryngopharyngeal Endoscopy

At the same time as the early descriptions of endoscopy in the sinonasal cavity was first being described, Strong, Jako, Steiner, and others[7,8] began to develop the field of endoscopic laser surgery (ELS) for the larynx. This led the way to transoral laser microsurgery (TLM). Since that time, techniques and instruments have evolved to the point where almost all regions of the upper aerodigestive tract are accessible for surgical endoscopy and resection of tumors.

As is true with sinonasal endoscopy, endoscopy of the larynx required a continued expansion of the instruments, optics, and hemostatic methods to aid in its wider application. A variety of laryngoscopes, laryngeal microinstruments, specialized endotracheal tubes and suspension techniques have been designed to maximize the ability to visualize and safely operate in this tight space. The CO_2 laser was an important tool for the safe performance of this surgery, as both an instrument of resection as well as a hemostatic tool. Its long wavelength (10,600 nm) and other physical properties originally required that it be delivered via a microscope-mounted beam splitter (or a direct mounted beam) into the surgical site. Until recently, the use of the CO_2 laser has required a direct line of site from the laser emitter to the surgical site, often creating significant difficulty in both visualizing and manipulating the tumor. Recently, the invention of a hollow-core fiber to deliver the CO_2 laser (OmniGuide system, OmniGuide Inc., Cambridge, MA) (**Fig. 36.1**) has broadened the indications for this surgery. It has removed the line of site necessary for management of the tumor and has brought the laser into the field on a flexible fiber. This, in combination with angled endoscopes, microinstruments and high-definition optics, has allowed for continued expansion of the use of this TLM.

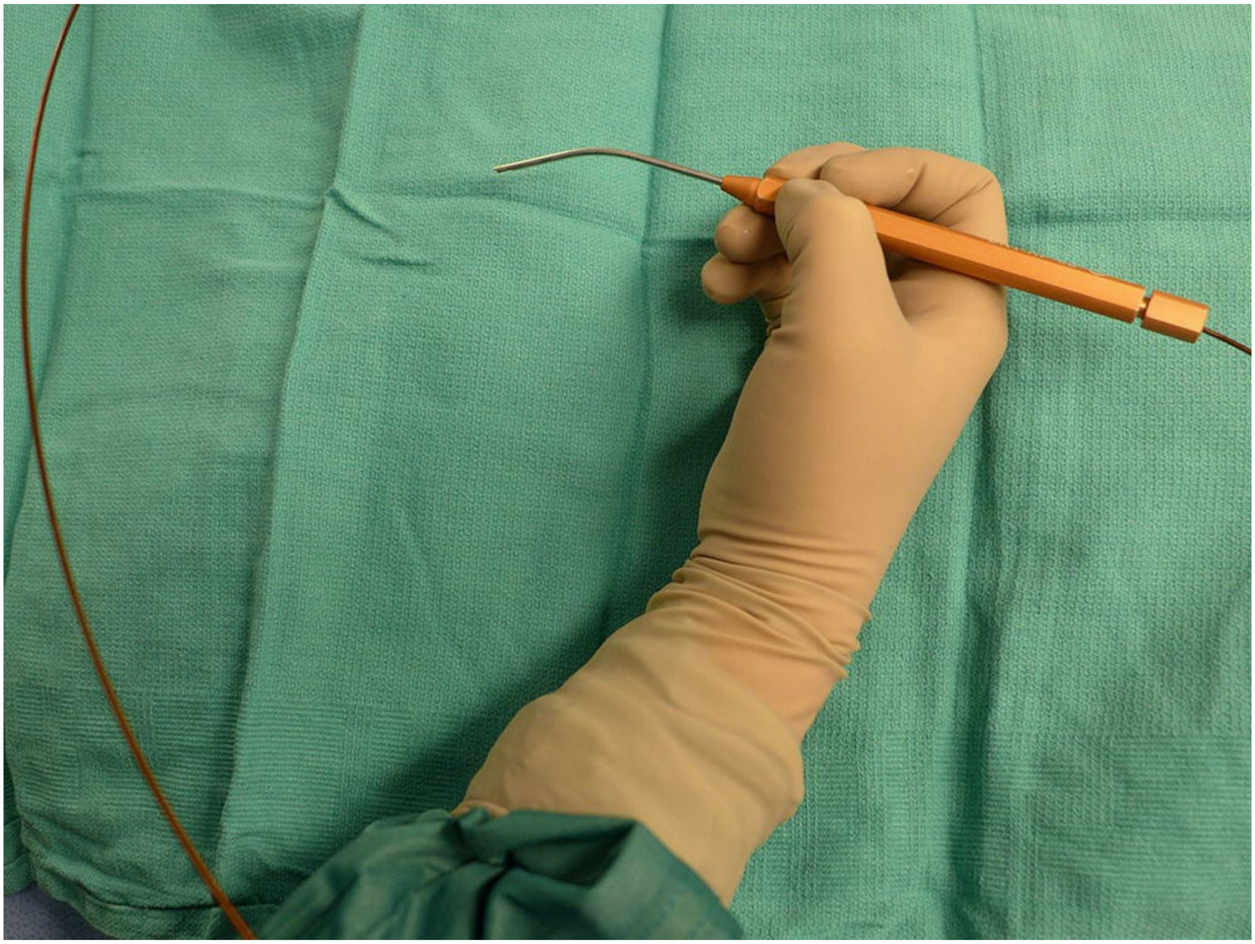

Figure 36.1. One of many interchangeable handpieces for the OmniGuide flexible CO_2 laser.

History of Robotics in Otolaryngology

In many ways, robotic surgery is the natural extension of endoscopic surgery. Although the endoscope has allowed our optical equipment to move into the field, it has also made distal control of instrumentation more challenging. Thus, the obvious target for surgical innovation as it relates to minimally invasive surgery is to explore the notion of improved distal control of instruments. This is one of the areas in which robotics excels.

The presence of robotics in surgery has been a relatively recent phenomenon. In fact, despite the presence of robotics in nonmedical industries for over 60 years, the first reported robotic surgical case was performed in 1985. The Puma 560 was used to accurately localize neurosurgical biopsies. The same device was then used to perform

transurethral biopsies of the prostate.[9] In 1992, the U.S. Food and Drug Administration (FDA) approved the first medical use of a robot. During the same time period, NASA and the Department of Defense became interested in the notion of remote battlefield surgery. Through DARPA, these agencies funded this technology. It was conceptualized that deploying a remote controllable (telepresence) robot into the front lines of battle would allow a wounded soldier to be stabilized during the "golden hour" of trauma. This robot would be controlled by surgeons in a safe zone, allowing them to perform surgery during this critical window for survival, but without putting the surgeon in harm's way. The funding for this project helped catalyze the creation of the first commercially available robotic systems, the AESOP (Computer Motion of Santa Barbara, CA) and the da Vinci (Intuitive Surgical, Sunnyvale, CA). Variations of these systems are the backbones for the robotic systems we use today.

In otolaryngology (OTO-HNS), the primary robot in use today is the da Vinci system. In some ways, the word "robot" is a misnomer, in that full control of the instruments still rests in the hands of the operating surgeon. However, what sets it apart from other surgical tools is that the surgeon is controlling the instruments remote from the patient's bedside. In its current form, the da Vinci robot consists primarily of two components. One is the surgeon console, where the operating surgeon sits. This consists of a stereoscopic (three-dimensional image) set of goggles, as well as controls for the robotic instruments (**Figs. 36.2 to 36.6**). The second component is the bedside patient cart, which consists of three separate instrument arms, with interchangeable instruments, and a camera arm all controlled by the operating surgeon. What makes these instruments different than most others is that they are designed with distally wristed function, so that they have the capacity to mimic or even exceed the natural range of motion of a human wrist. This gives the operating surgeon seven degrees of freedom with movement of the instruments. In combination with the stereoscopic view afforded by the dual optic rigid camera arm, these small wristed instruments are well suited for surgery around corners or in tight spaces.

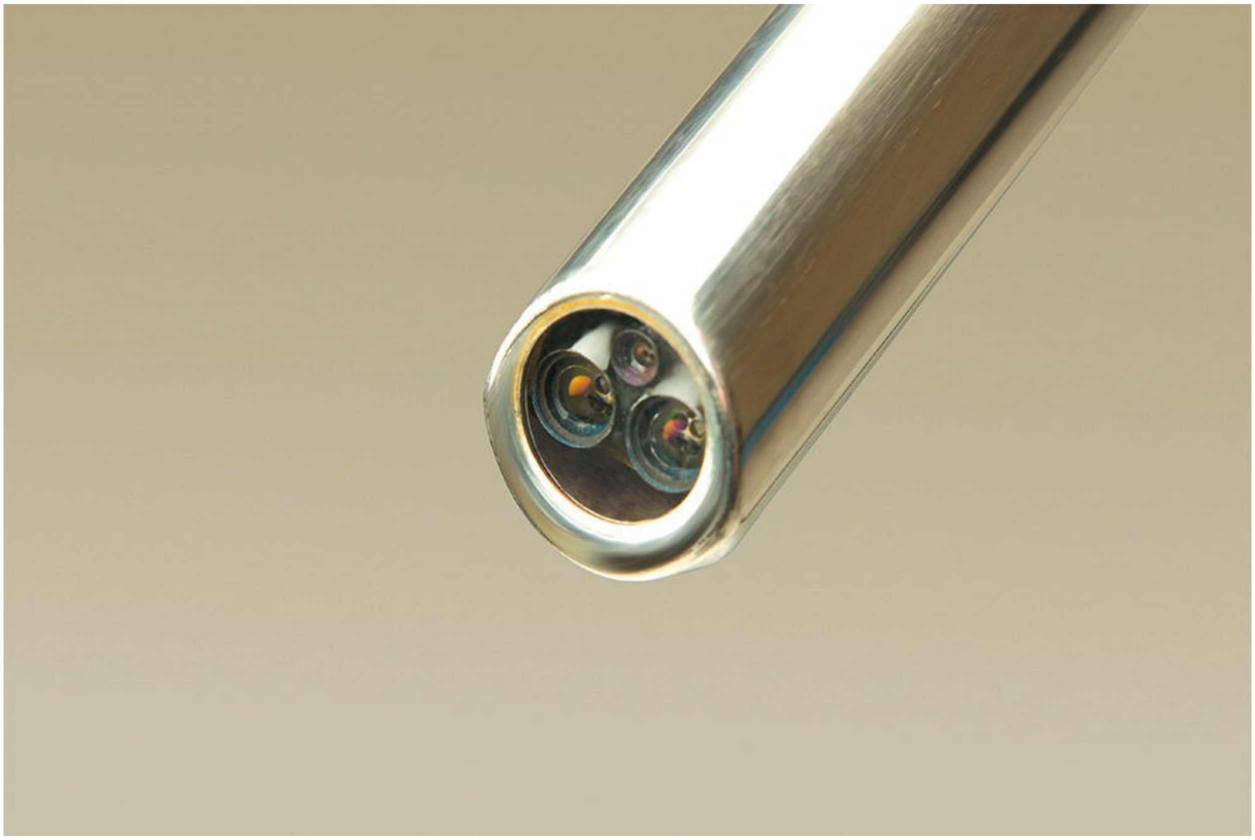

Figure 36.6. Close-up of the end of the camera arm, which houses two separate high-definition cameras and a light source.

The introduction of robotics to the field of OTO-HNS only occurred in the early 2000s. Initial reports described the use of the robot to help avoid neck incisions for surgery such as resection of a submandibular gland.[10,11] The first use of the robot in a live patient was for the removal of a vallecular cyst, published in 2005.[12] Within the next year, Drs. O'Malley and Hockstein described the first preclinical experiments that helped to establish transoral robotic surgery (TORS).[13] Building upon these original experiments, Drs. Hockstein, Weinstein, and O'Malley at the University of Pennsylvania developed preclinical models to demonstrate the feasibility, safety, and efficacy of TORS. This included application of the technology to cadaver, and live canine procedures, prior to performing human studies.[14–17]

Initial experiments surrounded the appropriate instrumentation for use with the robotic console. Most conventional laryngoscopes have a narrow inlet. This only allows for small, relatively parallel instruments to be inserted and used in the field. However, the robotic arms required broader access to

the field. This obstacle was overcome by the incorporation of several different retractors. Early use of the Dingman, Crow Davis, and FK-WO laryngoscope provided enough room for the arms of the robot to access the pharynx (**Figs. 36.7** and **36.8**).

Figure 36.7. Dr. Gregory Weinstein in an early case of TORS, placing a retractor into the patient’s mouth.

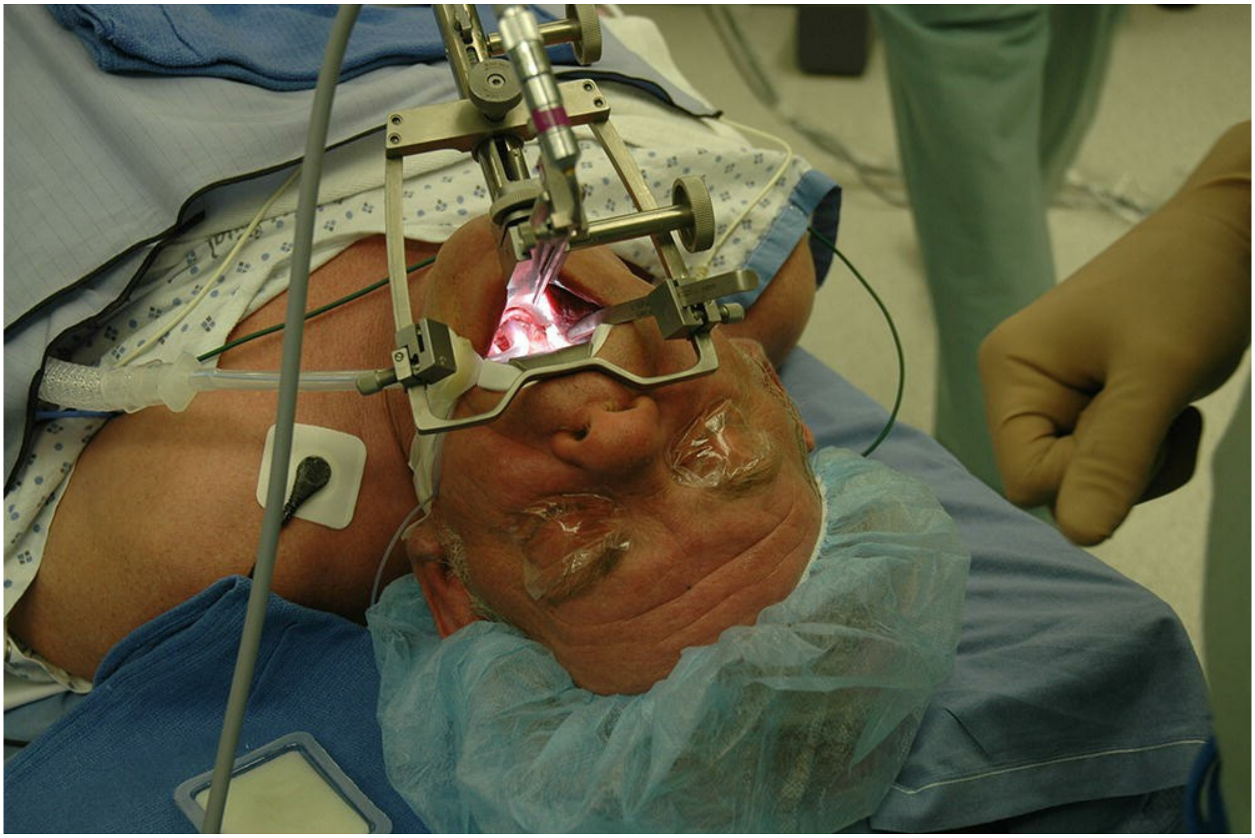

Figure 36.8. FK retractor in place, giving exposure of the surgical site and allowing adequate movement of the surgical arms.

After appropriate access to the surgical site was accomplished, creating a safe set of procedures with low-risk profile was the next priority. Additional studies were performed to look at these parameters. We concluded that transoral robotics surgery was safe and effective. This set the stage for human clinical trials.

Weinstein and O'Malley established a prospective human trial and conducted the first human experiments for TORS. The experiments included patients with various pathologies, including cancers of the oropharynx, larynx, and a variety or other benign and malignant conditions in the head and neck. These data,[16] pooled with the data from several other authors,[18] led to the approval from the FDA in December of 2009 of TORS for use in benign and select malignant lesions of the head and neck.

CURRENT INDICATIONS FOR

ENDOSCOPY AND ROBOTICS

Oropharynx

Endoscopy

Due to the somewhat restricted access to tumors of the oropharynx, open surgery to this area is particularly complex. This approach often involves a mandibulotomy for access, a tracheostomy to secure the airway, and often a feeding tube to allow for healing of the surgical site postoperatively (**Fig. 36.9**). In addition, just achieving adequate exposure can result in one or more cranial neuropathies. Fortunately, alternatives to the open approach began to show promise. Beginning in the 1970s, radiation began to play a role in the postoperative setting and then as primary therapy for cancer of the oropharynx. As the results began to demonstrate efficacy, many centers began to favor a radiation-based approach to these cancers. In many cases, a completely nonsurgical approach to this area was gaining acceptance. The combination of chemotherapy and radiation has now become one of the standard options for the management of cancer of the oropharynx. The oncologic outcomes are generally good, leading to 3-year overall survival rates between 23% and 88%.[19,20] However, posttreatment sequelae can be significant with gastrostomy tube dependence rates ranging from 0% to 26% in the same literature.

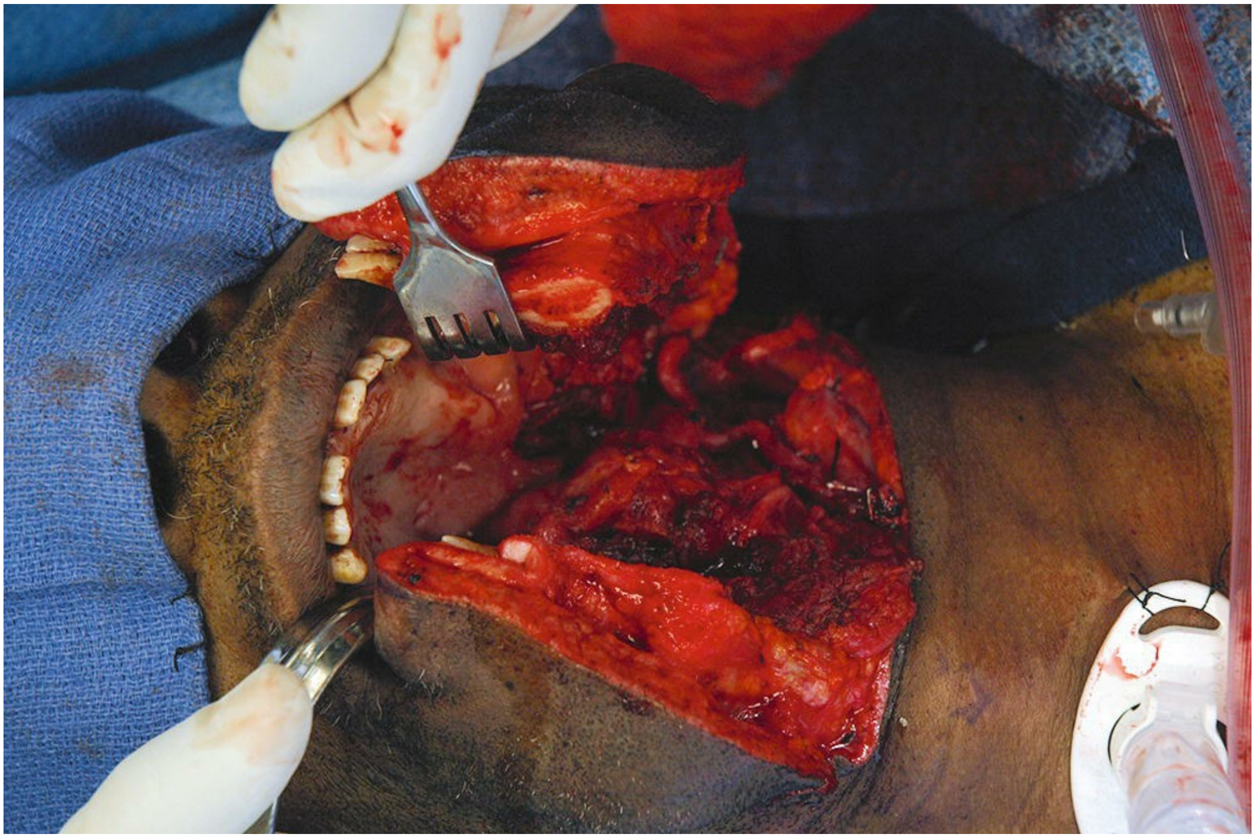

Figure 36.9. Traditional approach to tumors of the oropharynx. Note the mandibulotomy and tracheostomy.

The disease significantly increased in incidence over the same time period that the nonsurgical management of oropharyngeal cancer continued to gain acceptance. What was once an uncommon cancer primarily associated with smoking and drinking, largely affecting men in their 60s or older, has now become predominantly a virally induced (HPV) cancer, affecting many nonsmokers, often in their 40s and 50s. This change in the etiology of the cancer has been associated with an improved response to therapy and overall survival of patients with HPV positive tumors. Concurrent with our enhanced understanding of the biology and clinical behavior of HPV positive oropharyngeal cancers, the technology used to treat them has also evolved. The options for surgical management of primary cancer of the oropharynx have developed considerably and will be discussed below. In addition, even the management of the neck, once limited to a radical neck dissection, has now been shown to be amenable to more limited selective neck dissections.

At the same time that many centers were advocating a nonsurgical approach to cancers in the oropharynx, surgeons in Europe including

Professor Wolfgang Steiner are credited with expanding the nascent field of TLM.[7] This surgery is an alternative to primary radiation and at present is also an alternative to robotic surgery for the oropharynx. TLM, much like TORS, has benefitted from the evolution of optics and instrumentation and has the potential to give excellent outcomes without the need for open surgery. Steiner's approach involves the use of distending bivalve laryngoscopes. This allows the surgeon to apply tension to the cancer and resect using the CO_2 laser at the appropriate distance from the tumor. This approach often requires a "piece-meal" transection of the cancer in order to continuously evaluate the depth of the tumor and to obtain clear its margins. Although the adoption of this technique has been slow, it has resulted in excellent outcomes in repeated studies, from multiple institutions. Several studies have demonstrated an excellent overall survival for patients using this technique, with rates from 52% to 87%.[21–24]

Robotics

The anatomic site that has benefitted most from the use of robotics in the field of head and neck surgery is the oropharynx. Although some of the earliest robotics experiments were performed in the larynx and neck, the robotic technology appeared best suited for the management of cancer in the oropharynx.[25] The combination of improved visualization, four-handed management of the cancer, and relatively easy instrument access to the surgical site made this an obvious choice. Cancers in the tonsil and base of tongue are the primary targets for TORS (**Fig. 36.10**).

Figure 36.10. Early photo demonstrating the technique for surgical setup for TORS.

Prior to the creation of TORS, many of the patients with cancer of the oropharynx had limited surgical options. Open approaches are associated with significant morbidity and in the current era are often reserved for recurrent cancer after nonsurgical treatment. Although TLM has clearly demonstrated the feasibility of a nonopen approach to cancer of the oropharynx, the technical challenges of this approach have limited its acceptance.[26] This combination of feasibility and technical challenges of TLM paved the way to the introduction of TORS for management of cancer of the oropharynx. Several of the obstacles facing a surgeon with TLM are removed with TORS. Reduction of the need for line of sight, the ability to use four-handed technique, improved hemostasis, a wider field of view, and wristed distal dexterity instruments have all made the resection of tumors in this area less challenging (**Fig. 36.11**). Although still less than a decade since its inception, the early results are good. Several studies have reported 2- and 3-year overall survival results from 85% to 92% in selected patients.[27–29]

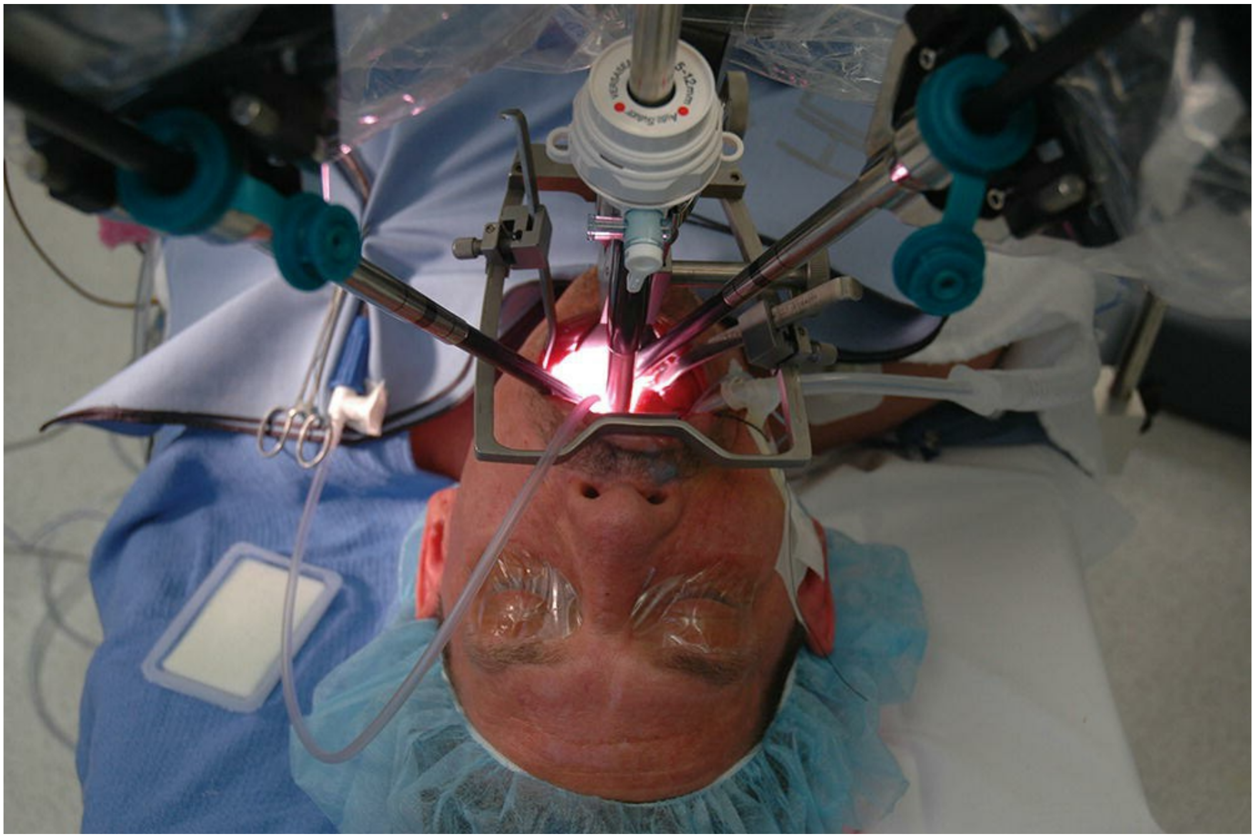

Figure 36.11. Surgical setup, demonstrating the position of the instrument arms and the camera arm.

TORS is performed using a variety of laryngeal and oropharyngeal retractors. Once adequate visualization of the cancer is obtained, the robotic arms are brought into place in the oral cavity. The primary surgeon sits at the console, and the assistant at the patient bedside, at the head of the patient (**Figs. 36.12** and **36.13**). This two-surgeon approach allows for excellent suctioning, retraction, and hemostasis, as four hands are in the field at once. Because this exposure generally allows for a view of the entire tumor, an "en-bloc" approach is often possible and favored.

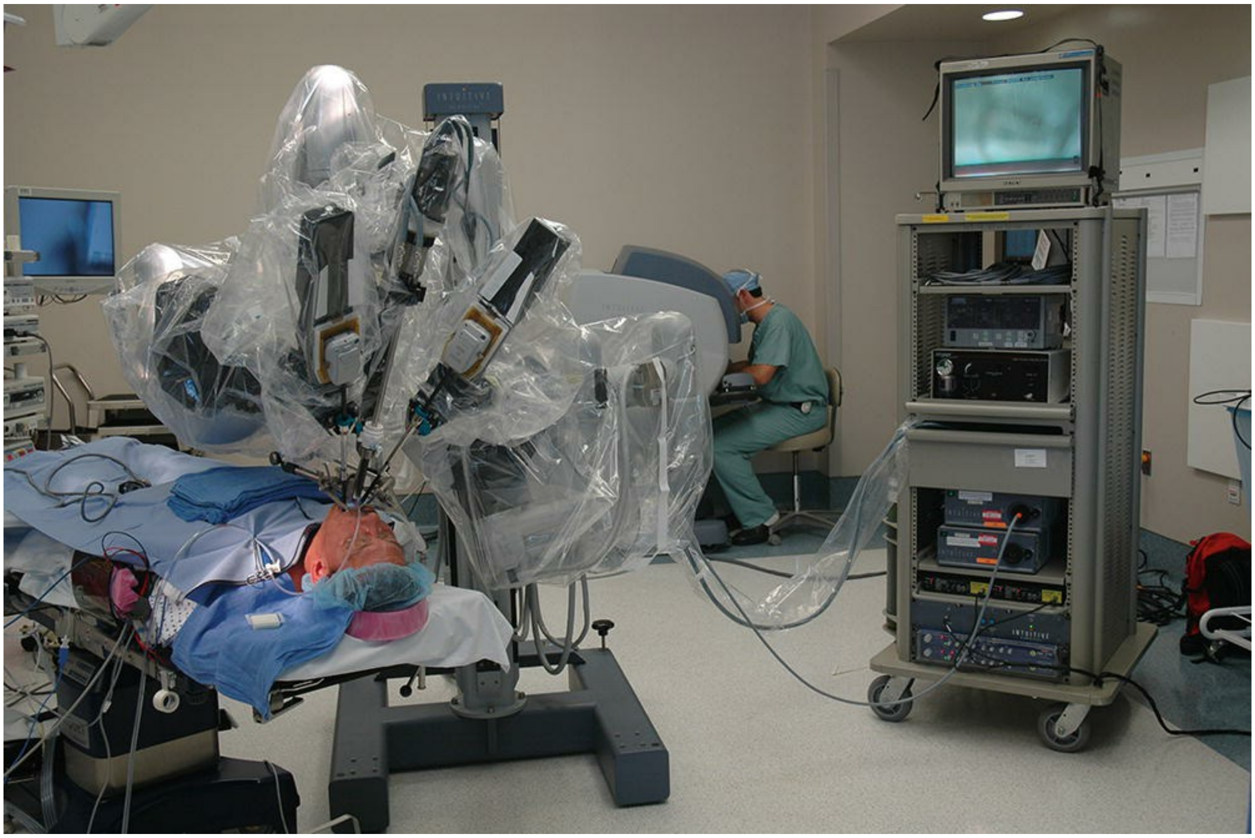

Figure 36.12. Setup of the room and the robotic instruments in an early surgical case. The bedside console, the vision cart, and the surgeon console are all visible.

Figure 36.13. Operating room setup for TORS.

Clear indications, tumor characteristics, and contraindications have now been set out for TORS. They include features listed in **Table 36.1**.[9]

Table 36.1 Indications and Contraindications for TORS

Indications
1. Adequate visualization of the tumor
2. Adequate exposure for resection
During staged laryngoscopy, the appropriate retractors may need to be inserted to determine if the tumor will be amenable to negative-margin resection with TORS techniques
Characteristics such as trismus, anterior positioned larynx, large tongue, or morbid obesity often make placement of the pharyngeal retractors impossible
Contraindications
Unresectability of involved neck nodes
Invasion of the mandible
Involvement of the base of the tongue requiring resection of >50% of the tongue base
Involvement of the pharyngeal wall requiring resection of >50% of the posterior pharyngeal wall
Radiographic confirmation of carotid artery involvement
Fixation of the tumor to the prevertebral fascia

The timing of management of the neck in patients undergoing TORS continues to evolve, as does the procedure itself. Initially, the neck dissection was routinely staged after the primary surgery, to reduce postoperative pharyngeal edema as well as to reduce the incidence of fistulization. Recently, many surgeons have begun to stage the neck component of the surgery before or at the same time as the resection of the primary. This may help to reduce the incidence of postoperative bleeding.

Larynx

Endoscopy

TLM (the history of which is described above) is an accepted standard in the treatment of well-selected patients with cancer of the larynx. There is an extensive literature demonstrating the safety, efficacy, and outcomes of this technique.[30–34] It is most often used in the management of previously untreated cancers, but results in the face of recurrence following radiation have also been quite good. Because good exposure is one of the keys to success in this surgery, a combination of closed or distending laryngoscopes is used to visualize the cancer.[31] The technique, especially for larger cancers, often involves a stepwise resection of the cancer by cutting through the cancer with the laser in order to create a three-dimensional map of the depth and extent of the cancer. Specific blocks of cancer are then removed until the entire cancer is resected with frozen section evaluation of the margins. The laryngoscopes are repositioned as necessary during surgery in order to optimize exposure.[35] TLM has been advocated for use in many early-staged glottis cancers, but has also been shown to be effective in the treatment of selected patients with more advanced, staged T3 and T4 cancers[36] (**Fig. 36.14**). In select cases, it may also be an option for treating recurrent cancers after surgery or radiation-based therapies.[37]

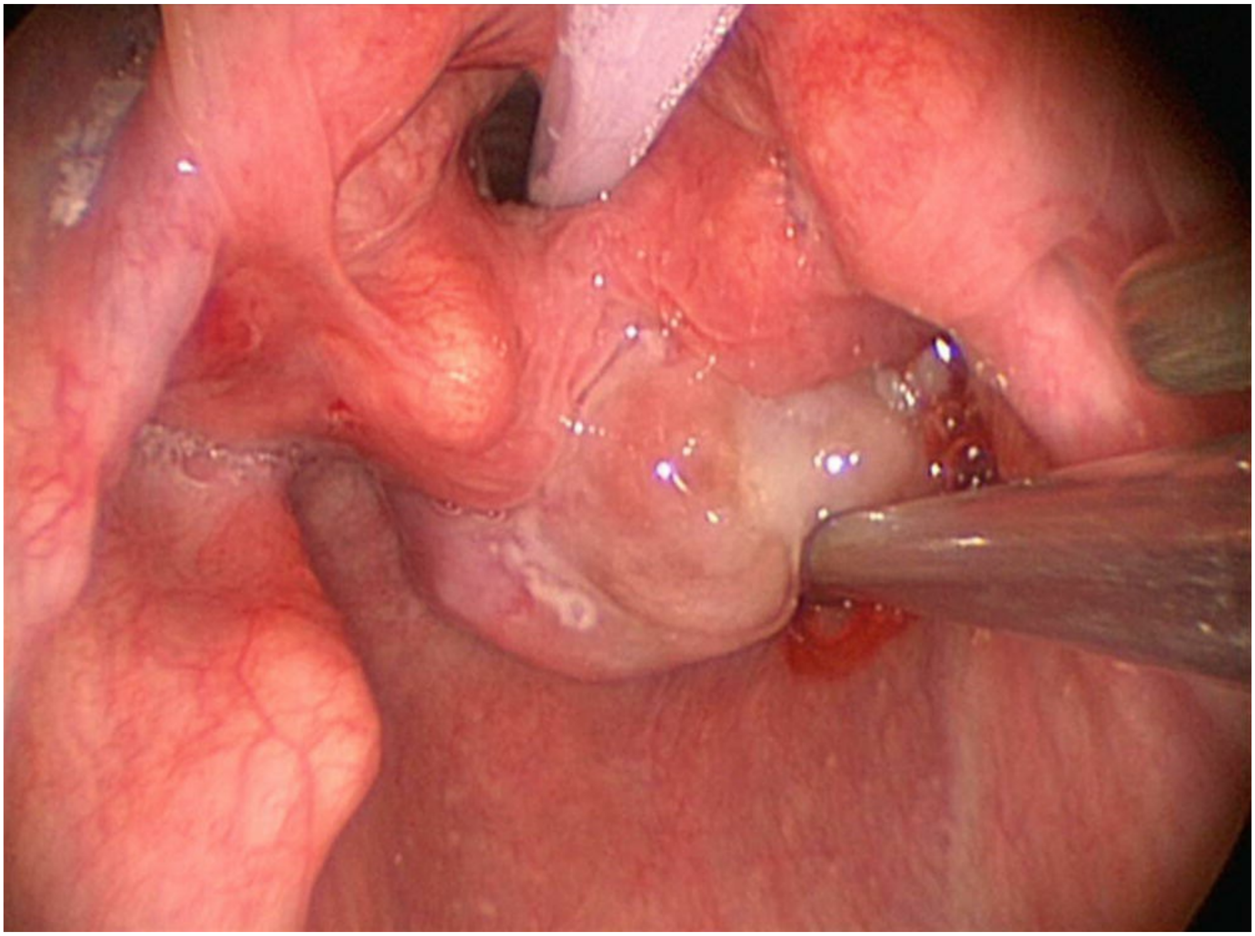

Figure 36.14. Excellent exposure can be achieved with the endoscopic approach to the larynx and hypopharynx, as is the case with this postcricoid tumor.

Robotics

Despite the early interest in the larynx as the main target of robotic surgery, it has not become the primary target of this new technology. Most current robotics series show fewer than 10% of cases to involve the larynx and even fewer of them to be cancers. This is due to a combination of factors. The da Vinci robot, as currently configured, lacks the microinstrumentation needed to operate on many regions of the larynx. Not only are the 5-mm instruments significantly larger than what is used in the nonrobotic approach but the instrument choices are still quite limited. Additionally, as the robotic instrument arms are placed further into the oral cavity and oropharynx, they begin to reach the limit of their practical utility. The range or motion and rate of "collisions" at the proximal end of the arms become an obstacle to safe

surgery at this depth.

Additional factors are also responsible for the small percentage of cases of laryngeal cancer treated robotically. Primarily, there are at least two excellent competing options for their management. One is nonsurgical therapy, which, for many primary laryngeal cancers, has been demonstrated to be a good choice.[38,39] The other alternative, for appropriate lesions, is TLM. Until the results of TORS are able to compete with either of these options, it will continue to play only a small role in the management of most laryngeal cancers.

Recently, several robotics companies have designed new systems to help address the difficulty in accessing the narrow confines and delicate anatomy of the larynx and other areas of the head and neck. These systems use special retractors and flexible snake-like cameras and smaller instruments to achieve this goal. As this technology continues to evolve, some of the obstacles that we currently face in the use of robotics will be eliminated, and greater applicability of this technology will inevitably occur.

The one area of the larynx, which may benefit from the use of TORS in its current form, is the supraglottis.[40,41] In the appropriate patient, supraglottic laryngectomy performed with the robot is safe, efficient, and perhaps easier than with TLM. Several larger series of TORS have included a small fraction of patients who have undergone supraglottic laryngectomy using the robot. Although most of the outcomes are early, the results so far are favorable.[29,42–44]

There have been several papers published on the results of small series of patients undergoing more extensive robotic surgery, including total laryngectomy.[45,46] This type of innovation will continue to push forward the frontier of surgical robotics, broadening the indications and helping to create better technology for the future of surgery.

Sinonasal and Skull Base

Sinonasal and Skull Base Endoscopy

Although the use of the endoscope for nonmalignant lesions of the sinonasal region dates back to the 1970s, it was less than two decades ago that the first report of management of a series of patients with sinonasal malignancies

(esthesioneuroblastoma) was reported by Casiano et al.[4] Since that time, endoscopy has played a significant and continuing role in the management of sinonasal and skull base malignancy. In fact, for many diseases, a completely endoscopic endonasal approach has become the standard approach.

As technology and techniques developed, surgeons grew more comfortable with managing more complex diseases through the endonasal corridor. Initial endoscopic assistance to open procedures led to eventual adoption of a completely endoscopic approach to many diseases. Early papers focused on the safety and feasibility of a completely endoscopic approach.[5,47,48] The management of CSF leaks and then of pituitary tumors were among the early procedures in which purely endoscopic approaches were adopted. These early experiences led the way to creating safe and effective techniques for both the resection and repair of the cranial base. In fact, one of the significant limiting factors in the endoscopic management of cranial base tumors was the challenge of separating the intracranial from the sinonasal space postoperatively.

Early attempts to resect tumors that involved large areas of the cranial base were fraught with high rates of CSF leak.[6,49–51] Many efforts have been made to solve this problem. Various grafting techniques, biologic materials, glues, and flaps have been designed. In 2004, Hadad et al.[52,53] described the first use of a vascularized, pedicled nasoseptal flap. This flap provided a wide, thick vascularized piece of tissue that could be used to help aid in the closure of the often large defects left by resection of the bone and dura of the anterior cranial base (**Fig. 36.15**). This solved, to a significant degree, the high rate of CSF leaks that were being seen as a result of resection of the cranial base. Once able to prevent the CSF leaks, more advanced procedures were designed to access tumors of the sinonasal spaces and cranial base. At the same time, the literature was beginning to show the equivalence and, in many cases, the superiority of endoscopic over open approaches in the treatment of tumors of the sinonasal and cranial base regions.[6,50,54–56]

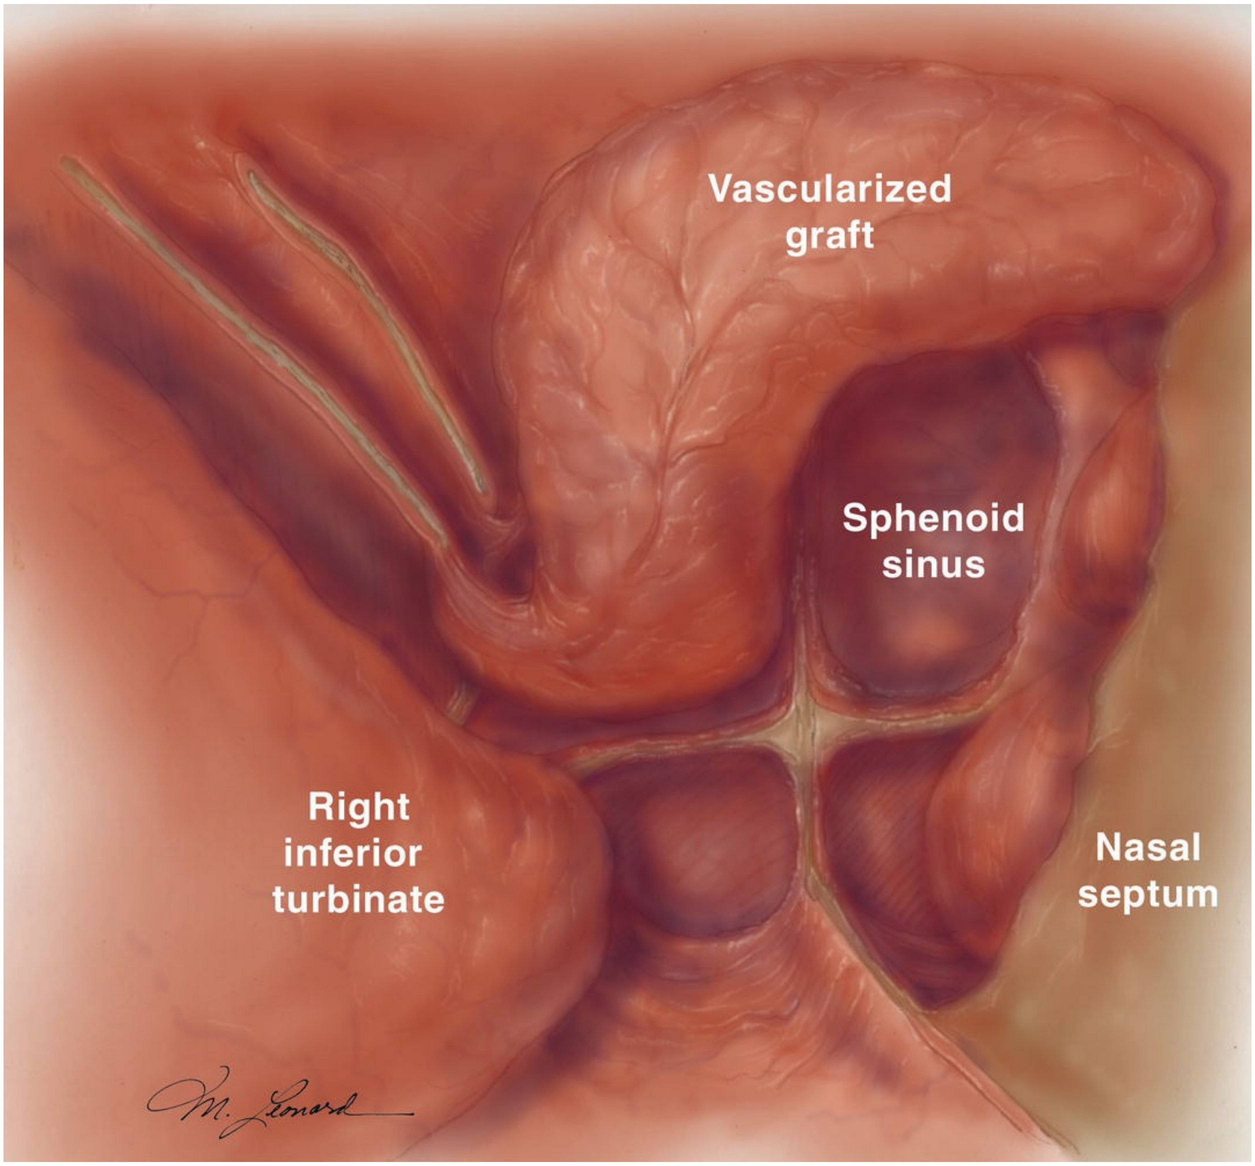

Figure 36.15. This represents an endonasal view, with depiction of an open sphenoid cavity, posterior septectomy, with a nasoseptal flap pedicled off of the right posterior septal artery and draped superiorly over an anterior cranial base defect.

At present, the entire sinonasal cavity and ventral skull base are appropriate targets of an EEA. Descriptions of approaches along the entire skull base along both the sagittal and coronal plane have been made. Each space along the ventral skull base has a separate set of parameters, which will guide the surgeon in the approach. In each approach, management of the instruments and the endoscope are key in helping to create a safe corridor to the region of concern[57] (**Fig. 36.16**).

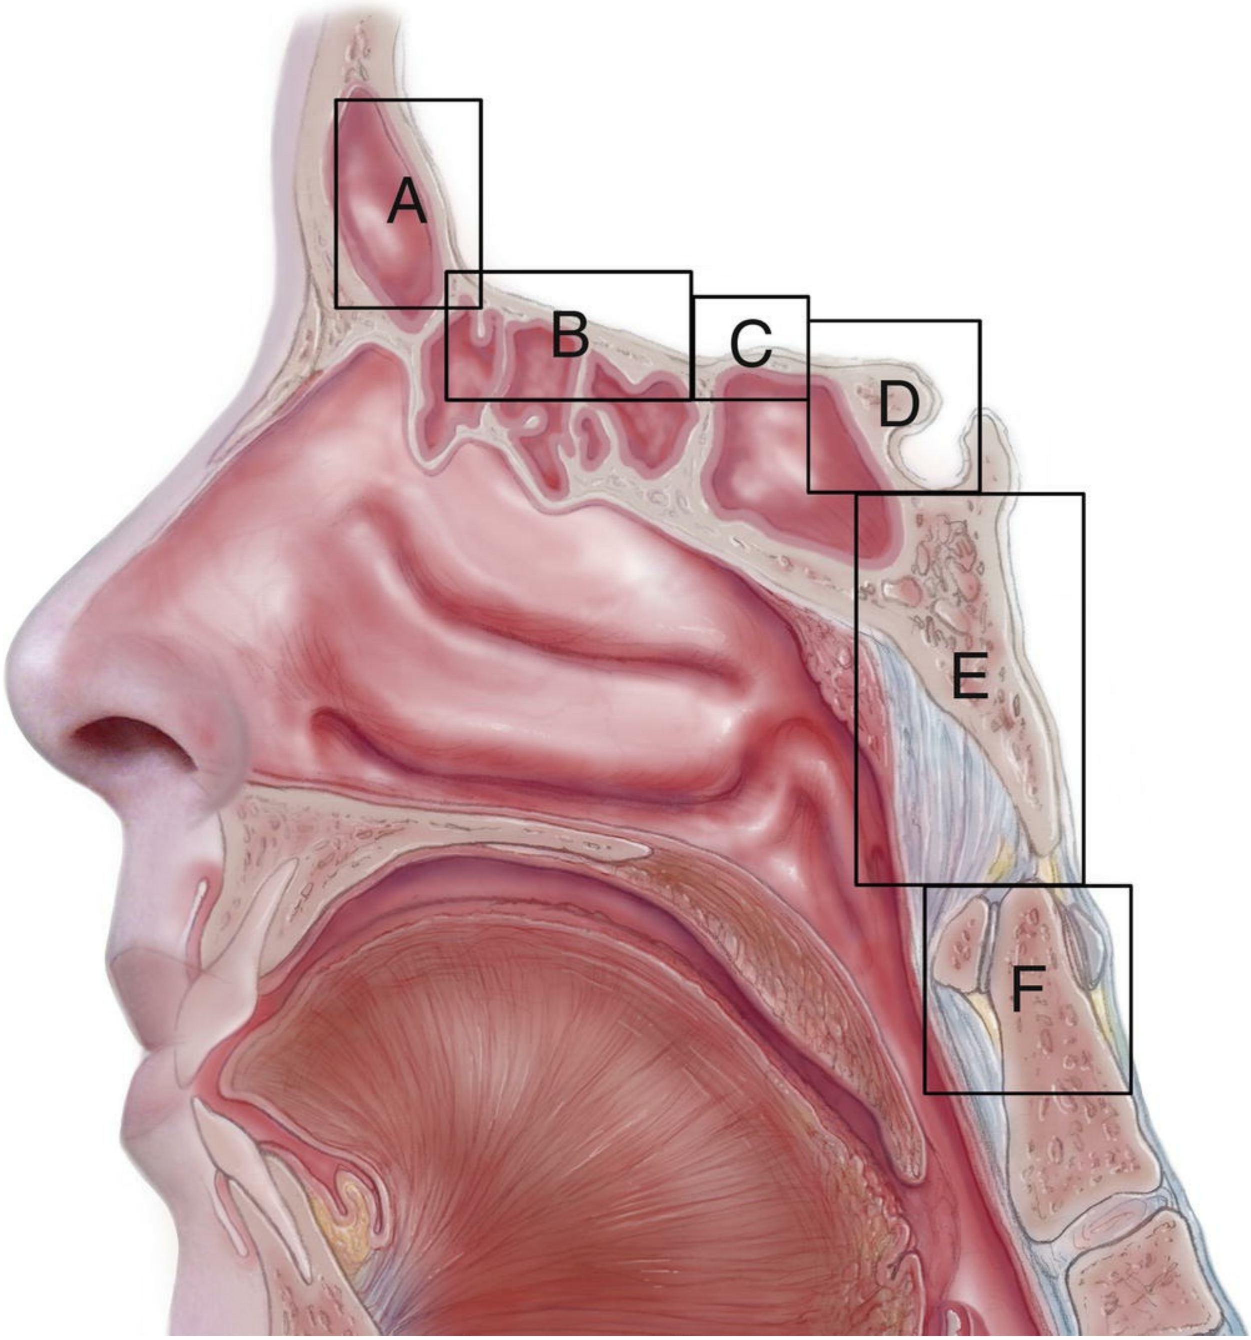

Figure 36.16. The multiple corridors accessible via a transnasal approach to the skull base. *A*, transfrontal; *B*, transcribriform; *C*, transplanum/transtuburculum; *D*, transsellar; *E*, transclival; *F*, transodontoid.

Having the technical capacity to approach tumors along the entire ventral cranial base is not the equivalent to being able to safely resect all tumors along this corridor. There are still several contraindications to EEA management of tumors of the cranial base. They are included in **Table**

36.2[55]: Of course, as instrumentation and technology evolve, these contraindications will continue to change.

Table 36.2 Contraindications for Endoscopic Endonasal Resection of Cranial Base Tumors
Involvement of the dura beyond the midorbital roof
Gross intraorbital extension
Involvement of the anterior table or far lateral recess of the frontal sinus
Extension into the facial soft tissues
Relative contraindications include Gross brain involvement Extension to the lateral wall of the maxillary sinus Extension to the lateral infratemporal fossa

An important aspect in the evolution of the endoscope as a tool in the management of sinonasal and skull base tumors is the evolution of the equipment and instrumentation used for these procedures (**Fig. 36.17**). In comparison to the original endoscopes used to perform early sinus endoscopy, significant progress has occurred. Not only has the optical clarity of the image been transformed but many other components of the visual experience have been augmented. Angled telescopes have allowed a modified view, around corners, and out of the direct line of site. High-definition cameras have created a clearer and more magnified picture of the surgical field. Systems to manage debris or blood on the end of the endoscope have made it possible to keep the endoscope in the field, without the need to disrupt the surgery. Recently, stereoscopic endoscopes have allowed surgeons to eliminate the distortion and reduced visual input that occur with use of a two-dimensional endoscope (**Fig. 36.18**).

Figure 36.17. Some of the equipment routinely used during endoscopy for skull base surgery includes a high-definition camera, surgical navigation, and irrigation sheath for the endoscope.

ALM

Figure 36.18. Surgeons performing endoscopic three-dimensional endonasal surgery.

Surgical navigation has also significantly affected the advancement of techniques in the sinonasal region. The bony anatomy of the cranial base is the perfect target for accurate anatomic navigation. It is possible to fuse CT and MRI images, in some cases being done in real time, in order to more safely and confidently navigate the bony and even soft tissue anatomy in this region (**Fig. 36.19**).

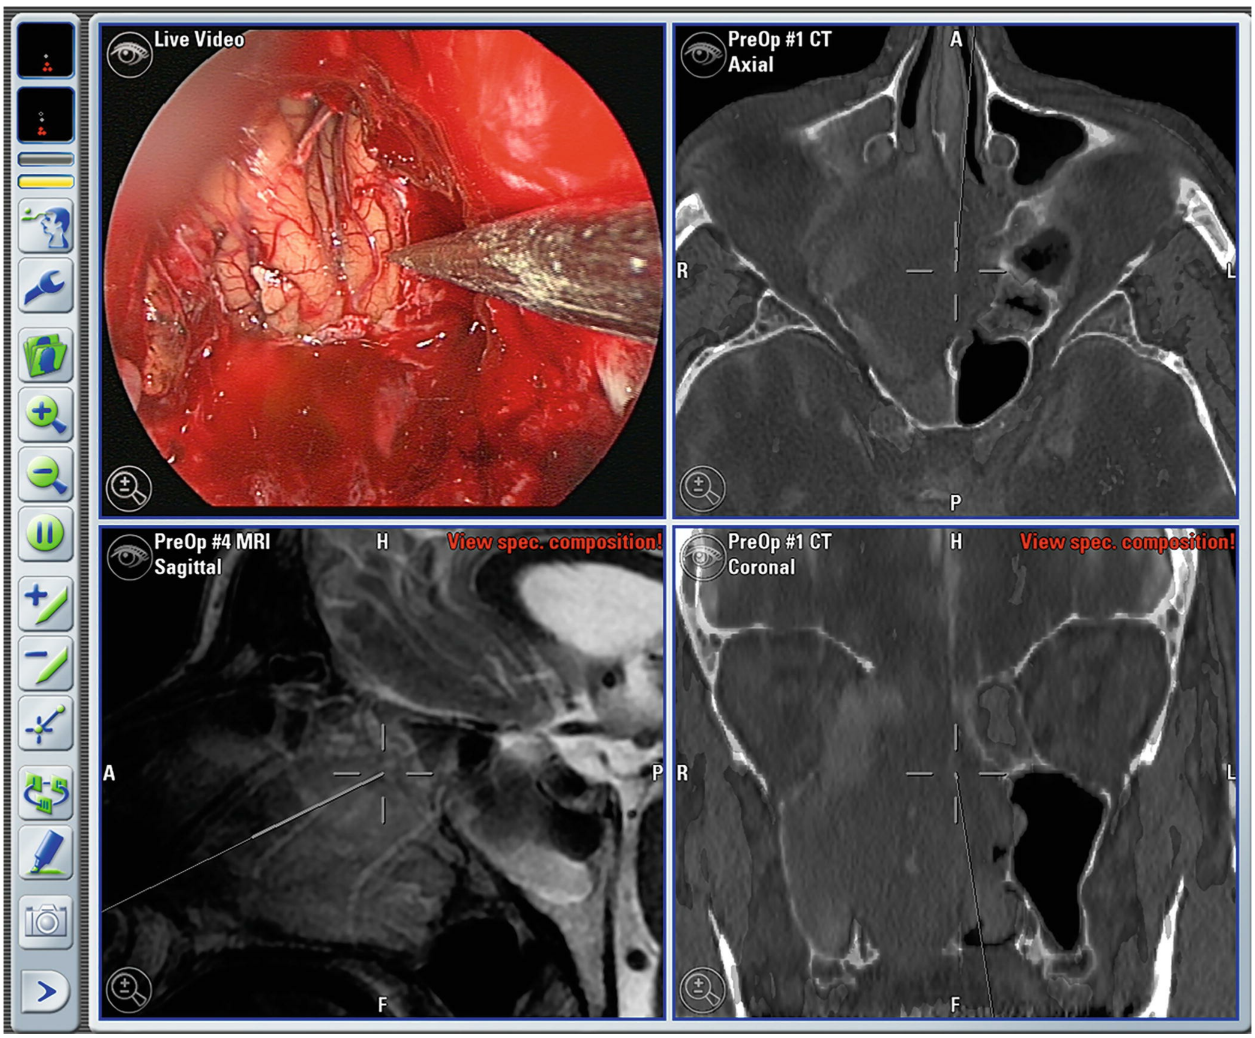

Figure 36.19. Four-panel view demonstrating the endoscopic view as well as fused MRI/CT views of the patient anatomy.

Instrumentation, including the microdebrider and the endoscopic drill,

has allowed the operating surgeon to effectively and safely manage both soft tissue and bony anatomy along the base of the skull. Newer instrumentation, including ultrasonic aspirators (**Fig. 36.20**) and tissue coblators, promises to deliver more precise tissue management to this area. The endoscopic ultrasound probe provides an additional level of assurance in the management of tumor abutting critical vascular structures including the carotid artery.

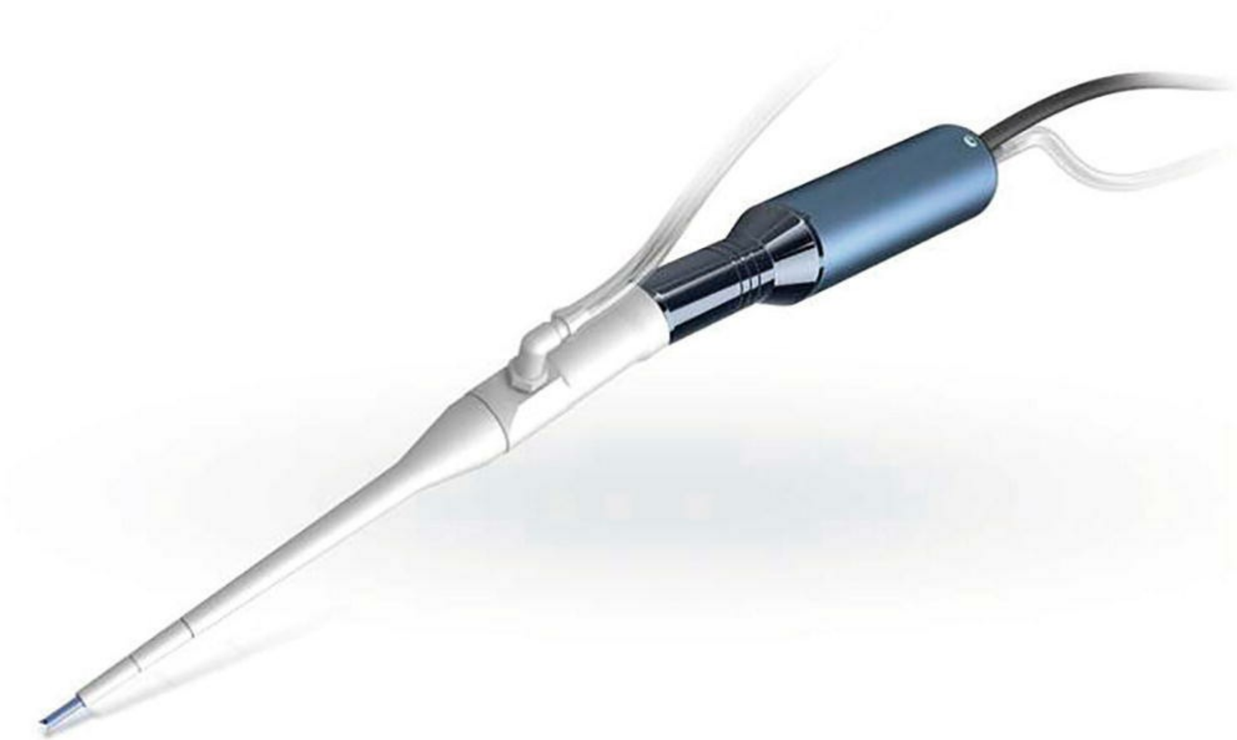

Figure 36.20. An endoscopic ultrasonic aspirator, the Stryker Sonopet.

Both synthetic and biologic products play significant roles in the advancement of endoscopy for lesions in the skull base. Hemostatic agents, dural and bony replacements, and tissue adhesives are three of the categories that have had the most significant impact.

Sinonasal and Skull Base Robotics

Robotic surgery for lesions of the anterior cranial base is still in its infancy. Several papers have been published describing the approach[58,59] with possible applications of this technology, but practically speaking, the instrumentation and setup of the currently available robotic system do not allow for a safe transnasal approach to this region. As soon as the

instrumentation and console can be designed to meet these parameters, it is nearly certain that transnasal robotic access to the anterior cranial base will become a reality.

Other parts of the cranial base, and other corridors, are now being explored by some surgeons as alternatives to open or endoscopic surgeries. Specifically, access to the parapharyngeal space has now been well described, and this route is being used in select cases of tumors in this region[60,61] (**Fig. 36.21**). The most common approach is transoral, with a lateral dissection involving a portion of the soft palate and lateral oropharyngeal wall. The most common indication is for prestyloid tumors, including salivary gland, neurogenic, and vascular tumors.[62] Potential advantages to this approach include excellent visualization compared to the transcervical open approach, the lack of an external incision, and reduction of first-bite syndrome. Much like conventional TORS, the addition of the robot to the approach to the parapharyngeal space adds the ability to place four hands into the surgical field (two of them being the robotic arms), to achieve excellent magnified visualization and to use angled endoscopes and instrumentation to access regions than cannot be accessed via nonrobotic approaches (**Fig. 36.22**).

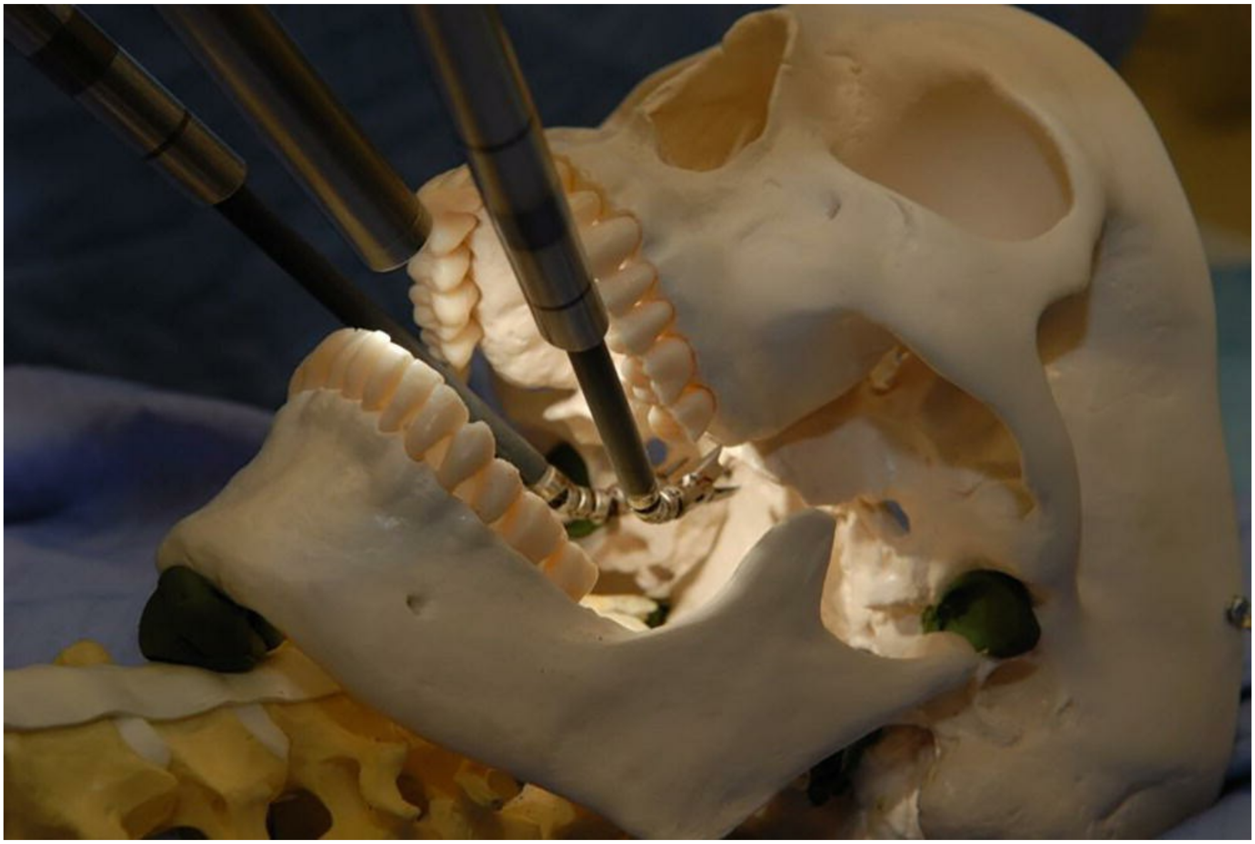

Figure 36.21. Conceptual approach to the base of the skull via the oral cavity. Note the wristed instrumentation.

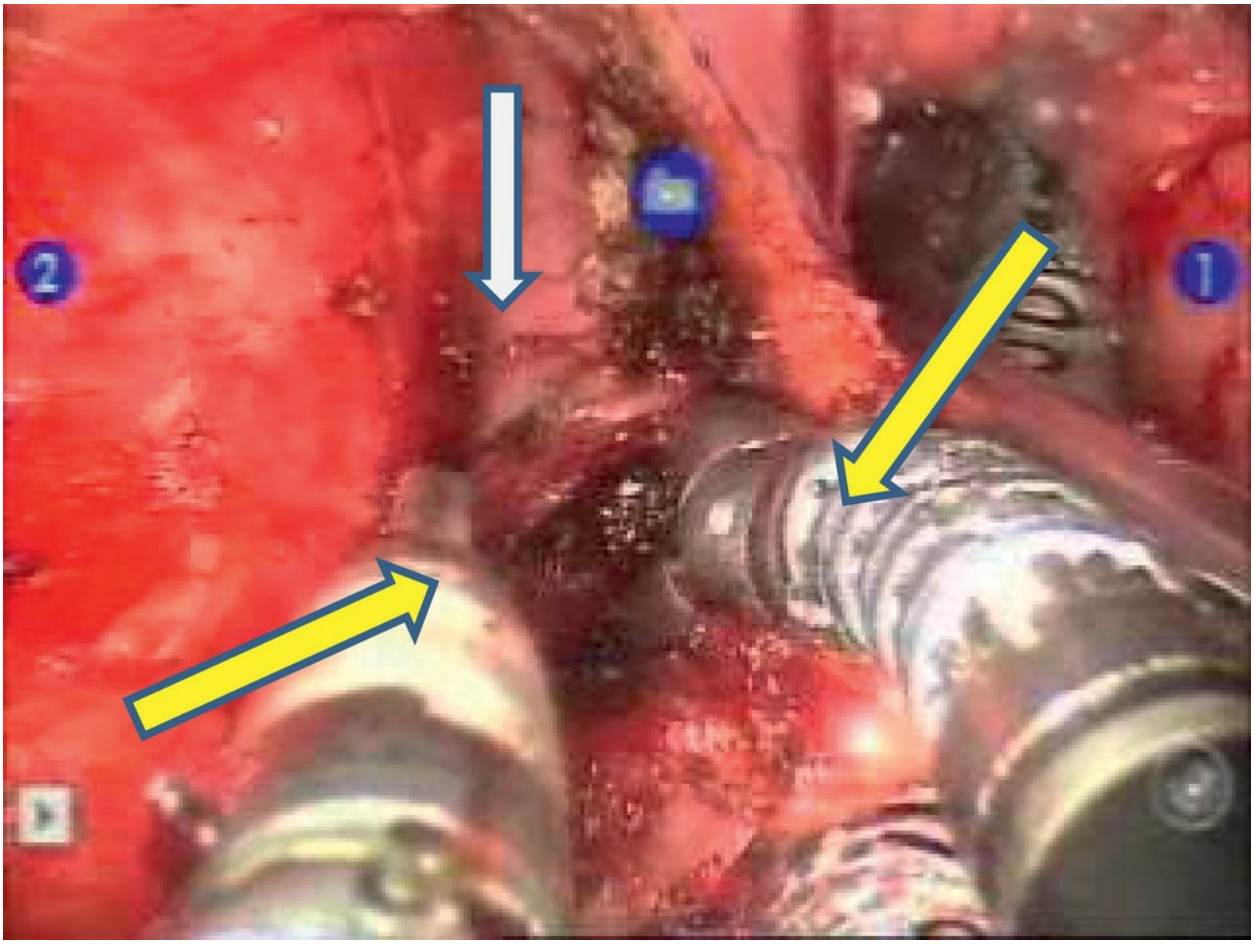

Figure 36.22. Transoral resection of a right parapharyngeal space tumor. *Yellow arrows* show robot Maryland forceps on right and Bovie dissector on left. A dissection is being performed in the parapharyngeal space at the junction of the pleomorphic adenoma tumor capsule and the constrictor musculature (*white arrow*).

Additionally, the transoral route has created robotic access to several other parts of the skull base, including the odontoid, craniocervical junction, infratemporal fossa, and[58,63–65] atlantoaxial spine (**Fig. 36.23**). As the technology and instrumentation evolve, these corridors and the procedures that can be performed through them will continue to expand (**Fig. 36.24**).

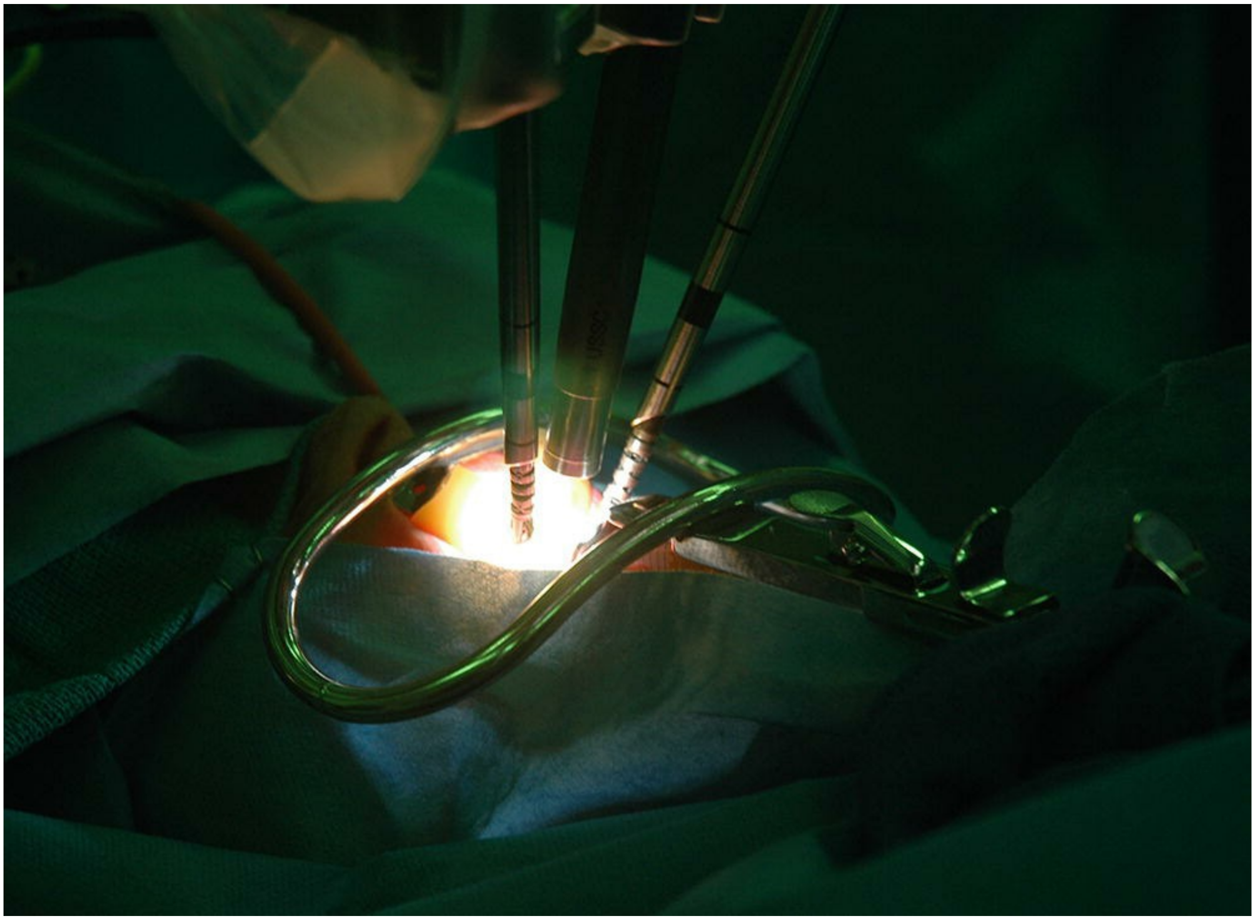

Figure 36.23. Robot docked for approach to the atlantoaxial spine. Note the instruments and camera are oriented toward the cephalad direction, unlike traditional TORS.

Figure 36.24. Early cadaver work demonstrating approach to the odontoid

via the oral cavity.

Thyroid and Neck

Endoscopy

In 1996, Gagner described the first report of an endoscopic approach to the parathyroid.[66] This was followed closely by Hüscher, who described a video-assisted hemithyroidectomy.[67] These early studies led the way to a concept of further reducing the size of the access corridor to the anterior neck. One of the driving forces behind this minimal access surgery is patient preference. Especially for young, otherwise healthy patients, continued attempts to minimize or hide the anterior neck incision are appealing. The first series of patients treated with minimally invasive video-assisted thyroidectomy (MIVAT) was reported by Miccoli et al.[68] in 1999. One of the original goals of this surgery was to perform safely a "diagnostic" surgery on patients with follicular nodules of the thyroid. The surgery was performed through a 15-mm incision, and the combination of partial delivery of the thyroid and partial endoscopic techniques allowed for safe removal of the gland. Since that time, there has been significant expansion of the indications and techniques for this procedure. Although the main indication for this procedure remains diagnostic for follicular lesions of the thyroid, other indications, including the management of low-risk differentiated thyroid cancer (DTC) and small-volume benign disease, have been validated as a safe alternative to more open approaches.[69,70] Most commonly, the patients undergoing this approach are younger and more likely to be female than those who undergo an open approach to the thyroid.[71–73] This approach has become a standard option in many centers (**Figs. 36.25** and **36.26**).

Figure 36.25. OR setup for minimally invasive video-assisted thyroidectomy (MIVAT).

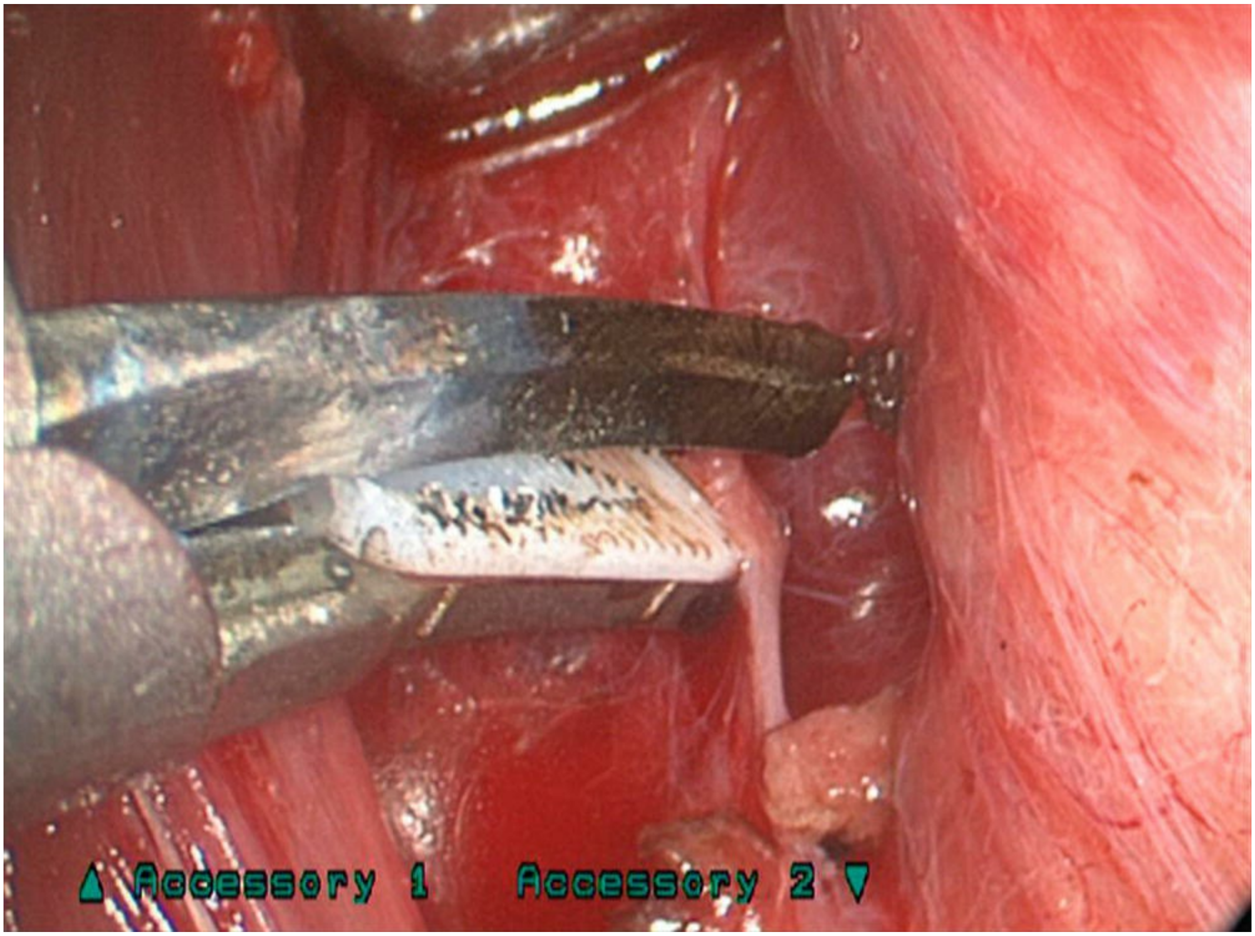

Figure 36.26. Close-up of the endoscopic view of the right superior pole of the thyroid, in preparation for ligating the vessels in this region.

Robotics

The endoscopic approach to the thyroid led the way to the application of robotic technology to this region. In 2006, Yoon et al.[74] described a gasless endoscopic approach to the thyroid via a transaxillary route. This approach completely eliminated the need for an incision in the neck. However, the endoscopic instrumentation made the surgery very challenging. In theory, some of the limitations of endoscopy, like the lack of stereoscopic view and the difficulty in manipulating nonwristed endoscopic instrumentation, could be overcome with robotic technology. In 2005, the robotic technique was first applied to the thyroid by Lobe et al.[75] The technique was then quickly brought into clinical practice by Kang, Chung et al. in South Korea, who in 2009 published their first experience with over 300 patients.[76] The technique involves making an incision in the axilla and then creating a working space

through this incision (**Figs. 36.27** and **36.28**). Retractors are placed into this space to allow dissection superficial to the pectoralis muscle. The robotic instruments are then introduced through this working space and used to visualize and dissect the thyroid via a lateral approach, retracting the strap muscles both above and below this field (**Fig. 36.29**). Once the thyroid has been resected, the incision in the axilla is closed, often with the placement of a drain.[9,77] Results from these surgeries are encouraging, and several studies have demonstrated both the safety and efficacy of this approach.[78–81] The cosmetic outcome is excellent, as the patient has a scar hidden in the axilla. There is no neck incision. However, due to the expense, added complexity, and the need for a relatively low-BMI patient, the surgery continues to fill only a small niche in its application to thyroid surgery in the United States.[82,83]

Figure 36.27. Patient positioning for transaxillary thyroid surgery. The patient's arm is extended and supported over the head.

Figure 36.28. Patient positioning for a left transaxillary thyroid surgery. The patient's arm is extended and supported over the head.

Figure 36.29. Operating room setup for transaxillary thyroid surgery. Note the angle of the robotic arms, docked in place to access the thyroid via the axilla.

Despite the lack of significant volume of transaxillary thyroidectomy being performed in the United States, the axilla as a corridor to the neck continues to have appeal. The transaxillary approach to the thyroid has paved the way for continued expansion of this corridor as an access route to the neck. Several authors have recently published an approach to the lateral cervical lymph nodes via this route, for the management of metastasis to the lateral neck.[84–86] Additionally, the concept of remote-access surgery to the thyroid gland has now been expanded to include a variety of different entry points. Terris et al.[87,88] described an alternate approach to the thyroid through a facelift incision, which may eliminate or reduce some of the difficulties encountered via a transaxillary approach (**Figs. 36.30** and **36.31**). As with early experience in the nasal and oral corridors, continued development of techniques and instrumentation will surely lead to further expansion of these techniques over time.

THE FUTURE

The technology and ingenuity in the fields of surgical endoscopy and robotics continue to change at a rapid pace. Even as this chapter is being written, several new technologies are on the horizon, including flexible robots, haptic feedback, and navigation-based robotic protocols. As the ability to scale this technology grows, as the costs come down, and as the indications expand, endoscopic and robotic technology will become increasingly useful in the world of surgery. It is likely that these fields will continue to play a greater role in the management of surgical diseases of the head and neck as we move into the future.

37 Hemangiomas and Vascular Malformations of the Head and Neck

James Y. Suen Gresham T. Richter

INTRODUCTION

Hemangiomas and vascular malformations (VMs) are not cancers, but they occur frequently in the head and neck region and commonly present to the head and neck surgeon. These can be very destructive and even life threatening. The head and neck surgeon needs to know how to identify and manage these uncommon but complex benign vascular lesions. Furthermore, there is increasing evidence that many vascular malformations exhibit behavior similar to low-grade malignancies.

The treatment of vascular anomalies should be performed by an experienced team of specialists, consisting of surgeons, diagnostic radiologists, interventional radiologists, dermatologists, pediatricians, medical oncologists, and other specialties. Because of the psychological impact on these patients, it is important to understand and address this issue as well. Vascular anomalies may cause aesthetic complications, functional disorders, physical disabilities, and pain. These patients can become quite withdrawn and depressed, and these aspects should be similarly addressed by the multidisciplinary team, including psychologists, to improve quality of life and patient satisfaction.

Many of the VMs cannot be cured but can only be controlled. It is important to convey full understanding of this concept, when counseling patients and their families at the onset of diagnosis in order to set appropriate levels of expectation from treatment. Frequently multiple treatments are required to control vascular anomalies, which may require lifelong medical and psychological care.

Classification

Vascular anomalies are divided into vascular tumors, of which infantile hemangiomas (IHs) are by far the most common type, and VMs. The natural history of these two groups is quite different. These lesions are also fundamentally distinct in their radiographic and histologic appearances as well as their biologic behavior and prognosis. All vascular anomalies are best classified using the scheme introduced by Muliken and Glowaki and recently codified by the International Society for the Study of Vascular Anomalies. In the past, VMs were erroneously called hemangiomas, which led to fundamental errors in management and patient outcomes.

IHs are vascular tumors composed of rapidly dividing hematogenous endothelial cells. These lesions will be noticed during the first few months of life and can grow rapidly until about 1 year of age. At this age, IHs begin to regress or involute. Over several years, many IHs will eventually disappear but may leave evidence, or sequelae, of their early presence. True IHs are histologically similar to placenta and may be the result of early stem cell progenitors from this tissue. The clinical similarities between IHs and placenta in their growth patterns are convincing. Placenta will grow for 9 months and involute when a baby is born—IHs grow for about 1 year and then begin to involute and eventually disappear.

VMs are anomalous vascular channels lined by a single endothelium that are usually present at birth. VMs are classified based upon their blood vessel type and can be seen early in life. Depending on the depth of the VMs, they may not appear obvious until later in life. They do not involute and will continue to slowly grow with ultimately destructive and life-threatening consequences. This distinction between IH and VM is extremely important to understand. Later in this chapter, the criteria for diagnosis of each type of vascular malformation will be addressed. **Table** 37.1 lists the classification of vascular anomalies.

Table 37.1 ISSVA Classification of Vascular Anomalies

Vascular Anomalies				
Vascular Tumors			Vascular Malformations	
Benign	**Locally Aggressive**	**Malignant**	**Simple**	**Combined**
Infantile hemangioma	Kaposiform hemangioendothelioma	Angiosarcoma	Capillary malformation (C)	CVM and CLM
Congenital hemangioma	Retiform hemangioendothelioma	Epithelioid hemangioendothelioma	Lymphatic malformation (LM)	LVM and CLVM
Tufted hemangioma	PILA and Dabska tumor		Venous malformation (VM)	CAVM
Spindle cell hemangioma	Composite hemangioendothelioma		Arteriovenous malformation (AVM)	CLAVM
Epithelioid hemangioma	Kaposi sarcoma		Arteriovenous fistula	
Pyogenic granuloma

HEMANGIOMAS

IHs are composed of proliferating immature endothelial cells that express histologic markers found on placental blood vessels as reported by North et al.[1] These are the most common tumor of infancy and are present in ~5% of the population. They occur more frequently in infants from mothers with early trimester bleeding, preeclampsia, and placental anomalies.[2] IHs are rarely noted at birth, but commonly a macular erythema area of the skin is noted in the first 6 weeks of life and then a rapid growth is usually noted. These lesions present in the head and neck region in over 60% of cases. Most IHs grow within the first 3 months of life and continue to grow up to 1 year of age and may be very extensive. After 1 year of age, IHs will go into a quiescent phase and began to involute and eventually resolve. Most will involute completely by 7 years of age. This natural history is important to differentiate IHs from other congenital vascular lesions and will help to guide management decisions.

IHs can present as focal or segmental lesions involving multiple areas. They are also characterized as superficial, deep, or compound. It is rare for a focal IH to involve muscle or penetrate beyond subcutaneous fat. However, an IH involving the parotid gland can involve the gland itself.

When IHs involve the lip, eyelids, orbit, and nose, or subglottic region, they may lead to significant functional and/or aesthetic problems during the

rapid proliferation phase (**Fig.** 37.1A–C).

Figure 37.1. A: Ulcerative hemangioma of the lower lip. **B:** Paranasal hemangioma. **C:** Segmental hemangioma involving the temple area and the orbit causing visual obstruction.

Infants with five or more focal IHs may also have hepatic involvement and should undergo abdominal ultrasound. Segmental IHs are usually more complex and in the head and neck will follow a trigeminal nerve distribution. They are diffuse and compound and maintain irregular borders. It is common to see more than one facial subunit involved (**Fig.** 37.2). They commonly penetrate into deep fascial planes of the head and neck. IHs involving the beard distribution are those most commonly described. These usually involve the lower lip, chin, neck, and preauricular areas, and ulcerations are frequently present. As many as 60% of IHs with a segmental beard distribution will involve the subglottis and require airway endoscopy.[3] Patients with segmentally distributed IHs should be evaluated for PHACES syndrome (posterior fossa malformations, hemangiomas, arterial lesions, cardiac abnormalities, eye abnormalities, and sternal clefts).

Figure 37.2. Right facial segmental hemangioma in child with PHACES.

The diagnosis of IHs is primarily clinical. They are not usually noticed at birth, and when the child is between 1 and 3 months old, these lesions will begin growing and after 1 year, they will begin to involute. Biopsies are not usually necessary and scans are not usually indicated unless there is a concern for the PHACES syndrome.

The management of IHs has improved significantly in recent years. Because of their natural involution, IHs were historically managed with observation only. Even though they resolve spontaneously, they can cause significant functional and disfiguring sequelae. Most problematic events from IHs will occur during the proliferative phase and may include ulceration, bleeding, pain, disturbance of vision, airway compromise, and feeding

difficulties. The late sequelae will include scarring, telangiectasias, and fibrofatty residuum.

The treatment of IHs may involve surgical excision, laser therapy, topical therapy, intralesional corticosteroids, systemic corticosteroids, systemic β-blockers, and vincristine chemotherapy. If an infant has a focal hemangioma, which is primarily deep, the lesion can typically be observed unless ulceration or bleeding occurs. For the superficial focal lesions, laser therapy or surgery can be used to control the IH. For the problematic hemangiomas, β-blockers have been found to be effective in over 95% of the cases with rapid involution. The most common dose of β-blockers has been 2 mg/kg/day in divided doses two to three times daily.[4] During the involution phase, surgical excision can give excellent results and prevent late sequelae.

VASCULAR MALFORMATIONS

As mentioned previously, VMs are very different from IHs. They do not involute and will continue to progress throughout life. They may have rapid growth spurts at different times of life. Our research has shown that many VMs have progesterone receptors[5] and this is associated with growth spurts during puberty, use of oral contraceptives, and pregnancy. We commonly see patients who did not notice their malformation until these events occurred. There are also unknown causes for growth spurts, which have not been identified yet. The destructive and life-threatening events that occur from many VMs will be illustrated.

Capillary/Venular Malformations

Capillary/venular malformations (CM) are histologically composed of congenital ectasia of thin-walled, small-caliber capillaries and veins of the skin. The simplest presentation of a capillary malformation is known as a nevus flammeus or “port-wine stain” (PWS). They occur in 0.3% of newborns and are visible at birth. They commonly appear as sharply demarcated, homogeneous, erythematous macules, typically located on the face or neck. They can also involve the mucosa of the upper aerodigestive track when the overlying skin is involved, such as the lip and cheek areas. If left untreated, CMs will darken in color and develop nodular changes. Hyperplasia of the underlying soft tissues commonly occurs (**Fig.** 37.3).

Figure 37.3. Capillary malformation (PWS) of the right face with tissue hypertrophy.

Capillary malformations usually occur spontaneously within a population and are the most common cutaneous vascular malformation seen. There is not an identifiable genetic component, although a subclass of CMs associated with arteriovenous malformations (AVMs) has been identified as having autosomal dominant transmission and associated mutations in the RASA1 gene.[6]

Approximately 75% of capillary malformations are located in the head and neck. Extracutaneous involvement can also occur and affect the central nervous system, eyes, or other organs.

Capillary malformations may be an isolated cutaneous lesion or a syndrome-related lesion. Parkes-Weber syndrome presents as a cutaneous

capillary malformation with hypertrophy of limbs and can have arteriovenous fistulas and congenital varicose veins.[7] Klippel-Trenaunay syndrome (KTS) is associated with three distinct features: the presence of a PWS, soft tissue or bony hypertrophy (or both) of the extremities, and varicose veins or venous malformations. Diagnosis is confirmed by the presence of any two of the three features.[8]

The treatment for capillary malformations is primarily performed using lasers. If left untreated, the affected area of skin darkens and hypertrophies to cause thick and nodular lesions that lead to disfigurement and often subsequent psychological disturbance. The pulsed-dye laser (PDL) has been the most commonly used laser for cutaneous involvement of PWSs. It commonly requires multiple, frequent treatments and may lighten and maintain a sustained response for several years after PDL therapy. The intense pulsed light (IPL) laser is also shown to be effective for PWSs.

Only about 10% of patients with PWS can be cured with laser therapy, and these are usually those individuals with small superficial lesions. Treatment during infancy can lighten the PWS after an average of three or four sessions.[9] It is rare to see skin complications from these two lasers.

Older patients with very thick and nodular PWSs may require surgery to remove the most disfiguring and symptomatic lesions (**Fig.** 37.4).

Figure 37.4. Two older patients with typical untreated capillary malformations with color changes, hypertrophy, and cobblestone appearance.

Lymphatic Malformations

Lymphatic malformations (LMs) can be classified as macrocystic, microcystic, or mixed. The old terminology, cystic hygromas and lymphangiomas, is no longer recommended. Large macrocystic LMs can present during early infancy and are frequently life threatening.[10] They can be very large and obstruct the airway or involve the chest as well. They require emergent treatment (**Fig.** 37.5).

Figure 37.5. Extensive macrocystic LM or the neck and chest in a newborn causing airway obstruction.

The diagnosis of LMs is usually not difficult. The history can vary, but they commonly enlarge during childhood or during puberty. They can be cystic and translucent, and they are not typically compressible like venous malformations. When the mucosa or skin is involved, vesicles are visible and obvious. Vesicles are pathognomonic of LMs, especially the microcystic forms. The vesicles are usually clear but may have blood in the vesicles because of local trauma. The appearance of the vesicles has been compared to “fish eggs” or caviar (**Fig.** 37.6).

Figure 37.6. Vesicles seen only with lymphatic malformations. The blood in the vesicles reflects local trauma.

LMs may be isolated lesions, but more commonly, they involve multiple sites, such as the face, tongue, mandible, larynx, and neck.[10] The bones of the face or mandible involved with LM usually hypertrophy causing bony distortion of the face. Also, it is not uncommon for LMs to have a component of venous malformations.

The most serious potential complication of LM is airway obstruction, which may be caused by an enlarged tongue filled with an LM or a large lesion of the neck causing compression of the trachea, larynx, and/or pharynx. When the tongue is involved, it is usually microcystic and diffusely enlarged and can fill the entire oral cavity and protrude out of the mouth (**Fig.** 37.7A and B). Most macrocystic LMs are found in the neck and usually

consist of multiple large cysts and commonly cause airway obstruction.

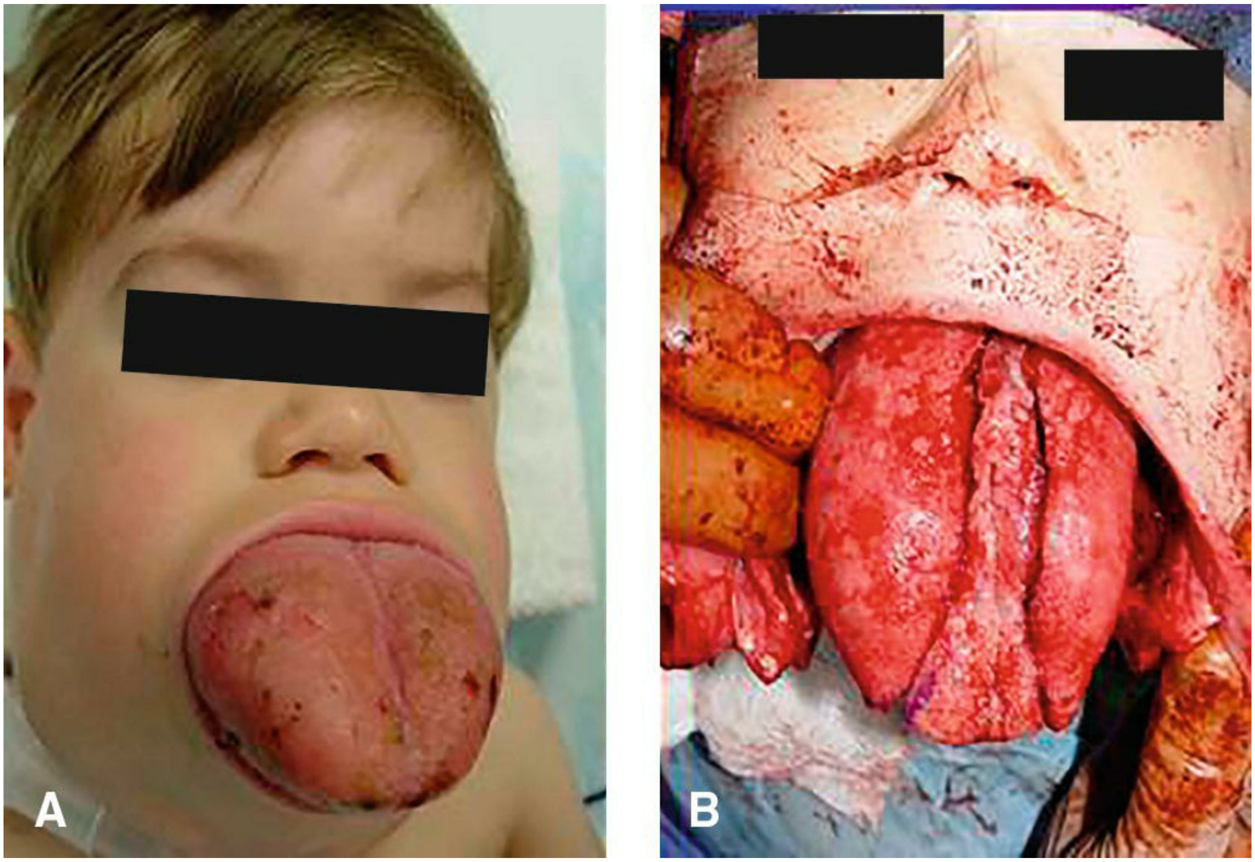

Figure 37.7. A: Extensive microcystic LM of the tongue. **B:** Surgical reduction of tongue.

With regard to imaging, the MRIs with T2-weighted images are the most useful images, as the LM will appear as hyperintense areas on these images. They can appear similar to venous malformations on these scans, but the physical examination can differentiate the two lesions. Also, on the MRI, the LM frequently will have "fluid–fluid" levels, which represent two different fluid densities and are diagnostic. CT scans or angiograms are not particularly helpful and should not be ordered if the diagnosis of LM is highly suspected.

Management of LMs commonly depends upon the expertise of the treating physician or team.[11] During infancy, the baby may present with a huge mass in the neck causing airway distress. A tracheotomy may be necessary to ensure the airway. If there is no urgency, sclerotherapy can be attempted and can be successful. There are various sclerosing agents that can

be used. Outside of the United States, it is common to use OK-432, which is a streptococcus toxin, but it is not approved by the FDA in the United States except on clinical trials. We have used alcohol and doxycycline, and more recently, we are using bleomycin in low doses. If there is an urgency to treat the large cystic LMs, surgery by an experienced surgeon should be considered. It is important for the surgeon to realize that a suction drain is important and must be left in place for a prolonged period of 2 to 4 weeks. Also, antibiotics and steroids are important for several weeks after surgery. If there are only limited macrocystic LM lesions, in the neck, it may be possible to cure the LM.

With the LMs that involve the tongue and face, surgery has been very useful, but the facial nerve is at significant risk. In the past, sclerotherapy has not been effective for microcystic LM, but in the past few years, bleomycin has been found to be effective in treating lingual LM. It is injected directly into the tongue and can shrink the lesions and the tongue. Often multiple sclerotherapy treatment sessions are necessary to obtain significant shrinkage. Although this approach does not cure the LM, it can control these lesions for many years.

A total or subtotal resection of the tongue should be avoided because it can result in severe permanent functional disabilities with inability to speak or swallow. Also, without the mass of the tongue, the mandible tends to collapse medially resulting in loss of the space where the tongue normally is located. This in turn can lead to major mandibular hypertrophy and severe malocclusion requiring major surgical reconstruction and orthodontics (**Fig.** 37.8). Also, dental caries are common and may require dental rehabilitation or extraction.

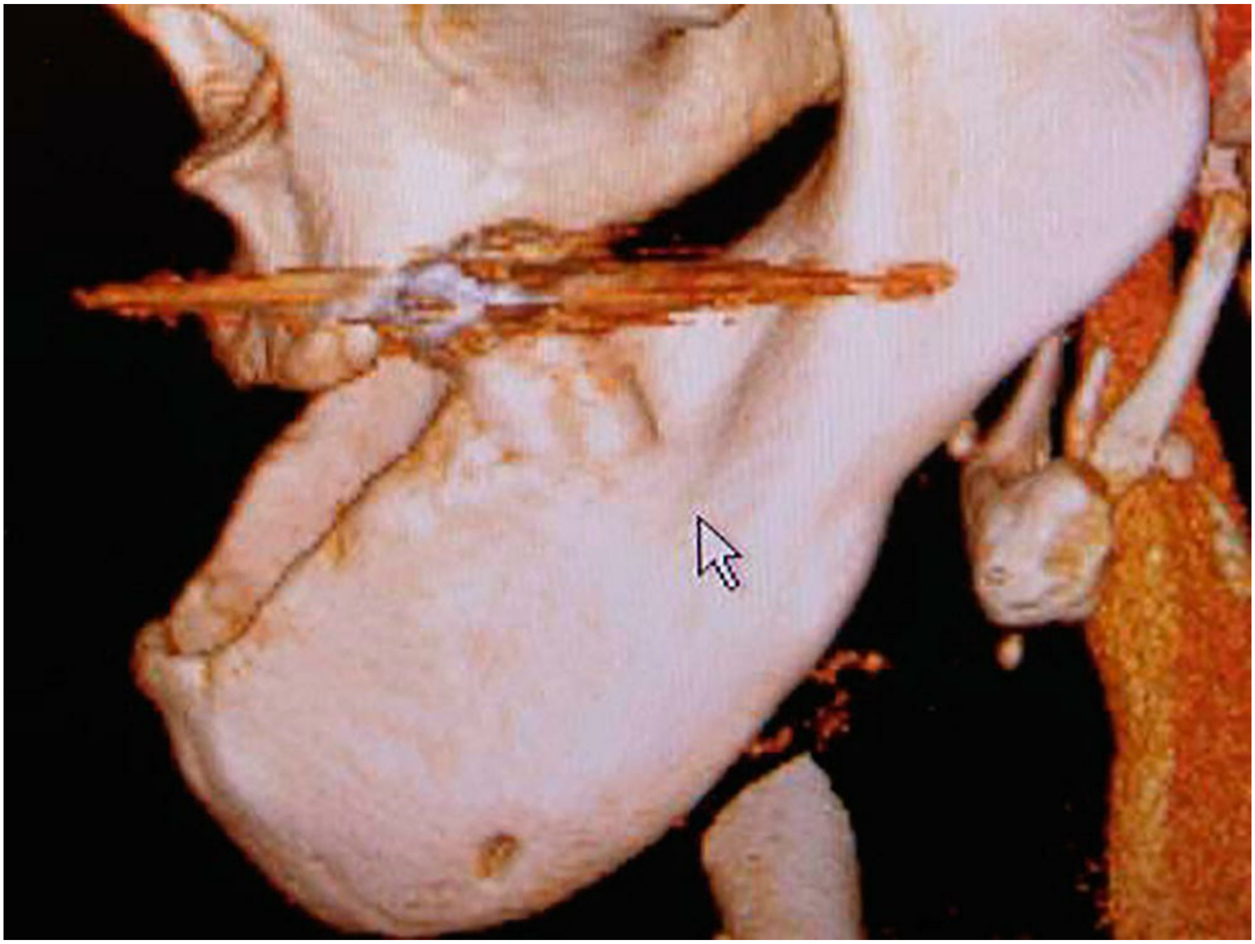

Figure 37.8. Hypertrophy of the mandible with extensive LM of the tongue and face.

Lasers can also be helpful in the treatment of LM. The carbon dioxide (CO_2) laser is the primary laser used and it is used to vaporize the superficial lesions and vesicles down to the submucosal tissues, such as those on the tongue.[10] Large mucosal lesions on the palate or larynx can be lasered down to normal underlying tissue. An Nd:YAG laser can be helpful with the deeper component of the LM.

Venous Malformations

Venous malformations are usually present at birth but may not be noticed until later in life. They consist of abnormal veins and may be small and isolated or can be multifocal and very extensive. The diagnosis is usually very easy to make, as these lesions will typically have a bluish discoloration when near a surface, such as skin or mucosa[12] (**Fig.** 37.9). In addition, they

are compressible and will refill when pressure is released. Another distinguishing characteristic of venous malformations is that when the area involved is in a dependent position, the venous malformation will enlarge or engorge and when elevated, the engorgement will decrease.

Figure 37.9. A–D: Examples of head and neck venous malformations involving skin and mucosa.

It is very common to have pain associated with venous malformations, especially around the eye and temple area, and this pain may be quite severe even requiring narcotics for control. The tongue, oropharynx, and hypopharynx can be involved, and when this occurs, it can lead to airway obstruction, especially when reclining in a supine position. Furthermore,

when the mucosal surface is involved, bleeding may occur which may be life threatening.

The best imaging study for venous malformations is an MRI with T2-weighted images, which will demonstrate the malformation as hyperintense areas (**Fig.** 37.10). Phleboliths can commonly be seen within the hyperintense area as circular flow voids. These represent calcified blood clots. On a CT scan, the phleboliths will show up as calcifications. LMs will also be hyperintense on the MRI, but the physical examination can usually differentiate between an LM and venous malformation.

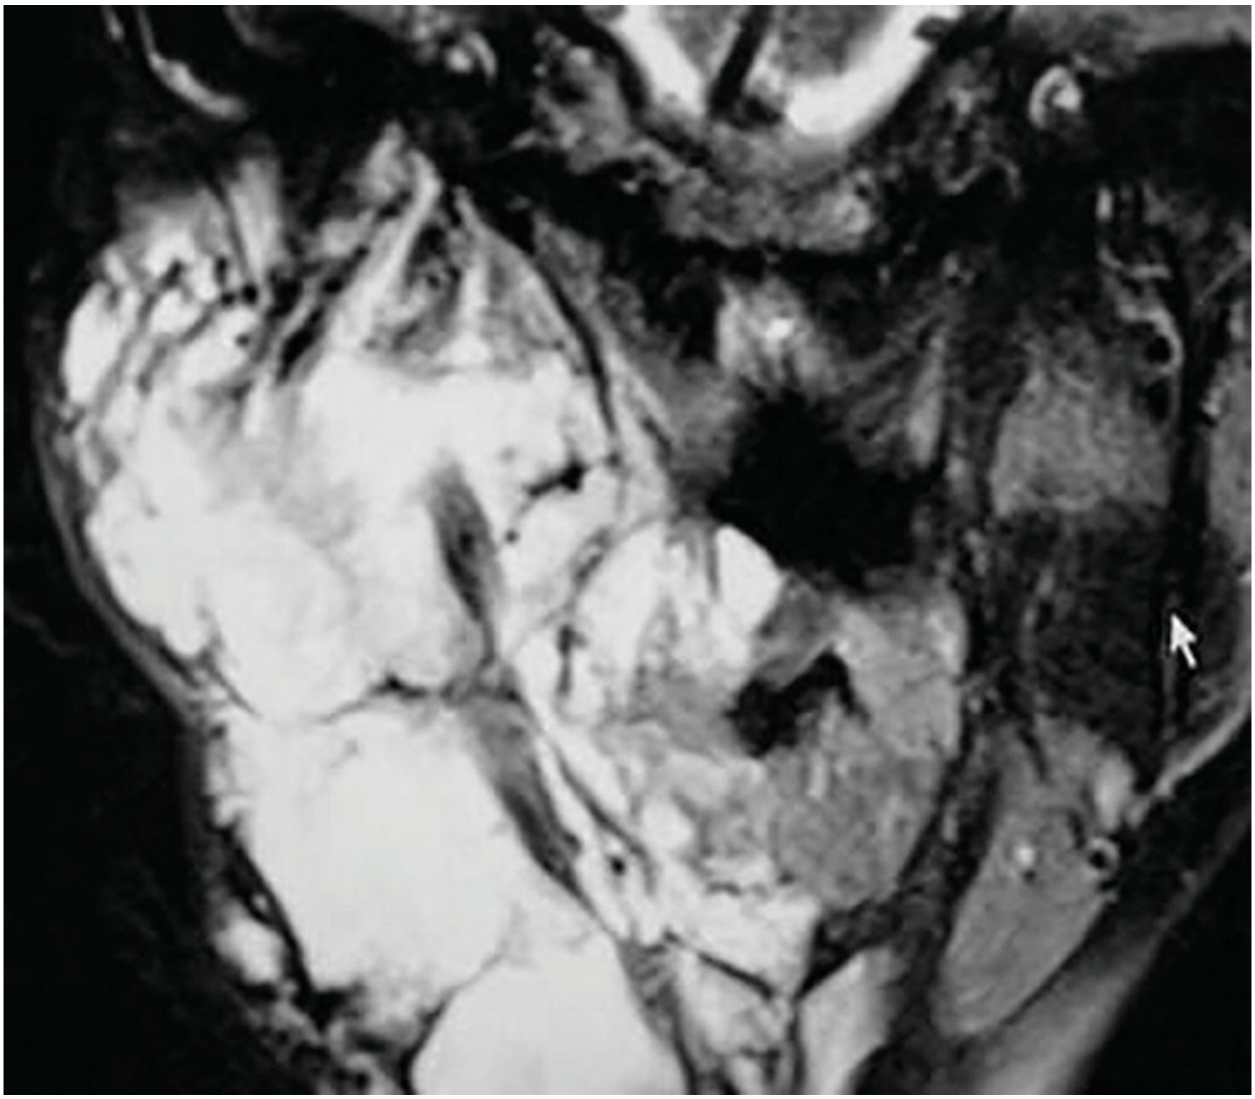

Figure 37.10. MRI of venous malformation demonstrating extensive involvement of the neck and tongue. This is a T2-weighted image showing the VM as hyperintense.

An arteriogram or MRA will not demonstrate a venous malformation because there are usually no arterial feeders. Therefore, these imaging studies are not recommended in the evaluation of suspected venous malformations.

With regard to management, the small, superficial, isolated lesions can be treated with surgery or using an ND:YAG laser. We do not recommend alcohol sclerotherapy on superficial lesions because of the potential for sloughing of the overlying skin or mucosa.

The multifocal, larger venous malformations are much more difficult to treat.[12] If there are lesions that appear circumscribed with definitive margins, they can usually be resected adequately (**Fig.** 37.11). If they intimately involve the skin or mucosa, those areas should be removed with the lesions.

Figure 37.11. A large venous malformation of the neck, which had distinct borders on MRI indicating possible role for resection.

Most of the larger, multifocal venous malformations are best treated with sclerotherapy, primarily using alcohol.[13] In the past few years, bleomycin has become more popular for sclerotherapy and can be very effective.[14] It can be used when skin or mucosa is involved without much risk of sloughing. Since bleomycin is a chemotherapy agent, it is best to give small doses each treatment and the total amount monitored to avoid risk of pulmonary fibrosis, which can occur when over 200 units total dose have been given. When bleomycin is used, we use only about 6 to 15 units at a time. We dilute a 15-unit vial of bleomycin with 7 mL of 2% lidocaine and 1 mL of Decadron, or it can be mixed with albumin and air to make foam, which can stay in the VM longer. The bleomycin or alcohol can destroy the endothelium of the venous malformations causing blood clots, and as the blood clots shrink, the malformations shrink with it. However, the adjacent areas, which are untreated, will continue to expand with time.

It is rare for one sclerotherapy treatment to destroy multifocal venous malformations. It is also common for patients to undergo multiple sclerotherapy treatments. Many of these large, multifocal venous malformations cannot be cured but can be well controlled with proper treatment. It is important to inform the patients and their families that the goal is to control the disease rather than cure it, so that they understand repeated treatments are necessary and that follow-up care throughout life is important.

When mucosa is involved and the VM is superficial and bluish, it is best to use an Nd:YAG laser with a power setting of 15 to 25 watts and duration of 0.5 to 1.0 seconds exposure time. Shrinkage of the VM occurs immediately and leaves a white spot. A polka-dot pattern is important because if the treated spots are too close and overlapping, sloughing of the mucosa and bleeding may occur. In the pharynx, the laser treatment should begin distally and progress proximally. This can be repeated every 2 months or more. The laser treatment will shrink the VM and also thicken the mucosa so that bleeding later is unlikely.

Arteriovenous Malformations

AVMs are congenital vascular anomalies where there is an aberration of the capillary bed and the arterial blood flow shunts through the bed into the venous system almost directly. This abnormal capillary bed is called a nidus. The arterial feeder vessels and the draining veins will get very large because

of this rapid flow of blood. The nidus will also get larger because of hemodynamic changes. An AV fistula usually has only one or two arteries, which shunt into the adjacent vein(s), whereas an AV malformation has multiple arteries and veins involved. The following discussion involves extracranial AVMs.

AVMs appear to be heterogenous. There are some AVMs that have a distinct history of trauma to the site involved and probably are AV fistulas that can become identical to AVMs when left untreated. There are others that are more focal and seem to expand through hemodynamic factors. Then, there is a group of AVM that are very aggressive and seem to expand through invasion and destruction of adjacent tissue.

As mentioned in the introduction, some AVMs have many similarities to low-grade malignancies, and we feel they should be treated as such. Our philosophy is to treat AVMs as early as possible and to be aggressive. This may be the only chance for cure. Because many AVMs involve the face, eyes, ears, nose, and tongue, the treating team must weigh the consequences of treatment versus the natural history of the AVM. AVMs are very destructive, and we have shown in our research that they have both clinical and molecular characteristics of low-grade malignancies. It is important to understand the natural history of AVMs in order to decide on the most appropriate treatment.[15]

Many AVMs cannot be cured but can be controlled with proper treatment. The treating team, the patients, and their families should be aware of this and counseled properly.

AVMs may be focal or multifocal. The focal AVMs have a better chance for cure and should be treated as early as possible. We disagree with the philosophy that AVMs should not be treated until they become symptomatic because they may be incurable at that time.

We have seen AVMs that had a definite history of trauma to the involved area and feel that these AVMs may have started as AV fistulas and, left untreated, become AVMs. These entities usually involve more superficial areas, such as the lip, nose, eyelids, or ear. There is a much better chance for cure with this type of AVM.

Multifocal AVMs are much more difficult to treat and cure. All of the sites involved may not be obvious initially. Also, it is common to think that

an AVM is cured with surgery or embolizations and to find a few weeks or months later that the AVM is growing with a vengeance. We have patients whose recurrences were not identified until 10 years later. We rarely tell a patient that we feel his or her AVM is cured.

The diagnosis of an AVM is not always easy. It is based on the history, physical examination, and special radiologic studies.[16] An AVM can occur at any age. However, it is rare to see an AVM in an infant, but when it occurs, these lesions are usually very aggressive. It is more common to see an AVM present when a child is undergoing puberty, around 10 to 13 years of age. The AVM has been there since birth but is being stimulated to grow related to hormone receptors. They will expand rapidly during this phase unless treated. Also, it is common to see an AVM recognized during pregnancy or when oral contraception is used. It is less common to see an AVM present after the age of 30, but it can occur. We feel that many of these that occur later in life are probably related to trauma and were AV fistulas that progressed to AV malformations.

A common history for an AVM is that the patient or parent will notice a red blush in the skin and that the tissues underneath that area are enlarging. They may or may not have noticed a pulsation in that area, and bleeding can occur if the area begins to ulcerate when involving the skin or the mucosa of the nose or mouth. It is quite common for patients to be told that they have a hemangioma and that it will go away with time.

On the physical examination, an AVM often appears as an erythematous area, which may have small varicosities in the skin or mucosa, and can resemble a PWS. Early in the disease process, the area involved may just look enlarged. In addition, AVMs can cause hypertrophy of the soft tissues it involves and the adjacent bones because of the rich blood supply (**Fig.** 37.12). Pulsation may or may not be palpable, and there is usually no thrill or bruit in the early stages. As the AVM enlarges, pulsation is more noticeable by the patient and the overlying skin or mucosa ulcerate and bleed intermittently. Bleeding is usually bright red and may be profuse and difficult to control. If the mandible or gum tissue is involved, it is common for bleeding to occur while brushing the teeth.

Figure 37.12. A 23-year-old male with an AVM of the face with hypertrophy of the tissues and varicosities of the overlying skin.

With regard to imaging studies, an arteriogram is the most definitive test. A CT arteriogram (CTA) (**Fig.** 37.13) or an MR arteriogram is very helpful to diagnose and delineate the extent of an AVM as well as its feeding vessels. The three-dimensional views of a CTA can be very helpful, especially with superficial lesions (**Fig.** 37.14). We prefer a CTA because it can be done quickly and is less expensive than an MRA. Arteriography is usually not performed unless the treatment plan includes using embolization followed by surgery, in which case embolization should be performed 1 to 3 days prior to the planned surgical procedure.

An arteriogram of an AVM demonstrates a vascular blush, which is the nidus, with the feeder arterial vessels and early venous outflow tracts. When evaluating an arteriogram for the extent of an AVM, one must be very careful in the interpretation, because some, or a lot of the nidus, may be hidden. Understanding the flow dynamics is crucial. The largest arteries may shunt most of the contrast dye into one nidus, and there may be other multifocal areas fed by smaller vessels that may not reveal themselves. During embolization when the embolic material blocks off a nidus and more contrast is injected, other parts of the nidus may become evident, which explains why the extent of many AVMs may be underestimated.

Treatment for extracranial AV malformations can be very complex and should be performed by experienced teams who specialize in vascular anomalies.[16] A team approach is very important. A surgeon without other

team support will most often offer surgery as the primary treatment modality, and an interventional radiologist, practicing without other specialists, may choose embolization alone as the primary treatment modality. A pediatrician, dermatologist, or plastic surgeon who does not treat VMs may recommend watching and waiting, because "they may go away with time." To make a proper decision, all specialties should be involved in treatment selection and planning.

We have classified AVMs as focal or multifocal. The focal AVMs are most often localized and the extent of involvement can usually be determined. We feel that the majority of focal AVMs can be treated surgically and if adequately resected can be cured (**Fig.** 37.15). Embolization can be used, but, in our experience, is often associated with recurrence. Furthermore, when the focal AVMs involve the overlying skin or mucosa, embolization, even with small amounts of embolic material, can cause significant sloughing of tissue (**Fig.** 37.16).

Figure 37.15. A and B: Focal AVM of the lip treated with surgical resection.

Figure 37.16. AVM of lip treated with only 1 mL alcohol resulting in sloughing of the lips.

Multifocal AVMs are the biggest challenge and rarely can be cured. The primary treatment modalities have been embolization and surgery, but as described below, pharmacotherapy with doxycycline or propranolol may be useful and play a larger role in the future.

Embolization of AVMs is now the treatment utilized most commonly.[16] One major reason is that there are very few surgeons who are capable and willing to operate on AVMs. Embolization is usually performed through an arteriogram but can also be performed through a direct puncture technique. This technique should be performed by an experienced interventional radiologist. The most common embolic material used is alcohol, but also, glue and onyx are commonly used. When mucosa or skin is involved, alcohol and glue can cause sloughing of the tissues. It would be rare for one embolization procedure to destroy or cure an AVM. It is not uncommon for

patients to undergo 10 or more embolization procedures over time with persistence of the AVM (**Fig.** 37.17). Embolization can also be performed as a preoperative procedure.[17] If this is the situation, we recommend that surgery be performed within 1 to 3 days, because revascularization occurs.

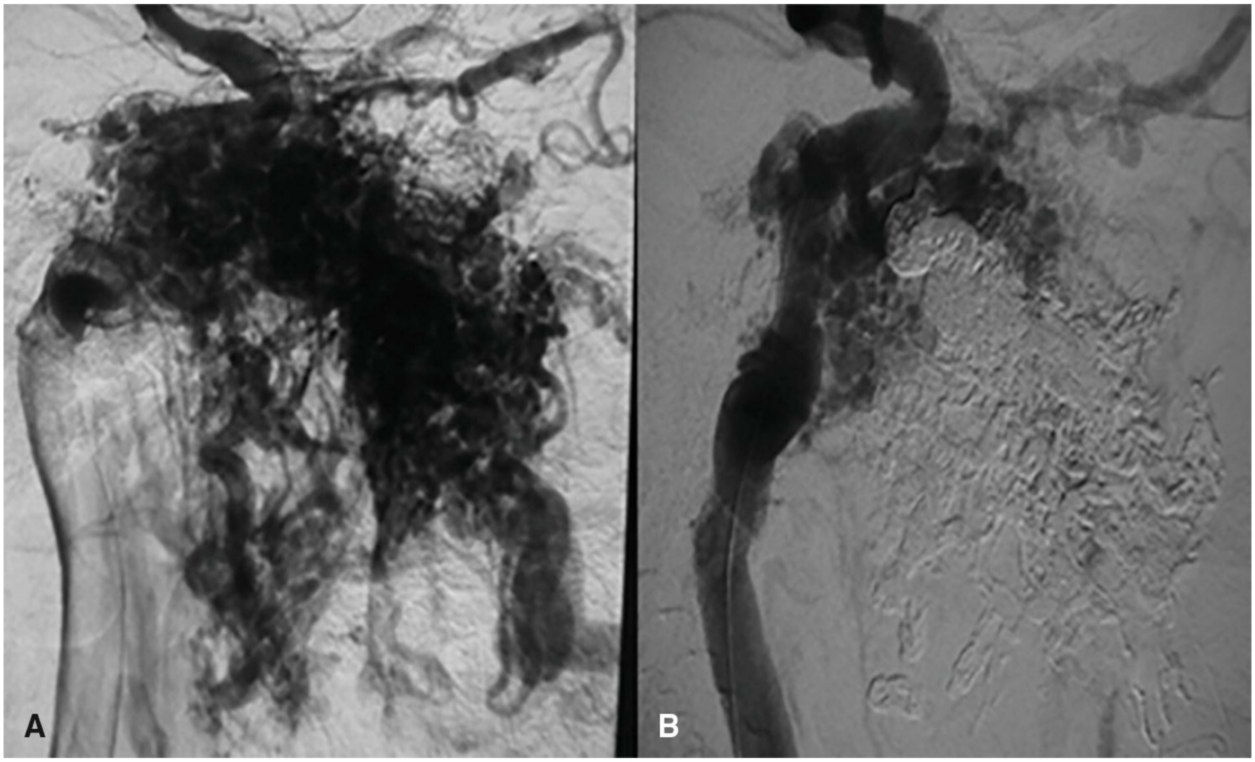

Figure 18.10. A: Contrast dye in AVM deep in the face fed by branches of the internal carotid artery. **B:** Onyx can be seen in the AVM after embolization.

We have monitored patients who have embolization procedures for large AVMs and require multiple treatments, and we have found that there is significant radiation exposure during the procedures. We have found that a patient can have as much as 600 cGy of radiation exposure during one prolonged treatment. This can cause cataracts, skin or other cancers, and poor healing if they undergo surgery. Patients and their families should be aware that this may occur. It is necessary to use embolizations for AVMs because of the major tissue destruction and potential for death if these lesions are not controlled.

Surgery may be the best choice when the AVMs are very extensive and embolization procedures have failed. Major bleeding is a concern and should

not be underestimated. Partial resection is not usually helpful and may result in more rapid growth of the residual AVM. An experienced head and neck surgeon should perform surgical resection (**Fig.** 37.18). We try to preserve the facial nerve during surgery, and if preserved, facial function may return 6 to 12 months later. However, the patient will have a facial nerve paralysis due to the difficulty in dissection, but alternatively, if the AVM is not properly resected, it may destroy the entire face. When the orbit is involved, exenteration of the orbit may be necessary (**Fig.** 37.19). For extensive surgical resections, reconstruction with microvascular free flaps may be required.

Figure 37.19. A and B: Extensive, destructive AVM of the face and orbit, before and after resection with free flap reconstruction.

Lasers have very little role in treating AVMs. We have had some success using an Nd:YAG using both gentle superficial and interstitial techniques, but success with this approach requires significant experience using this modality.

We have treated a number of AVM patients with different medications targeting their underlying biology and have seen some favorable responses. Evaluation of AVMs for expression of MMP-9 (matrix metalloproteinase) by our group has revealed significant expression of this enzyme in AVMs. Based on this, we have hypothesized that the enzyme may increase tissue breakdown allowing for expansion of the vessels and have proposed the use of doxycycline, a nonspecific inhibitor of MMP for the treatment of AVMs. In our experience treating patients with AVMs with doxycycline (100 mg BID), 50% state that they have decreased symptoms, such as less bleeding, indicating that it can stabilize AVMs in certain cases.

Based on the success in using propranolol in treating IH, we have tested its use in treating patients with AVMs and found that between 25% and 50% of the patients notice decreased pressure and bleeding. We feel that propranolol may decrease the blood pressure and heart rate, which can decrease flow pressures in the nidus of an AVM in some patients. The dosage of propranolol is 1 to 2 mg/kg/day depending on the patient's tolerance for

the medication.

Based on our research showing that there are biologic and clinical similarities of AVMs to low-grade cancers, we feel that pharmacotherapy may be the answer to finding a cure for some AVMs. This is ongoing research on our Department.
